*5 Therapeutic Results in Patients With Urinary Tract Infection*—Ten patients with acute or subacute exacerbations of chronic urinary tract infections were treated. They had little or no obstructive uropathy, and all had failed to respond to therapy with sulfonamides and streptomycin. The infecting agents were uniformly resistant to streptomycin *in vitro*. Before, during, and after treatment, a complete blood count, urinalysis, phenolsulfonylphthalein test, and determination of nonprotein nitrogen in the blood were obtained for every patient. The subjects were hospitalized and closely observed clinically, and quantitative bacteriologic studies were carried out on the catheterized urine every two days during therapy and at frequent intervals thereafter.\* Most patients were afebrile.

Polymyxin was injected intramuscularly in amounts of 20 mg every four to eight hours for three or four days. By frequent determinations, an effort was made to keep serum levels between 2 and 10  $\mu\text{g}$  per milliliter. Some of the data obtained in these patients are shown in Table III. When the infecting organism was inhibited *in vitro* by 0.4  $\mu\text{g}$  per milliliter, the short course of therapy with Polymyxin B led to negative urine cultures for one to three weeks. Bacteriologic relapses occurred, usually within one month, even when the patients remained symptomatically well. A detailed example of this temporary response to therapy is shown in Table IV.

*6 Toxicity*—After intramuscular injection of Polymyxin B (13 mg per milliliter), most subjects experienced local pain with persistent tenderness severe enough to warrant the addition of a local anesthetic for routine administration of the drug. With procaine the injections were well tolerated.

In spite of careful search, no evidence of renal damage could be detected with the short course (three to four days) of Polymyxin B used in this study. There was no hematuria or proteinuria and there were no changes in the sediment or nitrogen retention during or after therapy. The proteinuria of patients with chronic pyelonephritis was not aggravated by the drug. This is in contrast with the experience of others<sup>16</sup> who found proteinuria and hematuria at least transiently when the drug was given for more than seven days.

One of the patients developed a drug fever on the third day of treatment. It promptly subsided when the injections were stopped, but recurred when

\*We wish to thank Dr. Frank Hinman, Dr. Frank Hinman, Jr., Dr. Frederick S. Howard, Dr. John W. Schulte and others, and the members of the resident staff of the University of California Hospital and Franklin Hospital for permission to study their patients.

TABLE III TREATMENT OF PATIENTS WITH URINARY TRACT INFECTION WITH POLYMYXIN B BACTERIOLOGIC RESULTS

they were resumed. No effect was observed on the red or white cell count in the ten patients.

The most marked undesirable effect of Polymyxin B was on the central nervous system. Within forty-eight hours of inception of treatment, the majority of patients experienced circumoral paresthesias and "dizziness" without nausea, anorexia, or true vertigo. There was commonly mild ataxia and occasionally the feeling of weakness of the legs without objective evidence of diminished muscular strength. These symptoms lasted while the drug was administered and subsided in all patients in thirty-six to forty-eight hours after it was discontinued. No residual disturbances were observed in any patient.

With doses larger than those routinely used, more drastic effects on the central nervous system were observed. Two persons received 160 mg of Polymyxin B intramuscularly in twelve hours (i.e., 2.5 mg per kilogram per twelve hours). They experienced peripheral as well as circumoral paresthesias, severe incoordination, with dysarthria, dyssynergia, dysmetria, ataxia, a positive Romberg sign and marked past pointing. The reflexes were within physiologic limits. There was no true vertigo, only "lightheadedness," no tinnitus or impaired hearing, and the appetite was unimpaired. These symptoms and signs persisted for thirty-six hours while the serum concentration of the drug was in excess of 10  $\mu\text{g}$  per milliliter, they then gradually subsided and left no sequelae.

## DISCUSSION

The known antibiotic substances derived from *B. polymyxa* share a specific and powerful antibacterial action against gram negative bacteria. These peptides are bactericidal rather than bacteriostatic in vitro for susceptible bacteria. Resistant bacterial variants emerge infrequently. All these characteristics would make this group of compounds desirable in the treatment of infections with gram negative organisms were it not for significant toxic side effects.

Among organisms encountered in urinary tract infections susceptibility to Polymyxin B was uniformly high among strains of *Esch. coli*, and only slightly less with *A. aerogenes*. Many strains of *Pseudomonas* and *Proteus* on the other hand were fully resistant. This parallels the experience with other antibiotics especially streptomycin and to a lesser extent amikacin.<sup>1</sup> In some strains, resistance to Polymyxin B was induced in vitro with ease. The change did not appear to be related to the original sensitivity to the drug in the four strains tested. Studies based on large inocula suggested that the proportion of resistant organisms in a given bacterial population was small. Resistant variants did not develop in patients during a short course of treatment with Polymyxin B.

The natural history of chronic infection of the urinary tract does not support the idea that a short course of any antibacterial agent could "cure" the disease. Bacteria within the inflamed renal parenchyma and the proliferating fibrous tissue are shielded effectively from the immediate action of drugs. Prolonged therapy at best would be necessary to eradicate the infective organisms. In the present study no such attempt was made. Treatment with 300 to 500 mg of Aerosporin administered in three to four days resulted in a striking reduction of the bacterial content of the urine for one to three weeks in six of ten patients. Symptomatic improvement was satisfactory and usually lasted longer than the bacteriologic remission. Failure to respond was associated with relative resistance of the infecting organisms or with multiple infection. Within its scope the therapy may be said to have been successful. Whether prolonged treatment might yield more encouraging results cannot be predicted.

Trials of prolonged therapy were made inadvisable by toxic effects from the Polymyxin B used. The most dramatic were the neurological symptoms and signs which appeared in a majority of patients. Although these disturbances disappeared promptly after therapy was discontinued and did not leave any residual changes patients were uncomfortable and apprehensive; some refused further treatment. No renal toxicity or untoward effects on the hematopoietic system were noted with the short course of therapy used in this study.

The described side effects of Polymyxin B preclude the clinical use of the preparations presently available. The antibacterial features of the drug are so attractive however that it must be hoped that the toxic properties can be eliminated in the future and the agent made available for further clinical investigation.

## SUMMARY

1 Aerosporin brand Polymyxin B is a stable peptide derived from *B polymyxa* with marked antibacterial action against many gram-negative organisms. Among bacteria commonly isolated from urinary tract infections, *Esch coli* and *A aerogenes* were inhibited in vitro by less than 1  $\mu$ g per milliliter, while many strains of *Proteus* and *Pseudomonas* were more resistant.

2 Resistance could be induced in susceptible bacterial strains only with difficulty. The action of the antibiotic in vitro appeared to be bactericidal rather than bacteriostatic.

3 Multiple intramuscular injections of the drug resulted in cumulative serum levels. The serum levels were greatly increased in the presence of elevated nonprotein nitrogen of the blood.

4 In patients with chronic urinary tract infection, Polymyxin B administered for three to four days eliminated susceptible bacteria from the urine and controlled symptoms. The short course of treatment, however, was followed by a bacteriologic relapse within one to three weeks in all cases.

5 Prolonged therapy with the drug was not feasible because of toxic symptoms affecting particularly the nervous system. In its present form, Polymyxin B is therefore not suitable for general clinical application.

## THE COAGULATION DEFECT IN THROMBOCYTOPENIC PURPURA

ARMAND J. QUICK, M.D., PH.D., JACOB N. SHANBERGE, M.D.,\* AND  
MARIO STEFANINI, M.D.†  
MILWAUKEE, WIS.

**T**HE normal coagulation time observed in thrombocytopenic purpura has always puzzled students of coagulation and has led many to conclude that coagulation is not disturbed in this disease. Recently evidence has accumulated to show that the coagulation time may not always be a reliable measure of true coagulability.<sup>1</sup> In fact, it has long been recognized that in hypoprothrombinemia the coagulation time is much too insensitive to serve as a guide for estimating the severity of prothrombin deficiency. As a result of the development of the prothrombin time determination rapid progress, both clinical and theoretical, ensued in the group of diseases in which a deficiency of prothrombin occurs. The lack of a test comparable to the prothrombin time procedure to measure quantitatively the factors responsible for the activation of prothrombin has hampered and retarded progress in the study of such diseases as hemophilia and thrombocytopenic purpura. With the development of the prothrombin consumption time (serum prothrombin time) a new approach is offered for the study of the hemorrhagic diseases due to coagulation defects which are not in the prothrombin complex, i.e., diseases in which the prothrombin time is normal. With this test Quick<sup>2</sup> demonstrated that the prothrombin consumption was markedly delayed and incomplete in hemophilia and likewise in plasma from which most of the platelets were removed. These findings were subsequently verified by Soulier.<sup>3</sup> Earlier Brinkhous<sup>4</sup> had noted the incomplete conversion of prothrombin in clotted hemophilic blood which he attributed to a slow conversion rate of the prothrombin.

Clot retraction which is characteristically absent in severe thrombocytopenic purpura should no doubt be considered as a coagulation defect although it is difficult to find in the literature specific statements to support such a view. While it is recognized that clot retraction is dependent upon intact platelets a quantitative correlation between the number of platelets and the speed and degree of clot retraction was difficult to make until the introduction of silicone (Dri film) which made it possible to secure and keep native plasma with a minimum amount of platelet lysis. Whole blood is far less satisfactory for studying clot retraction since variations in cell volume markedly influence the

20	322	683	32	49	8	17	18
Average	250	531	29	47	8	22	26

\* Ratio of plasma volume obtained by centrifuging at 800 r.p.m. for ten minutes to total blood volume.

When the platelet count is normal, clot retraction of native plasma becomes detectable in about eight minutes. The range for the twenty subjects studied varied from six to eleven minutes. In confirmation of previous studies,<sup>6</sup> it was observed that when the platelet count of plasma is below approximately 150,000 the beginning of clot retraction becomes progressively delayed and finally retraction fails to occur altogether. Slight retraction still manifests itself when the count is over 20,000. Under ideal experimental conditions and with control of the various clotting factors the number of platelets quantitatively determines the speed with which clot retraction begins and also the size of the final clot.

The prothrombin consumption time likewise, depends on an adequate number of platelets. It has been postulated that platelets supply an enzyme which is essential for the conversion of thromboplastinogen to active thromboplastin. On removing platelets from plasma by centrifugation the prothrombin consumption is markedly delayed due to the inadequate conversion of thromboplastinogen. With an excess of platelets, sufficient platelet enzyme becomes available to permit a rapid consumption of prothrombin. Inspection of Table I shows that the prothrombin consumption time of serum, whether obtained from plasma or whole blood sixty minutes after coagulation is in most instances between 17 and 30 seconds. If these values are calculated in terms of prothrombin activity by means of Quick's prothrombin curve, one finds that from 60 to 80 per cent of the activity disappears in one hour.

A poor consumption of prothrombin is due generally either to a lack of platelets or to a deficiency of thromboplastin. In hemophilia the platelets are normal, since it has been shown that if platelets from hemophilic blood are added to normal deplateletized plasma, normal coagulation will occur.<sup>7</sup> It is most likely therefore that the basic defect in hemophilia is inadequate thromboplastinogen content in the blood.

To determine whether defects in coagulation other than lack of platelets occur in thrombocytopenic purpura, one must consider the various factors that enter into the clotting mechanism. Since the prothrombin time is usually entirely normal, it is evident that the prothrombin complex and fibrinogen are not involved and are normal. This is clearly illustrated by the following findings made on the blood and native plasma of a patient with severe thrombocytopenic purpura.

PATIENT R. P., 11 YEAR OLD GIRL

Coagulation time (Lee-White)	6 min
Prothrombin time	11½ sec
Prothrombin consumption time (whole blood)	10½ sec (after 1 hr)
Bleeding time	>30 min
Clot retraction (whole blood)	None (after 24 hr)
Platelet count	5,000 per cu mm

STUDY OF NATIVE PLASMA (OBTAINED BY SILICONE TECHNIQUE)

Coagulation began in	5 min
Coagulation completed in	12 min
Retraction	None in 2 hr
Prothrombin consumption time	10½ sec (after 2 hr)

From these results it can be seen that only a trace of prothrombin was consumed in the clotted blood after two hours. That this is due to lack of active thromboplastin is clearly shown by the effect of adding a small amount of rabbit brain extract to the serum (Table II). An immediate increase in the prothrombin consumption occurred, and when the amount of added thromboplastin was increased, the prothrombin consumption was also proportionately increased. Since the prothrombin consumption time tends to remain fairly constant for any concentration of thromboplastin for a period of one hour or more after its addition, it appears very likely that the reaction with prothrombin is stoichiometric rather than enzymatic. The lack of active thromboplastin is not due to a deficiency of thromboplastin as occurs in hemophilia, but to an inadequate amount of the activator which is furnished by the platelets.

TABLE II THE EFFECT OF ADDING THROMBOPLASTIN TO SERUM OF A PATIENT WITH THROMBOCYTOPENIC PURPURA ON PROTHROMBIN CONSUMPTION TIME

	PROTHROMBIN CONSUMPTION TIME			
	TIME IN MIN			
	0	15	30	60
Thromboplastin added to 1 cc of serum		21		
01 cc	10½	41	21	22
02 cc	10½		—	44

The correlation of prothrombin consumption time with the beginning of clot retraction time can be applied to study the course of the thrombocytopenic purpura, as illustrated by two cases, the laboratory findings of which are summarized in Tables III and IV

TABLE III THE COURSE OF THROMBOCYTOPENIC PURPURA AS MANIFESTED BY THE PLATELET COUNT, BLEEDING TIME, BEGINNING OF CLOT RETRACTION IN NATIVE PLASMA, AND PROTHROMBIN CONSUMPTION TIME

(Patient A boy, age 6, Diagnosis Secondary thrombocytopenic purpura)

DATE	PLATELET COUNT	BLEEDING TIME (MIN)	BEGINNING OF CLOT RETRACTION (PLASMA) (MIN)	PROTHROMBIN CONSUMPTION TIME (WHOLE BLOOD) (SEC)	CLINICAL CONDITION

July 1	29,000	9½	14	14	Marked bruising
July 14	98,000	2½	11	20	No bruising

\*Folic acid 20 mg daily

TABLE IV THE EFFECT OF SPLENECTOMY ON THE PLATELET COUNT AND PROTHROMBIN CONSUMPTION TIME IN A PATIENT WITH THROMBOCYTOPENIC PURPURA

(Patient A man age 32, Diagnosis Idiopathic thrombocytopenic purpura)

DATE (1948)	PLATELET COUNT OF WHOLE BLOOD (THOUSANDS)	CLOT RE TRACTION OF WHOLE BLOOD	PROTHROMBIN CONSUMPTION TIME (SEC)	REMARKS
April 1	80,000	None	10	
June 24	14,000	None	10	
June 25	39,000	Slight	12	Immediately after ligation of splenic vessel
	22,000		13	After 30 min.
	26,000		14	After 60 min
June 26	98,000	12½ min *	32	
June 28	342,000		50	

\*Native plasma

The first subject, a 6 year old boy, developed purpura two weeks following an attack of vomiting and diarrhea. He had no hematuria, melena or other type of bleeding except marked bruising. He had a consistently low platelet count over a period of six weeks. During this period the bleeding time was prolonged, the beginning of clot retraction delayed, and the prothrombin consumption time consistently shorter than normal. The clinical condition as judged by marked bruising remained unchanged. Two weeks following the daily administration of 20 mg folic acid, the bruising tendency disappeared, and an examination of the blood showed a striking increase in the platelet count and a return to normal of the bleeding time, clot retraction, and prothrombin consumption time. Whether the cure can be attributed to folic acid or whether recovery was spontaneous remains problematic, although favorable results from folic acid have been noted also in a few other cases of thrombocytopenia.

The second subject,\* a young man 32 years of age with idiopathic thrombocytopenic purpura, presented the opportunity to study the effect of splenectomy. It is obvious from the results recorded in Table IV that the favorable response to the removal of the spleen is shown both by the rise in the platelet count and by the increase in prothrombin consumption. It appears that the latter was even a more sensitive indicator than the platelet count, but that may perhaps be explained by the difficulty of avoiding errors in counting platelets especially when the collection of blood is beset with technical difficulties, such as are encountered in the operating room with the patient under anesthesia.

In both patients the prothrombin consumption time corresponded to the platelet count, and clinical improvement was promptly and accurately indicated by a rise both in the platelet count and in the prothrombin consumption.

The prothrombin consumption time test is at present the only method available to show a coagulation defect in thrombocytopenic purpura. When performed according to the directions as outlined in this paper, it is a fairly quantitative measure of platelet activity unless there is a deficiency of thromboplastinogen as in hemophilia. The test therefore becomes a useful addition to the list of laboratory procedures available for studying purpura. It will definitely complement the platelet count. From the studies made thus far, it can be stated that when the prothrombin consumption time is normal, no marked thrombocytopenia exists.

The new method for studying clot retraction by timing the beginning of the process in native plasma is a far more sensitive test than the clot retraction of whole blood. The latter method is essentially qualitative and therefore is only a rough index of the platelet count. Unfortunately the collection of native plasma is too exacting a procedure to warrant its general use in the clinical laboratory, but for investigative purposes, plasma is better suited to study clot retraction than is whole blood since the reaction can be directly watched and no correction for cell volume is required.

A close correlation exists between the platelet count, clot retraction, and the prothrombin consumption time since the latter two are directly dependent upon the former, assuming of course, that the activity per platelet is constant. The prolonged bleeding time, the easy bruising, the oozing of blood from mucous membranes, and the petechiae which are characteristic findings in thrombocytopenic purpura are in all probability not caused by the platelet deficiency. It is not unusual to find in such conditions as acute lymphatic leukemia a very low platelet count and yet no purpura or bleeding. It seems fairly certain that a toxic agent distinct from the platelets is responsible for the vascular dysfunction that causes purpura and that when this factor is superimposed on the coagulation defect due to lack of platelets, the hemorrhagic tendency is markedly accentuated.

#### SUMMARY

A correlation between the platelet count, the speed of clot retraction, and prothrombin consumption of normal human native plasma (obtained with the

\*The medical staff at Veterans Hospital Wood Wis kindly permitted us to study this patient.

and of silicone coated glassware) is presented. Incidental to this study, it was observed that the platelet count in plasma obtained by slow centrifugation is about twice as high as in whole blood.

In thrombocytopenic purpura a delayed clot retraction and a poor prothrombin consumption closely parallels the low platelet count. A clinical case is presented to illustrate the simultaneous and prompt return to normal of the prothrombin consumption time and the speed of clot retraction as the platelet count increased to 100 000 and the clinical condition improved. Another case is selected to show the expeditious response of the platelet count, prothrombin consumption, and clot retraction to splenectomy in idiopathic thrombocytopenic purpura (Weilhof's disease).

The prothrombin consumption test supplies the first strong evidence that a coagulation defect is present in thrombocytopenic purpura. The test offers a new measure of platelet activity, which is postulated to be that of activating plasma thromboplastinogen. Clot retraction likewise is a measure of intact platelet activity. When the test is carried out on native plasma, it has quantitative significance since the beginning and completion can be accurately determined by direct visual observation, and no correction is required for cell volume.

Patient 6 had an acquired hemolytic anemia four years previously which responded well to splenectomy. Although the anemia disappeared and there were no signs of increased blood destruction, spherocytosis continued and the developing test was positive. The patient died in uremia consequent to malignant hypertension.

Patient 7 had a typical symptomatic hemolytic anemia occurring in a case of reticulum cell sarcoma. Although slight spherocytosis was present in the film, the hypotonic saline fragility was within normal limits. Coating antibodies in cases of symptomatic hemolytic anemia have been observed by Boorman and associates<sup>10</sup> and Wagley and co-workers.<sup>17</sup>

Patient 8 showed a strongly positive Coombs test before splenectomy in the presence of a very severe anemia and 57 per cent reticulocytes. Two months after splenectomy, spherocytosis and the increased saline fragility disappeared and the hemoglobin and red cell count returned to normal values. The developing test also became negative. This case is an example of a complete cure of this disease which sometimes follows splenectomy.

**2 Hereditary Spherocytic Anemia**—Seven patients were examined (Table II). All of them had the typical features of spherocytosis and increased saline fragility. All but one had a negative developing test. Splenectomy was performed on Patient 3 only.

TABLE II RESULTS OF DEVELOPING TEST IN CONGENITAL HEMOLYTIC ANEMIA

PATIENT	AGE (YR)	SEX	HB (GM)	RBC (MILL)	RETIC (%)	DEVELOPING TEST	REMARKS
1	28	F	10.6	3.2	10.6	Negative	Diagnosis based on developing test only as family not available for examination
2	23	F	10.6	3.2	13.0	Negative	Son of Patient 2. Developing test still positive 12 days after splenectomy. Six weeks following operation test turned negative.
3	4	M	3.9	1.8	10.4	Positive	
4	49	F	11.7	3.6	6.6	Negative	Sister of Patient 4
5	45	F	11.7	3.5	8.6	Negative	
6	55	F	11.7	3.8	4.4	Negative	
7	21	M	14.3	4.6	0.2	Negative	Son of Patient 6

Two cases in this group are of particular interest. Patient 1 had a negative Coombs test on two occasions. It was not possible to examine the family. The classification of this case is therefore arbitrary and based only on the negative developing test.

Patient 3, the son of Patient 2, presented the most interesting problem—a positive developing test in a well established case of hereditary hemolytic anemia. This 4-year-old white boy entered the Sarah Morris Hospital because of accidental trauma. His mother (Patient 2) had always been anemic and had been advised to have a splenectomy several years ago. The child had been pale and icteric since the age of 4 months. Splenectomy, although repeatedly advised, had always been refused. Transfusions also had never been given.

Physical examination revealed a mildly jaundiced child with a large hematoma about the forehead. There was a loud systolic murmur at the apex. The liver was palpable 4 cm below the costal margin in the midclavicular line, and the spleen reached almost down to the iliac crest and had a definite palpable notch. Skull and chest films were within normal limits.

**Laboratory Data** Hematologic findings: Hb, 3.9 Gm (26 per cent) per 100 ml, RBC, 1.8 mill per cubic millimeter; WBC, 4,700; reticulocytes, 10.4 per cent; hematocrit, 12; CI, 0.72; MCV, 70 cu mm; platelets, 164,800. The blood film showed conspicuous

hypochromia and microcytosis as well as definite spherocytosis. The coexistence of both poorly stained hypochromic corpuscles and fully hemoglobinized spherocytes was very striking. The differential count was within normal limits. Saline fragility started at 0.8 per cent. Bleeding, clotting and prothrombin times were normal. Blood group formula: A MN, Rh<sub>1</sub> Rh<sub>2</sub> ( $\frac{CDE}{c}$ )\*. Bone marrow marked erythroid hyperplasia of normoblastic variety.

**Chemistry.** Serum bilirubin 3 mg per cent, cholesterol, 78 mg per cent (60 per cent esters), thymol turbidity 2.4 units, cephalin and thymol flocculation tests, negative, total protein, 7.2 Gm, true albumin 4.4 Gm, true globulin, 2.8 grams. The Kahn test was negative and the urine did not contain bilirubin.

The patient was splenectomized after the hemoglobin and cell count were brought to normal levels by means of several blood transfusions. He made an uneventful recovery. His blood findings were within normal limits seven weeks after splenectomy, and he is continuing to do well.

It should be emphasized that it is difficult to decide whether this patient was in crisis when he entered the hospital. His mother stated that his general condition did not differ from the usual and that she brought him to the hospital because of the trauma. Although blood examination revealed a very severe anemia, a slight leucopenia and thrombocytopenia, there was a definite elevation of reticulocytes and the marrow did not show any evidence of maturation arrest as described by Owren.<sup>10</sup> The hypochromia probably was caused by poor nutritional intake in this growing chronically ill patient.

The developing test was strongly positive on admission, and the same result was obtained five days later after several transfusions were given. On the twelfth day following splenectomy the test still was strongly positive but became negative five weeks later. The disappearance of the positive developing test after splenectomy should be stressed. Some of our own and previously published cases of acquired hemolytic anemia<sup>10, 13, 18</sup> showed persistence of a positive developing test for long periods after operation.

**3 Sick Cell Anemia in Crisis.**—Two patients with sickle cell anemia in crisis showed a negative developing test thus demonstrating that no coated cells are present during these episodes. This finding points against an immunologic extracorporeal mechanism operating during the crises of this disease.

**4 Miscellaneous.**—One syphilitic patient with a severe nonspherocytic hemolytic anemia and hepatitis probably caused by arsphenamine, showed a negative Coombs' test. Negative results also were obtained in a case of chronic myelogenous leukemia with strong autoagglutination and in another patient with spherocytic hemolytic anemia caused by a new sulfa compound (Sulphonation).

### 5 Results of Other Investigators—

(a) *Acquired Hemolytic Anemia (Idiopathic and Symptomatic)* The results of the developing test as obtained by other investigators are tabulated in Table III. In all of the twenty-four previously reported cases a positive developing test was regularly found. No negative results were encountered. Splenectomy did not lead to disappearance of the coated spherocytes although the hemolytic process had stopped. Boorman and co-workers<sup>10</sup> found a negative Coombs test

We are indebted to Dr. S. O. Levinson and Dr. A. Wolf of the Serum Center, Michael Reese Hospital, for establishing the exact Rh-Hr formula of this patient.

in five atypical nonspherocytic cases of acquired hemolytic anemia. These cases are omitted from this discussion as they do not exhibit the diagnostic criteria of a spherocytic acholuric jaundice. Loutit and Mollison<sup>18</sup> added two more cases to those already reported by Boorman and associates. One of these patients had a positive developing test, although it is stated that at the time of testing there was no spherocytosis and a normal saline fragility. This patient appears to have had a typical spherocytic hemolytic anemia, and she later died of this disease.

TABLE III RESULTS OF OTHER INVESTIGATORS

INVESTIGATORS	NUMBER OF CASES OF CONGENITAL HEMOLYTIC ANEMIA WITH NEGATIVE DEVELOPING TEST			NUMBER OF CASES OF ACQUIRED HEMOLYTIC ANEMIA WITH POSITIVE DEVELOPING TEST			REMARKS
	TOTAL	BEFORE SPLENECTOMY	AFTER SPLENECTOMY	TOTAL	BEFORE SPLENECTOMY	AFTER SPLENECTOMY	
Boorman and co workers <sup>10</sup>	17	8	9	5	2	3	One case of acquired hemolytic anemia of symptomatic variety. Persistence of positive developing test in one patient up to 2 yr after splenectomy.
Loutit and Mollison <sup>18</sup>	0	0	0	2	2	0	Strongly positive developing test in one case in absence of spherocytes and increased fragility. Patient had spherocytosis prior to test and later died of acholuric jaundice.
Evans and co workers <sup>14</sup> Sturgeon <sup>15</sup>	0	0	0	2	2	0	One patient with sickle cell anemia and two patients with Cooley's anemia also showed negative developing test.
	3	3	0	3	1	2	
Wagley and co workers <sup>17</sup>	3	3	0	12	Not specified	Not specified	At least two of the acquired cases are of the symptomatic type.

(b) *Hereditary Hemolytic Anemia* A negative developing test was found in all of the twenty-three cases reported so far (Table III). Our case showing a positive Coombs test appears to be the first observation of such an occurrence in the hereditary disease. However, Dameshek and Bloom,<sup>20</sup> without actually performing a developing test, have demonstrated incomplete antibodies in the plasma of two patients with hereditary hemolytic anemia in crisis using albumin as a diluent. Since in the presence of such antibodies the developing test always has been found positive, these two cases may be quoted as corroborative evidence.

## DISCUSSION

The interpretation of a positive developing test in acquired and in some instances of hereditary spherocytic jaundice requires a critical understanding of the pertinent facts concerning the pathogenesis of these syndromes. Because

of the controversial character of the currently favored theories it was deemed necessary to correlate and to consider these problems in greater detail

#### *A Theoretical Considerations —*

*Immunologic Nature of the Developing Test* Recent work has clearly established the existence of at least three different types of antibodies to the Rh factors. These are (1) the saline (complete, first order) antibody, (2) the albumin (incomplete, saline blocking,<sup>21, 22</sup> second order) antibody, and (3) the "true" blocking<sup>23</sup> (cryptagglutinoid<sup>23</sup> third order) antibody. The second order antibody blocks the activity of the saline antibody and can be removed from the red cells by extensive washing. The "true" blocking antibody blocks the reaction of the albumin agglutinin and cannot be washed off.<sup>23</sup>

Recently Mohn and Witebsky<sup>23, 24</sup> have shown that the last two mentioned varieties of immune bodies cause "coating" of the red cells. Consequently a positive developing test is indicative of the adsorption of either the second or third order antibodies onto the surface of the red cells. Failure to obtain agglutination in albumin in the presence of a positive developing test clearly establishes the existence of this "true" (third order) blocking antibody.

A positive developing test in spherocytic hemolytic anemia has been repeatedly demonstrated without any evidence of antibodies directed against the Rh Hr (CDE) system. It may be assumed that the agglutinins found in the spherocytic hemolytic anemias follow a similar immunologic pattern. Nothing is known, however, about antigenic or other mechanisms stimulating the production of these immune bodies.

The demonstration of a positive developing test in our case of hereditary hemolytic jaundice and the corroborative results of Dameshek and Bloom<sup>6</sup> prove the presence of an immunologic mechanism in these cases. Anti Rh Hr immune bodies are unlikely to be responsible for the positive developing test because our patient was Rh positive and splenectomy resulted in the disappearance of the positive Coombs test.

*Nature and Origin of Spherocytosis* Spherocytes are red cells with increased thickness, decreased mean cell diameter and normal volume. These physical alterations account for the globular shape of these cells as contrasted to the biconcavity of the normal erythrocytes. Spherocytosis may be found in a great variety of conditions. Experimentally it may be produced *in vivo* by burns<sup>5</sup> and by the injection of certain hemolytic agents (e.g. antired cell sera<sup>4</sup>, phenylhydrazine). *In vitro* it may be brought about by exposing red cells to certain chemicals (e.g. lysolecithin, saponin) or to lowered osmotic tension or even by firmly pressing a cover slip over a fresh preparation of blood.<sup>6</sup> Clinically, spherocytosis is always found in the hereditary type and in many cases of the acquired type of hemolytic anemias of various etiologies (immunologic, physical and chemical).

These observations clearly demonstrate that a multitude of mechanisms may be responsible for this change in the shape of the red cell. The common result of all these conditions is an alteration in the structure of the erythrocytes, leading to a disturbed equilibrium of the forces which keep the normal corpuscles in a biconcave shape. The nature of these forces is but poorly understood at the present time.<sup>6</sup>

Since the number of biologically significant alterations in shape which a red cell may assume appears to be limited, it is not permissible to deduce that a given morphologic anomaly is always produced by the same factors. Further, more, the functional behavior of red cells having the same abnormal shape may vary in many ways as determined by the original etiologic mechanisms. Functional differences between spherocytes are clearly shown by the reaction of these cells to the developing and the lysolecithin fragility tests. Recent survival time studies with sickle cell anemia and sickle cell trait cells also point to qualitative variations hiding behind the common feature of the sickling tendency.<sup>27-28</sup>

The recognition that several types of spherocytes exist must be taken into consideration by any theory as to the site of origin of this anomaly in shape which occurs in various clinical conditions. The spherocytes found in the circulation of severely burnt patients quite obviously originate in the damaged areas. It appears more than likely that the qualitatively different spherocytes found in the hereditary and acquired (immunologic) types of hemolytic anemia are also of different origin. This point of view may be helpful in evaluating the current hypotheses on the origin of spherocytosis.

According to Naegeli<sup>29</sup> the shape of any erythrocyte is primarily regulated in the marrow. In hereditary hemolytic jaundice many red cell precursors are, therefore, predestined to become spherocytes. According to this concept spherocytosis is a red cell anomaly under genetic control. The failure of spherocytosis to disappear following splenectomy in congenital acholuric jaundice is often cited to support this theory. It should be emphasized, however, that many cases of acquired hemolytic anemia also show persistent spherocytosis after splenectomy and that a positive developing test may remain demonstrable for many years.

Dameshek<sup>30</sup> objects to Naegeli's hypothesis on the ground that spherocytosis is never observed in the nucleated and reticulated red cells of the marrow. He postulates the action of an intravascular antibody on normal cells, thus rendering them spherocytic. According to this unitarian hypothesis, any spherocytosis—congenital or acquired—is caused by extracorporeal mechanisms. The fact that normal erythrocytes transfused into a patient with hereditary hemolytic anemia have a normal life span whereas the patient's own cells are prematurely destroyed<sup>8, 30</sup> is explained by the assumption that the postulated immune bodies are "autospesific"—attacking only the patient's own erythrocytes. Such an interpretation necessarily implies that the production of these hypothetical "auto-specific antibodies" is also controlled by an hereditary mechanism. It should be pointed out that the failure of nucleated and reticulated erythrocytes to exhibit spherical shape cannot be used to disprove their primary origin in the marrow. It is quite possible that the presence of nuclear material so alters the cytoskeleton that spheroidicity cannot be achieved. The fact that in nonhemolytic elliptocytosis the nucleated corpuscles also fail to show elliptic shape<sup>31</sup> may be quoted as another example of a genetic blood disorder not displaying the characteristic shape anomaly in the nucleated precursors.

In regard to the "autospesific" immune bodies it should be stated that the developing test is an unspecific test for globulin adsorbed to the surface of the erythrocytes. Since spherocytes found in the hereditary disease are usually

"uncoated" it follows that the hypothetical autoagglutinins or hemolysins are either not globulins or that the test is not sensitive enough to detect them. Even if such factors should be discovered it is more than likely that they would be found to differ qualitatively from the globulin immune bodies.

Ham and Castle<sup>1</sup> consider stasis to be an important factor producing spherocytosis. These investigators have shown that *in vitro* incubation of red cells and also stagnation of erythrocytes in the spleen result in increasing spheroidicity with increasing mechanical and osmotic fragility. Erythrostasis is supposed to cause an accumulation of metabolites with resulting swelling of the cells. This hypothesis does not account for the absence of spherocytosis in many splenomegalies (e.g., polycythemia) where severe congestion and stasis may be found.

Most of these hypotheses are *unitarian* in character, either disregarding the demonstrable qualitative differences of the spherocytes or requiring special assumptions for a satisfactory explanation of the known facts. Although these theories have been extremely useful in stimulating valuable experiments which uncovered new evidence we believe that at present the hypothesis of the *multiple origin of spherocytosis* is more adequate.

From this standpoint it seems quite probable that in the hereditary type of hemolytic anemia uncoated spherocytes develop in the marrow under genetic control whereas in the acquired variety spherocytes are formed after contact with coating antibodies originating in the spleen<sup>1</sup> or possibly other organs. Spherocytosis caused by physical and chemical factors results from the exposure of the erythrocytes to these agents either intravascularly or within the damaged tissue.

Fig. 1 represents a diagram summarizing the pertinent points of this hypothesis.

The exceptional presence of coated spherocytes in a proved case of hereditary hemolytic anemia is therefore interpreted as being caused by the simultaneous existence of two pathogenic mechanisms. After splenectomy the production of coating antibodies ceased and the developing test became negative. Spherocytes of the uncoated variety continued to be present.

*The Role of the Spleen in the Spherocytic Hemolytic Syndromes.* In hereditary spherocytic anemia the pathologically increased destruction of red cells disappears following splenectomy. It is usually assumed that the spleen participates physiologically in erythrocyte disintegration and that in the spherocytic anemia a hyperfunction (hemolytic hypersplenism) exists. Since the mode of red cell elimination under normal conditions is still a matter of debate various mechanisms like erythrophagocytosis,<sup>33</sup> erythrostasis,<sup>32</sup> or increased lysolecithin production,<sup>34-3</sup> are emphasized. Without going into any details all these hypotheses do not clearly explain why all the other nonspherocytic hemolytic syndromes (sickle cell anemia, Cooley's anemia, paroxysmal nocturnal hemoglobinuria, etc.) are admittedly not influenced by splenectomy. Survival time studies have shown that the life span of the red cells in normal persons following removal of the spleen remains unchanged.<sup>36-37</sup> It may be argued that this finding does not necessarily invalidate the theories of hemolytic *hypersplenism* because the

other constituents of the reticuloendothelial system substitute for the spleen. In hereditary spherocytosis, however, splenectomy stops permanently the increased rate of hemolysis, and no other organs come apparently into play<sup>36, 37</sup>. Therefore, the reticuloendothelial system does not act as a biologic unit in this syndrome. Consequently the theory of hemolytic hypersplenism could apply only to the spherocytic hemolytic anemias.

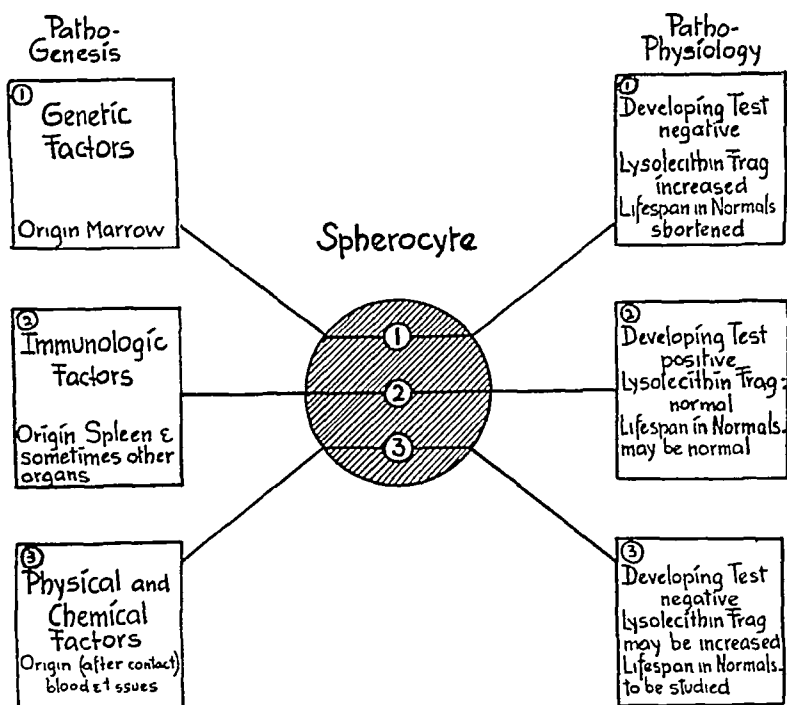

Fig. 1—Differences between morphologically identical spherocytes in clinical conditions

According to the *hypothesis of specific splenic hemolysis*, participation of the spleen in physiologic red cell disintegration is either absent or negligible<sup>39</sup>. The spleen may be the graveyard, but it is not the slaughterhouse of the normal corpuscles<sup>38</sup>. Recent studies have shown that physiologic erythrocyte elimination depends on the age of the cell and also on the mechanical factors to which it is exposed during its life span within the circulation<sup>39, 40</sup>. All hemolytic syndromes are characterized by erythrocytes with specific structural alterations of the cytoskeleton<sup>41</sup>. Such changes may manifest themselves either morphologically or functionally. They may be due to faulty production in the marrow (intra-corpuscular mechanisms) or may develop from the action of external agents on normally constructed erythrocytes (extra-corpuscular mechanisms). In some disorders a combination of both types may be demonstrable, some defective cells may even become vulnerable to physiologic mechanisms which do not attack normal corpuscles<sup>39</sup>.

Splenic hemolysis is predominantly involved in the spherocytic hemolytic syndromes. In the hereditary disorder the spleen selectively removes the un-

coated pathologic cells. In the immunologic acquired variety, the spleen produces the coating antibodies which it is assumed injure the cells and thus render them spherocytic. There is ample experimental evidence available to support these statements. Normal red cells transfused into a patient with familial spherocytosis, have a normal survival time. The patient's uncoated spherocytes, when transfused into a normal person are rapidly destroyed.<sup>8, 20</sup> When spleens, removed for nonhemolytic disorders, are perfused with normal erythrocytes and also with uncoated spherocytes the former pass through the splenic sinusoids whereas the latter are retained.<sup>16, 4</sup> When normal erythrocytes are brought into contact with splenic tissue obtained from patients with acquired spherocytic anemia, the red cells become coated showing distinct agglutination with the anti globulin serum. Control experiments with spleens from patients with hereditary spherocytosis and other conditions fail to give any indication of the presence of an adsorbable globulin.<sup>17</sup>

It is a well known clinical experience that patients with acquired hemolytic anemia may or may not respond to splenectomy whereas patients with the hereditary disorder almost always benefit from this operation.<sup>2</sup> Patients with the acquired disorder may be classified into three groups according to their response to removal of the spleen. In the first group of patients spherocytes disappear completely and permanently.<sup>43</sup> In the second group the coated cells *persist pathologic hemolysis stops* and these spherocytes exhibit a normal life time in the patient and even when transfused into a normal person.<sup>18</sup> In the third group coated spherocytes continue to be destroyed rapidly. These different responses require an adequate explanation.

In the first group antibody production is apparently restricted to the spleen. This was observed in Patient 8 of our series of acquired hemolytic anemia. Our patient with hereditary spherocytosis with a positive Coombs test also belongs to this category, the immunologic mechanism being superimposed upon the genetic anomaly.

The finding of a persistently positive Coombs test after splenectomy indicates that the manufacture of antibodies occurs in other organs also. The fact that splenectomy stops the pathologic hemolysis in some of these patients and does not in others may perhaps be explained on a quantitative basis. If the formation and release of damaging immune bodies proceed on a larger scale in the extra splenic tissues splenectomy will not be successful. However our present understanding of these mechanisms is too incomplete to rule out the possibility that qualitative differences in the coating antibodies and their associated damage to the cytoskeleton may not also be of importance.

The ways and means by which the spleen distinguishes between the different types of spherocytes are not quite clear. Whipple<sup>44</sup> believes that normal discoidal cells have no difficulty in traversing this organ whereas spherocytes being thicker, are unable to pass through the stomata of the splenic sinuses. The demonstration that coated spherocytes when transfused into normals have sometimes a normal survival time<sup>18, 4</sup> renders this hypothesis untenable. It seems however conceivable that the local concentration of antibodies may destroy the cells within the spleen.

other constituents of the reticuloendothelial system substitute for the spleen. In hereditary spherocytosis, however, splenectomy stops permanently the increased rate of hemolysis, and no other organs come apparently into play<sup>36, 37</sup>. Therefore, the reticuloendothelial system does not act as a biologic unit in this syndrome. Consequently the theory of hemolytic hypersplenism could apply only to the spherocytic hemolytic anemias.

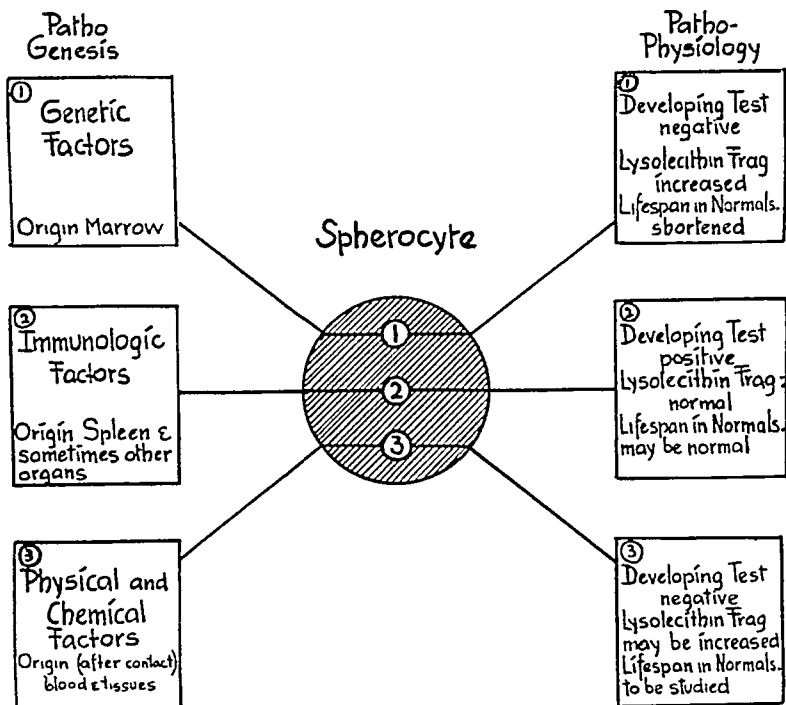

Fig 1—Differences between morphologically identical spherocytes in clinical conditions

According to the *hypothesis of specific splenic hemolysis*, participation of the spleen in physiologic red cell disintegration is either absent or negligible<sup>37</sup>. The spleen may be the graveyard, but it is not the slaughterhouse of the normal corpuscles<sup>38</sup>. Recent studies have shown that physiologic erythrocyte elimination depends on the age of the cell and also on the mechanical factors to which it is exposed during its life span within the circulation<sup>39, 40</sup>. All hemolytic syndromes are characterized by erythrocytes with specific structural alterations of the cytoskeleton<sup>41</sup>. Such changes may manifest themselves either morphologically or functionally. They may be due to faulty production in the marrow (intra-corpuscular mechanisms) or may develop from the action of external agents on normally constructed erythrocytes (extra-corpuscular mechanisms). In some disorders a combination of both types may be demonstrable, some defective cells may even become vulnerable to physiologic mechanisms which do not attack normal corpuscles<sup>39</sup>.

Splenic hemolysis is predominantly involved in the spherocytic hemolytic syndromes. In the hereditary disorder the spleen selectively removes the un-

As may be seen from this discussion our knowledge of the spherocytic hemolytic diseases is still very incomplete. Although the finding of a positive developing test in both the hereditary and the acquired variety diminishes the practical differential diagnostic value of the Coombs test its contribution to the understanding of these syndromes may become significant in the future.

### *B Practical Considerations—*

Any globulin which has become adsorbed onto the surface of the erythrocytes will give a positive developing test with the antiglobulin serum. Since the Coombs test is a nonspecific phenomenon a positive result can be used for differential diagnosis of the spherocytic hemolytic anemia only if any other cause of red cell sensitization has been ruled out. Isimmunization by the Rh II<sub>1</sub> factors must therefore always be considered in the interpretation of the results. The indirect developing test may be used to exclude this latter mechanism. By incubating the patient's serum with normal O Rh positive (CDE) as well as with O Rh negative (ede) cells and then running the test with the washed erythrocytes one may be able to differentiate between Rh sensitization and the immune bodies operating in the hemolytic anemias. If agglutination occurs with both Rh positive and Rh negative cells Rh antibodies can be excluded. The indirect developing test is based on the assumption that the plasma of the patient contains demonstrable circulating antibodies. However the concentration of these antibodies may be so small that only the sensitive direct Coombs test may betray their adsorption on the red cells. Furthermore, if only third order antibodies are present in the serum, agglutination will not occur even after addition of albumin, but may be detected by means of the developing test.<sup>23, 24</sup> Table V summarizes the results of the procedures to be employed in the differentiation

TABLE V DIFFERENTIATION BETWEEN Rh SENSITIZATION AND IMMUNOLOGIC HEMOLYTIC ANEMIAS

TESTS	Rh SENSITIZATION CIRCULATING ANTIBODIES DEMONSTRABLE	IMMUNOLOGIC HEMOLYTIC ANEMIA	
		WITH	WITHOUT
		CIRCULATING ANTIBODIES	
Direct developing test	Positive	Positive	Positive
Indirect developing test against O Rh positive (CDE) cells	Positive	Positive	Negative
Indirect developing test against O Rh negative (ede) cells	Negative	Positive	Negative

of these two conditions caused by qualitatively different immune bodies. No differentiation between these two states of immunization is possible at present if the patient is Rh negative and is known to have had Rh sensitization. In such cases the Coombs test may be misleading, if not properly evaluated.

"False positive" results<sup>25</sup> may be due to improper technique or to adsorption of globulins caused by nonimmunologic mechanisms. However such conditions, although theoretically conceivable are not known at present. The possible objection that the positive developing test in our case of congenital hemolytic anemia might be a 'false positive' one is disproved by the fact that it was

positive on repeated occasions when the controls were negative and became permanently negative after splenectomy, this patient who was Rh positive never had any transfusions previously—further proof that H<sub>1</sub> immunization could not have played a role either

Not all cells giving a positive developing test have a spherocytic shape. Although spherocytes are sometimes observed in erythroblastosis fetalis,<sup>50, 51</sup> in many cases of this disorder spheroidicity is not demonstrable on the film. Furthermore, cases of acquired hemolytic anemia in adults have been observed where spherocytosis was absent but the Coombs test was positive.<sup>18</sup> Whether coating and alteration in shape can be correlated to specific antibodies requires further studies.

The demonstration of a positive Coombs test in hereditary hemolytic anemia diminishes the value of this test as a means for the differential diagnosis between the congenital and the acquired spherocytic anemias. Since a positive developing test is indicative of an existing immunologic mechanism, a negative test excludes such a condition and speaks strongly for familial spherocytic anemia if drugs and other obvious hemolytic agents can be ruled out. Table VI contains a summary of the disorders in which the performance of the developing test may be of diagnostic value. In our opinion the developing test should become a necessary requirement in diagnosing hemolytic syndromes. If positive, the hemolytic anemia should be designated as being of the "immunologic" type. Such an immunologic hemolytic anemia may even be found superimposed on hereditary spherocytosis.

TABLE VI THE DEVELOPING TEST IN THE HEMOLYTIC ANEMIAS,  
RESULTS OBTAINED SO FAR<sup>10, 18</sup>

POSITIVE DEVELOPING TEST	NEGATIVE DEVELOPING TEST
(A) Acquired spherocytic hemolytic anemias	(A) Hereditary spherocytosis
(1) Idiopathic	(B) Spherocytic anemia due to physical or chemical factors (burns,* sulfa drugs, phenylhydrazine*)
(2) Symptomatic (Hodgkin's disease, leucemia, lymphomas, Boeck's sarcoid, Gaucher's disease,* ovarian tumors,* etc.)	(C) Sick cell anemia
(B) Hereditary spherocytosis (occasionally)	(D) Cooley's anemia
(C) Isoimmunization due to known immune bodies Rh, Hr, A, B, (M*)	(E) Paroxysmal nocturnal hemoglobinuria

#### SUMMARY

1 The developing (Coombs) test, using an antihuman globulin rabbit serum, demonstrates the presence of globulin antibodies adsorbed to the surface of erythrocytes. Thus "coated" and "uncoated" red cells can be distinguished.

2 Sixteen cases of spherocytic hemolytic anemia were investigated. All the seven cases of idiopathic acquired type and one case of symptomatic hemolytic anemia (reticulum cell sarcoma) gave a positive test. The result was negative in one patient with hemolytic anemia caused by a sulfa drug. Of the seven patients with hereditary spherocytosis, six showed a negative developing test whereas one severely ill patient displayed a strongly positive reaction.

3 Splenectomy in the acquired cases resulted either in disappearance of the coated spherocytes or the coated cells remained demonstrable, although the pathologic hemolysis ceased

Splenectomy in the case of hereditary spherocytosis with a positive Coombs test led to disappearance of the coating although spherocytosis persisted. This finding demonstrates that two different mechanisms were operating in this particular case

4 A positive developing test indicates the presence of immune bodies. The immune bodies which occur in spherocytic anemias are qualitatively different from the antibodies directed against the Rh H<sub>1</sub> antigens. A method is described to distinguish these two categories of antibodies

5 The existence of "coated" and "uncoated" spherocytes is explained by the hypothesis of the multiple origin of spherocytes. In the hereditary type of hemolytic anemia uncoated cells develop in the marrow under genetic control, whereas in the immunologic variety spherocytes are formed after contact with coating antibodies originating in the spleen and/or other organs. Spherocytosis caused by physical and chemical factors will result from the exposure of normal red cells to these agents either intravascularly or within damaged tissues

6 The theory of specific splenic hemolysis is advanced in order to explain the role of the spleen in spherocytic hemolytic syndromes as contrasted to the current hypotheses of hypersplenism. Participation of the spleen in physiologic red cell destruction is considered negligible. Splenic hemolysis is predominantly involved in the spherocytic hemolytic syndromes. In the hereditary disorder the spleen selectively removes the uncoated pathologic cells. In the immunologic variety the spleen produces the coating antibodies which probably injure the cells and render them spherocytic. Conceivably the cells may then be destroyed within the spleen by an increased concentration of antibodies in this organ

7 The finding of a persistently positive developing test following splenectomy indicates that the production of antibodies may occur in other tissues also. The fact that splenectomy stops the pathologic hemolysis in some patients with acquired hemolytic anemia and does not in others may perhaps be explained on a quantitative basis. If the formation and release of damaging immune bodies proceeds on a larger scale in the extrasplenic tissues splenectomy will not be successful. However, our present understanding of these mechanisms is still incomplete. The possibility exists that qualitative differences in the coating antibodies and their associated damage to the red cells may also be of importance

8 The demonstration of a positive Coombs test in hereditary hemolytic anemia diminishes the value of this test in the differential diagnosis between hereditary and acquired spherocytic anemia. Since a positive developing test is indicative of an existing immunologic mechanism a negative test speaks strongly for familial spherocytosis if drugs and other obvious hemolytic agents can be ruled out

9 The developing test should become a necessary requirement in diagnosing hemolytic syndromes. If positive the hemolytic anemia should be designated as being of the immunologic type. Such an immunologic hemolytic anemia may even be found superimposed on hereditary spherocytosis

## HYPERTENSION DURING BLOOD TRANSFUSIONS FOR HEMORRHAGIC SHOCK IN A PATIENT WITH UNILATERAL RENAL ISCHEMIA

ELMER L. DEGOWIN, M.D.  
IOWA CITY, IOWA

**D**URING the last twenty years the investigations of Goldblatt and many others have firmly established the main outlines of the humoral mechanism of renal hypertension. When renal ischemia occurs from any cause, renin is elaborated in the parenchyma of the kidney and is released into the blood stream. Renin itself has no vasopressor action but it combines with hypertensinogen (renin activator), which is normally present in excess in the plasma and lymph, to produce hypertensin (angiotonin). This latter substance has a definite vasopressor effect. A hydrolyzing enzyme, hypertensinase (angiotoninase), is present in various tissues and has the property of destroying or inactivating hypertensin. This agent is found in highest concentration in the intestine, kidney, pancreas, spleen, liver, and erythrocytes. It is present in only small amounts in blood plasma and serum.

Sapirstein, Ogden, and Southard<sup>1</sup> demonstrated a renin-like substance in the blood of dogs during severe hemorrhagic shock. Later they<sup>2</sup> proved that the arterial hypotension associated with extensive loss of blood in the dog was caused partly by exhaustion of renin activator (hypertensinogen). The injection intravenously of relatively small volumes of renin activator, prepared from the globin of ox plasma, would temporarily restore the blood pressure to normal.

Dogs in severe grades of hemorrhagic shock were studied by Collins and Hamilton<sup>3</sup> who found that the renin substrate (hypertensinogen) increased progressively in animals from which the kidneys previously had been removed. In intact dogs there was an initial rise in the concentration of renin substrate which was later followed by a significant reduction below normal as hemorrhage proceeded. They also obtained evidence of increases in the concentration of a substance giving the pharmacologic reactions of angiotonin (hypertensin). Late in the course of shock there was a secondary diminution in angiotonin which was attributed to exhaustion of the renin substrate.

By injecting renin and angiotonin into dogs in hemorrhagic shock, both before and after transfusions of blood were given, Middleton<sup>4</sup> showed that there was little support for the conclusion that there was a deficiency of renin substrate (hypertensinogen). He concluded that the renin-hypertensinogen mechanism was not involved in the occurrence of circulatory failure in shock and that the return of response to renin or hypertensin during circulatory failure remained unexplained.

From the Department of Internal Medicine, University Hospitals, State University of Iowa.

Received for publication Feb. 24, 1949.

The effect of blood transfusions on the blood pressure of human beings in hemorrhagic shock has been observed thousands of times. Although there may be an increase in the amount of renin produced during shock or an exhaustion of hypertensinogen, the transfusion of either fresh or preserved human blood usually does not result in hypertension in the patient in shock. It was therefore of particular interest to encounter a rare combination of circumstances which enabled observations to be made upon a man who received forty blood transfusions in the treatment of hemorrhagic shock. During and after many transfusions the arterial tension rose to abnormally high values for several hours. Autopsy subsequently revealed the presence of a ring of malignant lymphoma around the left renal artery in such a manner as to produce narrowing of the lumen.

#### CASE REPORT

Dr F E W, Hospital No 43 9556, a 53 year old male teacher of veterinary medicine, was examined in the University Hospitals Aug 30 1943, he complained of pain in the lower back and abdomen. In March 1942 he had developed painless swelling of the lymph nodes in the right side of the neck. Biopsy of a lymph node had been diagnosed as lymphoblastic lymphoma and x ray irradiation of the cervical region had resulted in the complete disappearance of palpable nodes in the region. Thereafter he had felt well until a few weeks before admission to the hospital when he experienced diffuse transient pains in the abdomen. He developed severe pain in the lower back which was augmented in the supine position and necessitated sleeping in a chair. The pain became more intense when the spine was hyperextended. There had been no radiation of pain in the distribution of the sciatic nerves. Several days before admission he had noted that the feces became black and his skin slightly pale.

The physical examination revealed a well developed and well nourished man who was not in acute distress. The skin and mucous membranes were pale. There was no cyanosis, dyspnea, or icterus. The pupils reacted to light and accommodation, the ocular fundi were negative. There was no evidence of arteriosclerosis of the retinal vessels. The nose, ears, teeth, and tongue were normal. No lymph nodes or other masses were palpable in the neck. The thorax was symmetrical. The heart was normal in size, rate, and rhythm. No murmurs were heard. The arterial blood pressure measured 130/80. The lungs were normal from percussion and auscultation. The abdominal wall was thick and well muscled. The area of splenic dullness was somewhat increased and a mass descended with inspiration beneath the left costal margin which was thought to be spleen. This was not tender. The liver was not palpable. There was no ascites. The genitalia and rectum were normal. The prostate gland was not enlarged. Feces removed during digital examination of the rectum were black and gave chemical tests for blood. There was pitting edema of the ankles to the depth of 1 mm to 2 mm. The tendon reflexes were physiologic. There were no areas of tenderness along the spine.

The initial urine specimen examined had a specific gravity of 1.020. It was clear acid and contained no albumin, glucose, or blood. The first blood count showed hemoglobin, 9.0 Gm per 100 ml (Haden-Hausser) erythrocytes 2.57 millions per cubic millimeter, leucocytes 6750. The differential leucocyte count was 66 per cent polymorphonuclear neutrophils, 1 per cent eosinophils, 1 per cent basophils, 27 per cent lymphocytes, 3 per cent monocytes, and 3 per cent unclassified cells.

An x ray examination of the chest and upper gastrointestinal tract was performed with the aid of a barium meal. The heart and great vessels were normal and there was no enlargement of the mediastinum. The lung fields were clear and the diaphragms were normal in position and function. There was no distortion of the stomach or duodenum although the fluoroscopist thought that the stomach was displaced anteriorly. The colon was examined radiographically with a barium enema but no abnormalities could be found.

The patient was admitted to a hospital bed on Sept 1, 1943. A sigmoidoscopic examination was made the next day. No abnormalities were found except a polyp on the left wall of the rectum which was not bleeding. On September 3 an attempt was made to pass a gastroscope but the procedure was abandoned when the instrument encountered an obstruction at the lower end of the esophagus.

Sept 12, 1943

# Blood Pressure Associated With Blood Transfusions

Fig 1

The pain in the back and the upper abdomen had been increasing daily so that sleep was interrupted. X-ray irradiation of the splenic area and epigastrium was begun September 4 and continued until September 10. During that time the patient was given 1,200 r to the retroperitoneal region and 800 r to the epigastrium in daily doses of 200 units on each side. Anorexia increased and the pain in the back and abdomen was augmented. In the evening of September 10 the patient vomited 20 ml of dark blood and passed a small amount of blood per rectum. There was profuse diaphoresis and the volume of the pulse was temporarily diminished. The next day he vomited 150 ml of dark red blood. He was found to belong to group O and was given a transfusion of 500 ml of blood of homologous group preserved in a modified Rous-Turner solution.

At 2350 hours on September 11, without warning the patient vomited a large amount of blood and felt very weak. Thirty minutes later (at 0020 hours September 12) there was another emesis of blood and the passage of a thin firm stool. At 1030 hours there was more vomiting of blood and a feeling of thirst. An hour later the patient suddenly went into profound shock and became unconscious. There had been no abdominal pain but he was under the influence of morphine. Typical Kussmaul breathing developed and the blood pressure

Sept 13 1943

# Blood Pressure Associated With Blood Transfusions

measured 40/0. Fig 1 depicts the response of the blood pressure to the transfusion of two liters of preserved blood. Consciousness was recovered at 1430 hours and the patient felt relatively comfortable for the rest of the day. That day the maximum value of the blood pressure after transfusion was 130/84.

On September 13 the patient passed several stools of bright red blood between 1400 and 1600 hours. He sweated moderately and complained of thirst. The blood pressure was 72/40. One liter of preserved blood was transfused with recovery from shock in approximately one and one-half hours. At 1800 hours the blood pressure was found to be 170/110 (see Fig 2). The measurements of arterial tension were checked several times within an hour and found to be correct. At 0830 hours on September 14 the blood pressure was still 168/106. By 1200 hours the tension had declined to 120/80. No blood transfusions were given that day.

The patient again lost large amounts of blood on September 16. There was blood in the vomitus and stools and he went into shock on two separate occasions. The response of the arterial tension to blood transfusions is indicated in Fig 3. With the third transfusion of 500 ml. of blood, the arterial pressure rose from 90/42 to 180/130 in thirty minutes.

During the fourth transfusion the blood pressure was augmented still further to 218/142 in another thirty minutes.

Fig 4 contains a summary of the transfusions of blood, the daily maximum and minimum blood pressure values, and the erythrocyte counts for most of the hospital stay. It will be noted that on September 19 the blood pressure measured 230/128 although the patient had received no blood transfusions for one and one half days. The next day normal values were observed.

On September 28 the erythrocyte count was 5.3 millions per cubic millimeter, in spite of the fact that there was daily bleeding from the gastrointestinal tract. Beginning September 12 the patient had a continuous low grade fever with rectal temperatures ranging

from 100° to 103° F. On September 20 the blood urea nitrogen was 14.7 mg per 100 ml and the creatinine, 1.0 milligram. The carbon dioxide combining power of the blood was 59.8 volumes per 100 milliliters. No further blood chemical studies were made. Urine specimens taken after transfusions were negative for hemoglobin. Six urine specimens were examined more completely, the last on September 29. The specific gravity ranged between 1.018 and 1.025. The reaction was always acid. None contained albumin, glucose, or blood. No casts or pus cells were seen in the sediment.

On September 30 the mass in the left upper quadrant of the abdomen was found to have enlarged considerably so that it protruded about four fingerbreadths below the costal margin. It seemed thicker than the spleen should have been with that degree of enlargement. By September 29 the patient was continuously disoriented and complained of terrible pain in the back and abdomen. There was frequent sweating, vomiting of blood, and the passage of bright red blood through the rectum.

On several occasions the patient was questioned concerning measurements of blood pressure before he entered the hospital. He was an eminent scientist who had considerable knowledge of medicine and took a keen interest in the scientific aspects of his condition. He stated that he had been examined several times during the preceding eighteen months at various clinics and the measurements of blood pressure always had been reported as normal.

TABLE I DATA ON THE DONORS AND THE STORAGE OF THEIR BLOOD FOR TRANSFUSION  
(ALL BELONGED TO GROUP O AND EACH TRANSFUSION WAS WITH 500 ML OF BLOOD)

R-T Blood preserved in modified Rous-Turner Solution

C Blood stored in sodium citrate solution

Altogether the patient received forty blood transfusions of 500 ml each. The blood was preserved in either a modified Rous-Turner solution or it was collected in sodium citrate solution and given within a few hours or days. The patient belonged to group O and, of course, received only blood of that group. Typing of the Rh antigen was not performed. There was one questionable hemolytic reaction after transfusion, all others were uncomplicated. The data on the donors whose blood the patient received are noted in Table I. Blood pressure measurements were not made on the donors.

## POST MORTEM FINDINGS

A complete autopsy was begun one hour and forty minutes after death.\*

The body was that of a well developed and well nourished man 166 cm in length and weighing 79.5 kilograms (175 pounds). There were no skin lesions or edema. The superficial lymph nodes were not enlarged.

*Peritoneal Cavity*—Before an incision was made a large mass could be seen and felt which occupied the left upper quadrant of the abdomen and the epigastric region. Section of the abdominal wall revealed good musculature and a layer of adipose tissue about 1.5 cm in thickness. Inspection of the peritoneal cavity disclosed a large nodular mass which occupied the left upper quadrant. It was firm and white. It involved the entire stomach, pancreas, pleural left adrenal gland and left kidney, the aorta and vena cava with their associated vessels, and retroperitoneal lymph node. The mesentery of the transverse colon and the splenic flexure was adherent to the mass but there was no constriction of the lumen of the bowel. The small intestine, right adrenal and right kidney were not involved. Some white strings of tumor tissue extended up into the hilus of the liver.

When the stomach was opened the crater of an ulcer the size of a man's fist was revealed in the posterior wall of the fundus. The ulcer had penetrated the spleen and excavated a cavity about 10 cm in diameter and 5 cm deep. The base of the ulcer lay deep in the spleen so that blood had passed freely from the splenic pulp into the stomach.

The retroperitoneal lymph nodes were enlarged to measure between 3 cm and 6 cm in diameter. They were soft white and cellular. They surrounded the aorta, vena cava, left renal vessel, the celiac axis and the superior mesenteric vessels. The pancreas was completely surrounded by tumor.

Microscopically it was seen that the normal architectural pattern had been completely replaced by a malignant neoplasm of the lymphoma group. The tumor for the most part, consisted of masses of lymphoblastic cells with a monotonously uniform pattern since there were no attempts at follicle formation. The lymphoblasts were round or oval and rather pale-staining. Scattered among the cells however, were numerous reticulohistiocytes in various stages of maturation. Many showed phagocytic activity. Scattered through the neoplastic tissue were several clumps of plasma cells. In other areas mononuclear cells probably monocytes were seen arising from the reticulum stroma particularly where there was hyperplasia of the reticuloendothelial elements. Occasionally there occurred rather large collections of the so called syncytial forms of primitive reticuloendothelial cells. These had dense masses of chromatin within the nuclei and only a slight amount of cytoplasm. These cells were arranged in cord and strands which separated the connective tissue stroma. Despite the various cell types present the lymphoblasts obviously predominated and it was apparent that the tumor was fundamentally of reticuloendothelial origin in which maturation had been arrested at the lymphoblastic stage. However, occasional clusters of immature lymphocytes also were observed which indicated that further maturation had occurred in some regions.

Many blood vessels particularly in the spleen were filled with neoplastic cells so that tumor thrombi were conspicuous. Numerous normal and pathologic mitotic figures were observed. In general the tumor appeared to be growing rapidly and was highly invasive. Local areas of necrosis especially in the spleen were found of which some were hemorrhagic from early infarction and others appeared older.

*Thoracic Cavity*—The left hemithorax contained 2500 ml of seroanguineous fluid. There were 100 ml of clear yellow fluid in the right hemithorax. The left lung was collapsed and the right was somewhat emphysematous.

*Mediastinum*—Just above the bifurcation of the trachea was a white cellular lymph node about 4 cm in diameter. Strings of white friable tumor tissue descended from this through the diaphragm and were interpreted to be lymphatic trunks filled with neoplasm.

\*The pertinent gross findings were reported by Dr. C. J. Mikkelsen while I am indebted to Dr. J. N. Cutler of the Department of Pathology for the microscopic findings.

*Heart*—The pericardial walls were smooth and glistening. The heart weighed 330 grams. The chambers were not dilated. The wall of the left ventricle was 1.5 cm in thickness, the right was 0.5 centimeter. The valve rings measured: aortic, 7.5 cm, pulmonary, 7.8 cm, mitral, 10.0 cm, and tricuspid, 11.8 centimeters. The foramen ovale was closed. The epicardium, endocardium, columnae carneae, papillary muscles, chordae tendineae, heart valves, and coronary vessels were normal.

Microscopic examination showed the epicardium to be thin and the epicardial fat abundant. There was no evidence of inflammation. The myocardium appeared virtually normal. There was no evidence of hypertrophy, infection, or infarction.

*Lungs*—The right lung weighed 400 grams. It was pale and the alveoli were slightly larger than normal. No lesions were found on section. The left lung weighed 420 grams. It was red, had the consistency of soft rubber, and sank when immersed in water. When sectioned, a red infarct about 8 mm in diameter was seen which contained one small, soft, yellow area.

Sections viewed microscopically showed focal aggregates of neoplastic cells in and beneath the pleura. The malignant cells extended a moderate distance into the parenchyma of the lung. Both arteries and veins were invaded by tumor cells. Focal atelectases were observed and adjacent to some were regions of compensatory emphysema. There was mild but definite thickening of the pulmonary arteries and arterioles. In one locus the parenchyma of the lung had been replaced by a mass of necrotic debris and hemorrhage. This area was well circumscribed and appeared consistent with an infarct about twelve hours old.

*Spleen*—The spleen could not be weighed accurately because it was embedded completely in neoplasm and surrounded by adherent omentum, diaphragm, and body wall. It measured about 15 by 20 centimeters. The upper medial portion formed a dark base for the ulcer in the stomach and the excavation was the size of a half grapefruit. Sections showed firm yellow areas in the parenchyma which were a maximum of 8 mm in diameter. Similar areas were barely visible to the naked eye. Very little red pulp was seen. No fresh infarcts were observed. The blood vessels at the base of the ulcer were patent and gaping, some of the lumens being 1 mm to 2 mm in diameter. The microscopic appearance is described under Peritoneal Cavity.

*Gastrointestinal Tract*—The esophagus was normal, but just above its entrance to the cardia of the stomach a neoplastic lymph node about 10 cm in diameter was situated anterior to the vertebral column so that it probably obstructed the passage of the gastroscope. Large masses of retroperitoneal nodes were filled with neoplasm in such a manner as to displace the stomach anteriorly. The upper half of the posterior wall of the stomach was completely adherent to the mass and to the spleen. In the posterior wall of the gastric fundus was the mouth of the ulcer which communicated with the interior of the spleen. This orifice was about 12 cm in diameter. The wall of the ulcer was so thin that soon it would have ruptured into the lesser omental sac.

The small intestine, colon, appendix, and rectum were normal except that the transverse and splenic portions of the colon were adherent to the spleen, although they were not invaded by neoplasm.

*Liver*—The liver weighed 1,900 grams. Section of the pedicle revealed white streaks extending into the parenchyma and yellow discrete areas measuring from 1 mm to 4 mm in diameter.

Microscopically much of the parenchyma appeared to have been replaced by masses of malignant cells. For the most part, the largest aggregates of neoplasm were in the portal areas. However, contiguous and ramifying masses of tumor cells involved the central and the mid zonal portions of the lobules. Mild fatty metamorphosis was present and there was active regeneration of liver cells in some areas, as evidenced by enlarged hyperchromic and frequently double nuclei. Small regions of necrosis were present.

*Pancreas*—This gland was surrounded by neoplastic tissue but microscopically the general architectural pattern seemed to be preserved. In several areas there was invasion of the gland by neoplastic cells, principally along the interlobar and interlobular septa. Small focal necroses had occurred and one zone of fat necrosis was seen. Invasion of the blood vessels by neoplasm was observed.

**Kidneys.**—The left kidney weighed 150 grams. The parenchyma appeared normal to the naked eye. The hilus was embedded in a mass of neoplasm which formed a complete ring around the renal artery. Longitudinal section of the vessel showed it to be patent but it was apparent that the lumen was narrowed by compression of the constricting ring of tumor (see Fig. 5).

Fig. 5—Photograph showing section of abdominal aorta and left renal artery laid open. On extreme right is the hilus of the left kidney. The renal artery is completely surrounded by a ring of lymphomatous tissue so that its lumen is compressed. (Photograph lightly retouched.)

The right kidney weighed 150 grams. Under the capsule were two yellow wedge shaped areas about 0.5 cm. in diameter. The parenchyma was otherwise normal.

Microscopically the architecture of both kidneys seemed to be well preserved. A few hyalinized and fibrotic glomeruli were present but most were within normal limit. Although there were a few degenerated tubules most were virtually normal. There was no evidence of lower nephron nephrosis or nephritis. Many of the tubules however contained precipitated protein and granular debris. The interstitial tissue was not edematous and the vessels in the parenchyma were normal. The capsule and superficial cortical tissue of the left kidney was invaded by solid masses of malignant cells. Large areas of necrosis were present in the neoplastic tissue. In the right kidney was seen a recent infarct which appeared to be about forty-eight to seventy-two hours old. Surrounding this there was a conspicuous zone of hyperemia and acute cellulitis.

Both pelves and ureters were normal and patent.

**Adrenals.**—The right adrenal gland appeared normal both grossly and microscopically. The left was fixed to the tumor tissue. In the microscope the capsule was seen to be invaded and replaced by masses of neoplasm. In a few regions there was also beginning invasion of the superficial portion of the cortex. For the most part however the cortex was well preserved. Foci of congestion were present in the medulla.

*Blood Vessels*—A few atheromatous plaques were seen in the aorta. In the upper abdomen the vessel was surrounded by neoplasm but there was no encroachment on the lumen. The greater portion of the left renal artery was surrounded by a thick collar of neoplastic cells, as seen microscopically. The cells had invaded and replaced the adventitia and were beginning to penetrate the media. For the most part, the neoplastic involvement was superficial. In some areas the intima was slightly thickened and the subintimal connective tissue was somewhat hyalinized. No thrombi were present.

*Diaphragm*—Microscopic sections showed invasion of the muscle bundles by strands and small masses of neoplastic cells.

*Brain, Genitalia, Gall Bladder, and Urinary Bladder*—These were entirely normal.

#### *Anatomic Diagnoses*—

Malignant lymphoma, mixed type, predominantly lymphoblastic, involving the retroperitoneal lymph nodes, spleen, liver, stomach, left kidney, left adrenal, pleura, and lung.

Massive ulceration of stomach into spleen with hemorrhage.

Recent infarcts of lungs, spleen, and kidneys.

Serosanguineous pleural effusion, left.

Partial collapse, left lung.

Compensatory emphysema, right lung.

Arteriosclerosis, generalized.

#### DISCUSSION

There can be little doubt that the patient did not have hypertension before the blood transfusions were given in the hospital. Several measurements of arterial tension were made before the onset of the severe hemorrhage by me and other members of the hospital staff and all values were found to be within the normal range. The patient had had several examinations by competent physicians in the eighteen months before admission to the hospital and hypertension had not been noted. Furthermore, the anatomic examination of the heart and blood vessels support the conclusion that essential hypertension was not a part of the clinical picture. The myocardium was not hypertrophied and the chambers of the heart were not dilated. There were few atheromata in the walls of the aorta. The coronary vessels appeared normal. There was little sclerosis of the smaller vessels.

All available evidence points to the conclusion that the transient episodes of arterial hypertension in this patient were caused by (1) the transfusions of blood, (2) the severe hemorrhage and shock caused by the erosion of splenic vessels with lumens of 1 mm to 2 mm in diameter and the loss of blood directly into the stomach, (3) the ischemia of the left kidney whose artery was constricted by a ring of neoplasm, or (4) a combination of two or more of the three factors.

It is probable that preserved human blood contains some hypertensinogen, renin, and hypertensin. Kohlstaedt, Page, and Helmer<sup>6</sup> noted that renin activator (hypertensinogen) disappeared in five or six hours from dog's blood kept at room temperature. It was present in similar blood stored at 10° C for a week. However, blood transfusions have not been observed to produce hypertension in the usual clinical experience. The blood pressure is measured frequently in patients in hemorrhagic shock who receive blood transfusions as the principal method of treatment. Yet hypertension is not usually associated

with recovery from shock. If the experimental studies previously quoted can be applied to human beings in shock it would seem that the loss of hypertensinogen by hemorrhage and the secretion of renin by the kidneys whose circulation is unimpaired are quantitatively not sufficient to produce an augmentation of arterial pressure above the normal when blood transfusions are given.

The unusual anatomic feature of the case under discussion was the compression of the left renal artery by neoplasm. Renal ischemia in comparable circumstances has been shown repeatedly to produce hypertension under experimental conditions. It remains to relate this to the facts which are known about transfusion and hemorrhagic shock. It is conceivable that if some renin is produced by the otherwise normal kidney when the organism undergoes severe hemorrhagic shock, more renin might be produced with the same degree of circulatory failure if the renal artery were already constricted. Although experimental evidence is not at hand, it seems that this much must be assumed to explain the facts in this case.

Two alternatives are possible to explain the association of the hypertension with blood transfusion: (1) that the transfusions were merely coincidental, or (2) that the transfused blood replaced hypertensinogen lost in hemorrhage so that the increased amount of renin was furnished with substrate to produce hypertension.

Since in each instance of hemorrhagic shock in this patient blood transfusions were given, it does not seem possible from the data presented to choose between the alternatives of coincidence and the replacement of hypertensinogen. It cannot even be assumed that the patient was not in shock when the blood pressure was at hypertensive levels because Middleton<sup>4</sup> demonstrated that renin or hypertension had vasopressor effects in the shocked dog even in the presence of circulatory failure. In the light of his work the fact that some transfusions were not associated with hypertension in the patient cannot be construed as evidence that the donor's blood lacked hypertensinogen or that the patient's kidney was not producing an increased amount of renin. Middleton found that dogs in shock responded to renin and hypertension at times but not at others and concluded that the cause of the irregularity was not yet elucidated.

#### SUMMARY

Observations on a patient with malignant lymphoma are recorded. Eroded blood vessels in the spleen led to extensive blood loss through a communicating ulcer in the stomach. A ring of neoplastic tissue surrounded and compressed the left renal artery. During a period of twenty-five days the patient received forty 500 ml blood transfusions after many of which the blood pressure ascended to hypertensive levels for many hours. It is concluded that the combination of hemorrhagic shock and renal ischemia from renal artery compression caused an unusual increase in the output of renin. No conclusion could be reached as to whether the occurrence of the hypertension after blood transfusion was coincidence or whether the donor's blood supplied hypertensinogen which had been exhausted by hemorrhage. Only experimental studies on animals can completely elucidate this point.

# THE EFFECT OF HEPARIN AND DICUMAROL IN INCREASING THE CORONARY FLOW VOLUME

N C GILBERT, M D, AND L A NALEFSKI, M D  
CHICAGO, ILL

## INTRODUCTION

**D**URING the past several years considerable interest has arisen in the results obtained in the treatment of coronary thrombosis with anticoagulant drugs. Several series of cases have been reported and important work has been carried out showing reduction of mortality and decrease in incidence of thromboembolic phenomena. This work has been amply reviewed by several authors, among whom are Wright, Marple, and Beck,<sup>1</sup> Nichol and Page, Parker and Barker.<sup>2</sup>

The results obtained with Dicumarol and heparin so closely approximate those which we have obtained with other coronary vasodilator drugs, such as the xanthine series, that the question arises whether or not the results obtained with the anticoagulant drugs are not due to some effect other than their anticoagulant action. It did not seem altogether reasonable that the lower mortality and fewer embolic accidents now being reported in patients treated with heparin and Dicumarol were due to the anticoagulant action alone.

When the patient is seen by the physician, the occlusion and the infarct are already an accomplished fact. Anticoagulant treatment cannot possibly alter the already formed thrombus or have any effect upon the infarct itself whatever effect it might have on future thrombotic processes. There is no definite evidence that the thrombus propagates or extends and there is a great deal of evidence that the thrombus does not propagate. Fooid,<sup>3</sup> who has made a careful study of thrombi occurring in coronary vessels states that when the major coronary vessels are dissected out in toto fixed in formalin, and decalcified the length of the thrombus in the artery, in almost all cases is a matter of only a few millimeters, and only occasionally is a thrombosed portion found to be 1 cm. in length in the right coronary artery. Another factor to be considered in the use of anticoagulants is that many cases of occlusion are initiated by subintimal hemorrhage. Wartman,<sup>4</sup> in a careful study of occluded coronary arteries found 14.6 per cent occluded solely by intiamural hematoma, while an additional 34.2 per cent showed a combination of intiamural hemorrhage and thrombosis. It is his current impression that subintimal hemorrhage is a rather common occurrence and can be demonstrated if especially looked for. Doles<sup>5</sup> has reported treating acute coronary occlusions with vitamin K with good results.

Nichol<sup>7</sup> in discussing a paper by Falk<sup>8</sup> as well as his own results with Dicumarol therapy in patients with coronary thrombosis stated that congestive failure of a severe degree is less frequent when Dicumarol is used. He also cites a number of patients with repeated coronary occlusions who when placed on

daily continued doses of Dicumaiol, showed no evidence of coronary insufficiency. When reported, these patients were under observation for periods ranging from six to thirty-three months. Coogan<sup>9</sup> reports a similar experience with Dicumaiol in the ambulatory management of six patients suffering from angina pectoris. This has been further confirmed by our own clinical observations of patients with coronary insufficiency who were treated with Dicumaiol. It is hardly to be assumed that relief of pain in angina pectoris would be due to any anticoagulant action. It is much more reasonable to assume that relief is due to the coronary vasodilating action increasing the coronary flow.

Cotlove and Voizimer,<sup>10</sup> in making serial prothrombin estimations in cardiac patients, concluded that little is known of the relation of the prothrombin activity of the blood to the occurrence of intravascular thrombosis. They state that there is no evidence that an increase in prothrombin activity leads to thrombosis and that perhaps the abnormal acceleration of the dilute plasma prothrombin time which has been observed in cases of thromboembolism may be entirely secondary to the thrombosis already formed. This study is substantiated by the work of Cumme and Lyons.<sup>11</sup>

In reviewing the clinical reports of coronary thrombosis receiving Dicumaiol treatment, we felt that perhaps some additional factor was responsible for the unquestioned, improved results. We therefore instituted a series of experiments upon animals and upon the empty beating heart. We have been able to show that the use of heparin or Dicumaiol increases the coronary flow volume. With heparin, the effect varies from no effect to moderate, depending upon the preparation. Dicumaiol, however, has a very definite and marked effect in increasing the coronary flow. The Dicumaiol effect is equal to that of the xanthenes and is of apparently longer duration.

#### MATERIALS AND METHODS

Healthy mongrel dogs of either sex were anesthetized with Dial and urethane, and under positive endotracheal oxygen pressure, the chest was opened parasternally on the right. The right auricular appendage was nicked, and a modified Morawitz Zahn cannula was inserted into the coronary sinus. This technique for measuring coronary flow is simple. It requires only a matter of three to five minutes to insert the cannula and for the blood to appear in the measuring cylinder. There is a minimum of trauma and the reflexes are not disturbed. The authors recognize that this method does not measure total coronary flow, but it does properly show variations in flow. For this purpose, we think this method better than more elaborate methods in which greater trauma is incurred.

During the heparin experiments, hirudin was used as an anticoagulant. During the Dicumaiol experiments either hirudin or a heparin which was known to have no vasodilator effect was used. Blood pressure recordings were made, using a mercury manometer connected to a cannula inserted into a carotid artery. This method was considered adequate for these experiments. Empty beating heart experiments were performed, in which the dogs' own blood was used for perfusing the coronary vessels, in order to show the changes in total coronary flow.

#### RESULTS

An aqueous solution of theobromine sodium acetate, freshly prepared each day, was used as a standard control in the experiments. If, after the intra

venous injection of this drug a prompt rise in coronary flow followed, it was considered that the apparatus was functioning properly. Fig 1 illustrates a typical coronary vasodilator response to the theobromine. Table I shows the results of a single dose of theobromine on the coronary flow.

Fig 1—This tracing illustrates the usual increase in coronary sinus flow following an injection of theobromine sodium acetate.

TABLE I

	BEFORE	20 SECONDS LATER	% CHANGE
Coronary flow (ml per min)	189	53.0	180.0 plus
Pulse	100	104	4.0 plus
Blood pressure (mm mercury)	12	74	2.8 plus

Dog 3 60.0 mg theobromine sodium acetate given I.V.

Following the same technique as with theobromine, heparin was used. As mentioned earlier, the effect with heparin varied from no effect to moderate, depending upon the preparation used. The sodium salt of heparin, which is used clinically, showed slight to moderate coronary vasodilator effect. The barium salt of heparin did not alter the rate of coronary flow, on repeated

Fig. 2—Following the administration of heparin an increase in coronary sinus flow follows with little associated change in blood pressure and pulse

tials, at various dosages. It has been our experience that soluble barium salts have a vasoconstricting action upon the coronaries<sup>12</sup>. It is reasonable to assume that the vasoconstricting action of the barium ion in the heparin preparation neutralizes the dilator effect of heparin. Fig. 2 and Table II illustrate the increase in coronary flow following intravenous administration of sodium heparin. The effect is not as marked as with the xanthines, but does show an increase in coronary flow of 77.6 per cent, with a fall in blood pressure of 2.7 per cent, and an increase in pulse rate of 4.2 per cent.

TABLE II

	BEFORE	20 SECONDS LATER	% CHANGE
Coronary flow (ml per min )	170	302	77.6 plus
Pulse	96	100	4.2 plus
Blood pressure (mm. mercury)	74	72	2.7 minus

Dog " 100 mg heparin given I V

Fig 3—That Dicumarol is a strong coronary vasodilator is shown by this kymograph tracing. The increase in coronary sinus flow following Dicumarol appeared to be of longer duration than that produced by xanthines.

In the Dicumarol experiments the disodium salt of Dicumarol was prepared from a Dicumarol base of high purity, melting at 288 to 289° C. This was diluted with physiologic saline solution and given intravenously. The effect of Dicumarol on coronary flow is illustrated in Fig 3 and in Table III. This type

Fig 5 —In the isolated heart experiment the total coronary flow shows a sharp increase in the rate of flow following the addition of Dicumarol to the perfusing blood

TABLE V

	BEFORE	20 SECONDS LATER*	% CHANGE
Coronary flow (ml per min )	85.0	179	111.0 plus
Pulse	128	148	15.6 plus

\*Dog 26 10.0 mg Dicumarol given

observation of profound capillary dilatation that follows administration of dicoumarin, even when only moderate doses are given, raises the question of a gross vascular factor in the hemorrhage manifestation of sweet clover disease in cattle." Bollman and Preston<sup>17</sup> report similar results, and Dale and Jaques<sup>18</sup> also state that they have confirmed the results of Bingham and his group

# SUMMARY

We have shown in these experiments that heparin and Dicumarol increase the coronary flow volume. We believe that the beneficial results of these drugs in coronary thrombosis and in angina pectoris are due to the increase in coronary flow which accompanies their use.

# THE ONE-STAGE AND TWO-STAGE PROTHROMBIN METHODS IN THE CONTROL OF DICUMAROL THERAPY, WITH REMARKS ON Ac-GLOBULIN

JOHN H. OLWIN, M.D.  
CHICAGO, ILL.

## PURPOSE

THE indications for the administration of Dicumarol have broadened in recent years, yet the effective methods for its control have not materially changed. Efforts have, for the most part, been directed toward developing a uniformly reactive thromboplastin for use in the one stage method for prothrombin determination, or toward altering the original one-stage procedure as described by Quick<sup>12</sup> to render it more uniform or more sensitive in reflecting prothrombin variations. This paper deals with comparative results of the one-stage and two-stage prothrombin methods on the blood of dicumarolized patients. In addition, early experience with the behavior of the Ac-globulin in dicumarolized patients is reported and suggestions are offered as to the possible relationship of this factor to disparities between the one-stage and two stage methods.

## GENERAL STATEMENT

In the one-stage prothrombin method as described by Quick,<sup>12</sup> thromboplastin, calcium, and temperature are controlled factors. Possible variables, including antithrombin,<sup>10</sup> antithromboplastin,<sup>13</sup> fibrinogen,<sup>8, 9, 16</sup> heparin,<sup>1, 2</sup> and the rate at which prothrombin is converted to thrombin,<sup>14, 17, 18, 20, 21</sup> are not controlled. The catalytic action of heparin on antithrombin<sup>15</sup> also may be a disturbing factor. In the two stage method, dilution of the plasma materially reduces the activity of the antithrombin<sup>22</sup> and antithromboplastin.<sup>3</sup> Standardized fibrinogen solution is added in the two stage test, and the two stage principle, with the addition of Ac-globulin, eliminates as a variable the conversion rate of prothrombin. Heparin may be a variable in either test and in sufficient concentration will influence the results.<sup>3</sup>

## METHODS AND PROCEDURE

This report is based on the study of 140 patients on Dicumarol therapy.

In the first ninety nine cases, the two stage prothrombin method, as devised by Warner, Brinkhous, and Smith,<sup>22</sup> was used throughout as the guide in administering Dicumarol. In the succeeding forty one cases, the Ac globulin factor was added according to the modification of Seegers.<sup>5</sup> The former procedure will be referred to in this paper as the unmodified two stage method, and the latter as the modified two stage method.

From the Department of Surgery, Presbyterian Hospital of the City of Chicago, affiliated with the University of Illinois.

Presented before the International Society of Hematology, Buffalo, N. Y., August 1948.

This work was made possible through a grant from Mr. William H. Kidston and the Otho S. A. Sprague Memorial Institute Fund.

Received for publication March 2, 1949.

In ninety five of the first ninety nine cases the one stage test as described by Quick<sup>12</sup> was run in parallel\* to the two stage determination. In the other cases it was run at frequent intervals, usually initially and nearly always when the two stage method gave a reading below 10 per cent of normal. In all instances the thromboplastin for the one stage test prepared from acetone dried rabbit brain met Quick's requirements for this reagent.

In ten of the first ninety nine cases the Quick test was run on plasma diluted to 12.5 per cent of normal according to the method of Link<sup>1</sup> and associates. In these, a per cent plasma was also used.

In eighteen patients, Ac globulin determinations were made according to the method of Ware and Seegers.<sup>13</sup> Blood was drawn by venepuncture into 3.2 per cent sodium citrate (13 volumes to 2 volumes respectively) and processed as previously described.<sup>6</sup> In seven of these the determinations were made from the beginning of the therapy, and in addition, the one stage and two stage prothrombin assays were made both with and without the addition of Ac globulin. In the case of the one stage test, the Ac globulin was added by mixing 0.1 cc of beef serum, a potent source of the factor<sup>13</sup> to 0.9 cc of whole human plasma. The procedure described by Quick<sup>1</sup> will be referred to as the unmodified one stage method, and the same procedure using 10 per cent beef serum will be designated as the modified one-stage method.

Original doses of Dicumarol varied between 200 and 500 mg depending on the original prothrombin level and the size of the patient. The following day 100 to 200 mg were given, and the succeeding doses were varied according to the prevailing prothrombin level. After proper stabilization prothrombin determinations were made at weekly intervals, and in some cases every two weeks. If bleeding occurred, Dicumarol was stopped or the dosage reduced. In three instances vitamin K was given intravenously in doses of 24 mg at intervals of two hours until the prothrombin rose to nonbleeding levels. Periods of therapy varied up to a maximum of two years with an average of sixty days.

## RESULTS

In all cases the two stage method with or without Ac globulin added, gave more uniform readings and provided for a more accurate maintenance of the prothrombin level (Fig 1). In most instances it was possible to maintain the prothrombin within a bracket of 5 to 35 per cent of normal with an occasional reading above or below these extremes. With the unmodified two stage test the ideal prothrombin range was 10 to 20 per cent. When the modified two stage procedure was used the ideal range was 20 to 30 per cent.

The one stage method in some instances gave results parallel to and usually higher than those of the two stage test but in most cases it varied widely from day to day (Fig 1). The one stage technique using 12.5 per cent and 5 per cent plasma likewise gave widely varying results (Fig 2). Bleeding occurred in 10.7 per cent of the patients. This usually consisted of hematuria gross or microscopic. A few patients showed subcutaneous hemorrhage or bleeding from the gastrointestinal tract. There were no instances of serious bleeding. Of nine patients on therapy during active menstruation, two bled longer and more profusely than ordinarily. The others noticed no variation from the usual period.

In the seven patients on whom Ac globulin determinations were made from the beginning of therapy, this factor dropped in the first few days and

\*Occasionally owing to technical or personnel difficulties a test, either one stage or two stage was omitted.

returned toward normal by the end of twenty-one days (Fig 3) The lowest level recorded was 28 per cent of normal In eleven patients who had been on Dicumaiol therapy for a period of three weeks or longer, some as long as eighteen months, there was no consistent variation from the normal

Fig 1—This chart represents the comparative prothrombin levels of a patient given Dicumaiol for a thrombophlebitis of the leg. Note the wide variations between the results of the two methods. According to the two-stage test the patient was well controlled on about 50 mg of Dicumaiol daily. Had the one-stage method been guiding the therapy he might at several points have been given 200 mg and the prothrombin depressed to bleeding levels.

In nearly all instances, the prothrombin estimate according to the unmodified two-stage method was 10 to 20 per cent lower than that of the modified two-stage procedure (Fig 3). This is consistent with the finding of Ware, Guest, and Seegers<sup>18</sup> that an increase in Ac-globulin is accompanied by an increase in the quantitative yield of thrombin from purified prothrombin. Variations between the two were not uniformly altered by marked variations in the Ac-globulin level. That is, when the Ac-globulin was low, the difference between the two tests did not uniformly become greater as might be expected (Fig 3).

The same situation was obtained with respect to the one-stage test with and without the serum factor. The range of variation between the two was

greater, however, than that between the two types of two stage tests, the widest difference being 52 per cent. This disparity did not uniformly follow variations in the A $\gamma$  globulin values (Fig 3)

Fig. —This chart represents the comparative prothrombin levels of a patient given Dicumarol because of a coronary thrombosis. In addition to the two stage and the one stage whole plasma methods the results of the one stage 1.5 per cent plasma method are shown. The readings of the two former tests are given in percentage on the left hand ordinate. The results of the 1.5 per cent plasma method are given in seconds on the right hand ordinate. When the prothrombin is low the prothrombin time of the 12.5 per cent plasma would be expected to remain elevated. Neither of the one stage tests is uniform as compared with the results of the two stage method.

In patients on Dicumarol therapy the one stage method usually gives a figure higher than that of the two stage with or without the serum factor. In the first week of therapy however this relationship may be altered and the one stage give a lower figure than the two stage (Fig 1). In 85 per cent of the cases in which the unmodified tests were run in parallel, the one stage on one or more days in the first ten days of dicumarolization gave a lower figure than the two stage test. In 42 per cent the rate of conversion of prothrombin in the two-stage test was increased. In all others it was unchanged.

## COMMENT

Properly controlled Dicumarol therapy provides for the maintenance of a patient within a desired prothrombin bracket. In this laboratory the two stage method has made this possible, whereas the one-stage method on whole or diluted plasma by comparison has shown wide variations. It is believed

Fig 3—This chart shows the relative variations of the Ac-globulin levels as compared with the one stage and two stage prothrombin values during the early days of Dicumarol therapy. Note that the two-stage tests modified and unmodified parallel each other rather closely. The unmodified one-stage test early shows a level well below the two-stage level and later is well above the two-stage value. The Ac-globulin falls in the early days of therapy and has returned to normal by the end of nineteen days. Between the twenty-second and twenty-seventh days the patient failed to take dicumarol and the prothrombin returned toward its original level. When this again dropped toward therapeutic levels the Ac-globulin again dropped and the one-stage prothrombin levels again dropped more rapidly than did the two-stage values. There is no uniform correlation between the variations between the modified and unmodified prothrombin methods and the Ac-globulin values. The percentage values of the modified one stage test are based on the time percentage curve of the unmodified test.

that instances of fatal hemorrhage have occurred because of erroneous prothrombin estimates, and that variation in factors other than prothrombin often are responsible for the one-stage result. This is less often true of the two-stage method. The one-stage test is of value, however, as a summation of the various clotting factors. In instances where the two stage reading is below 10 per cent of normal, and the one stage result is above 10 per cent, bleeding is not likely. When both are below 10 per cent, bleeding may be im

ninent As long as the prothrombin level is above 1 per cent according to the two stage test, the patient is never far below his bleeding threshold and bleeding may be controlled by proper measures

Fahey, Olwin, and Ware<sup>6</sup> found a drop in the Ac globulin in the plasma of dogs during the first ten to fourteen days of dicumarolization This was followed by an elevation above the normal, and then a return to normal levels during subsequent therapy The same authors,<sup>6</sup> studying human patients found a drop in this factor during the early phases of dicumarolization and a return to normal after three weeks The reason for this fall in Ac globulin during the early stages of dicumarolization is not clear If the factor is intimately associated with the prothrombin molecule, it might be expected to remain at a low level throughout Dicumarol therapy Regardless of extremely low prothrombin levels, however after the first three weeks in all cases studied the Ac globulin remained within normal ranges Of practical consideration is the possibility that it might be a factor in hemorrhage if the prothrombin is early reduced to a low level

Hurn, Barker, and Mann<sup>10</sup> found that early in the dicumarolization of patients the one stage method always showed a lower figure than did the two stage, and suggested that this would seem to indicate a decreased rate of conversion of prothrombin to thrombin Owen and Bollman,<sup>11</sup> using dogs, found that when the one stage yielded lower results than the two stage, the conversion of prothrombin was delayed When the tests agreed, the conversion rate was normal, and when the one stage gave a higher result, conversion rates were accelerated above normal They suggested that the discrepancy between the one and two stage tests appears to reside in a conversion factor

The drop in Ac globulin during the early stages of dicumarolization would support this premise The Ac globulin remains depressed, however, longer than the one stage level remains below the two stage It might be expected that the addition of serum rich in Ac globulin to human plasma would materially lessen the difference between the results of the one stage and two stage tests In this study such was not the case Furthermore, in this laboratory in most cases there was no change in the rate of conversion of prothrombin to thrombin when the one stage test gave a result lower than that of the two stage It is possible that other factors in the beef serum or human plasma may influence the activity of prothrombin It is also possible that Dicumarol may influence factors other than prothrombin and Ac globulin The problem will require further study

#### SUMMARY

- 1 The two stage prothrombin determination provides for a more accurate and a safer control of prothrombin during Dicumarol therapy than does the one stage method

- 2 The one stage method is of value, however in estimating the summation of the various clotting factors A reading of below 10 per cent by the

two-stage test does not necessarily mean that hemorrhage is imminent, particularly if the one-stage gives a reading of above 10 per cent

3 In seven patients studied from the beginning of therapy, the Ac-globulin values fell during the early days of dicumarolization and returned toward normal by the end of twenty one days. In patients who had been on therapy over longer periods of time, some as long as eighteen months, there was no material variation from the normal

4 The addition of beef serum in small amounts to both the one- and two-stage tests raises the values obtained for prothrombin. Variations between the modified (with serum added) and unmodified (without serum added) methods do not follow fluctuations in the Ac-globulin values as obtained in this study. Neither do the fluctuations between the one stage and two-stage tests. These findings would suggest that other factors in addition to Ac-globulin are responsible for the disparity between the one-stage and two-stage methods

# THE CAUSES FOR REJECTIONS OF BLOOD DONORS

## A STATISTICAL STUDY

CECIL M. ZUKERMAN, M.D.

DAVENPORT, IOWA

THE purpose of this paper is to present a statistical report of the causes for rejections of blood donors. Taylor and Heiss<sup>1, 2</sup> in previous papers have presented statistical reports covering the entire blood donor service of the American Red Cross.

It was felt that a more detailed report from a single large blood donor center might be of value at this time when blood procurement for civilian use is being undertaken.<sup>3, 4, 5, 6</sup>

The blood donor requirements used in this study were those set forth in the Technical Manual by the Technical Director of the American Red Cross Blood Donor Service.<sup>7</sup>

This report covers a seventeen-month period from January, 1944, through May, 1945, on donors who reported to the fixed center and the mobile unit of the American Red Cross Blood Donor Center of Chicago. Included in this report are causes for rejections whether permanent or temporary. During this period our percentage of repeat donors varied between 48 per cent and 62 per cent. The data presented no doubt include some duplications due to the fact that each time a donor registered a new number was assigned that donor.

A brief history and a preliminary examination was made on each donor prior to acceptance or rejection to rule out any acute infection or serious chronic illness.

A brief explanation of each donor requirement is presented.

**A Age** No donor was acceptable who was over 60 or under 18 years of age.

**B Minor** A minor was not acceptable unless he had a standard form signed by parent or legal guardian.

**C Underweight** The minimum weight for a donor was 110 pounds.

**D Anemia** This term was used to classify those donors who did not meet our hemoglobin requirement by our methods and our technique. In this category fell the highest number of rejections—49.84 per cent of all rejections. From January, 1944, until May, 1945, the Tallquist method for hemoglobin determination was used and a level of 80 per cent was necessary for acceptance. From May, 1945, on, the copper sulfate method<sup>8</sup> was used and it was necessary to have a level of approximately 12.3 Gm. to be acceptable.

**E Hypertension** The upper limit of the systolic pressure was 200 and the upper limit of diastolic was 110.

**F Hypotension** No donor was acceptable whose systolic pressure was below 100.

---

Data for this study were obtained from the American Red Cross Blood Donor Center Chicago, Ill.

Received for publication Feb. 18, 1949.

G Fatty foods Donors were refused or postponed who gave a history of having a fatty meal three to four hours prior to donation. This was done to avoid lipemia and there also was noted a tendency of reactions with gastrointestinal complications in donors who had eaten a heavy meal.

H Heart rate over 100 or under 60 (rejected). If any irregularity of pulse occurred the donor was checked by the physician in attendance and accepted or rejected according to his judgment.

I Temperature over 99.5 was not acceptable.

J Venepuncture in past eight weeks Donors were allowed to donate every eight weeks and were allowed five donations in a twelve month period.

K Cold in past week No donor with cold was acceptable to prevent false positive serologic reaction or transmission of disease in blood.

L Other recent illness or major surgery Donors were rejected who had had pneumonia yellow fever dengue or virus infections during the past six months. A donor was postponed until six months after major surgery. Minor surgery—judgment of the physician in attendance.

M Diabetes Anyone giving a history of diabetes was not acceptable even though the disease was controlled at that time.

N History of skull fractures or severe head injury with subsequent symptoms. These donors were rejected; there seemed an increased tendency toward syncope in this group of donors.

O Psychosis and psychoneurosis.

P Other chronic illness Malta fever marked arteriosclerosis history of liver disease chronic renal disease cerebral or coronary thrombosis were cause for rejection.

Q General physical debility General appearance of the donor as he appeared to the physician in attendance. Even though he met the minimum requirements the donor was rejected if deemed a "poor risk" by the physician in attendance.

R Pregnancy or childbirth No pregnant women were accepted or those who had delivered within the past nine months. No donor was accepted who had miscarried within the preceding six months.

S Malaria Any donor who had had malaria in the past fifteen years was not acceptable.

T Infectious or indeterminate jaundice or contact with one with jaundice Any donor who had jaundice within the past six months was disqualified. Each donor was asked whether any member of the immediate family had had jaundice within the past six months. A donor with contact was judged for acceptance only if it was obvious that the jaundice was not of the infectious type. A donor with jaundice in the immediate family was accepted only if there had been no contact. Taylor and Heiss<sup>2</sup> in their report found that in questioning three million donors 325 gave a history of jaundice in the past six months. Grossman and co-workers' present data which seem to indicate that a causative agent for hepatitis was being transmitted to patients through the medium of blood plasma and whole blood transfusion.

TABLE I

	MEN	WOMEN	TOTAL
Number of donors	158,858	216,910	375,768
Number rejected	15,865	63,876	79,741
Per cent of rejections	9.98	29.44	21.22

TABLE II

CODE	MEN			WOMEN			TOTAL
	NUMBER REJECTED	NUMERICAL SEQUENCE OF CAUSE OF REJECTIONS	PER CENT REJECTED	NUMBER REJECTED	NUMERICAL SEQUENCE OF CAUSE OF REJECTIONS	PER CENT REJECTED	
A Ages over 60, under 18	155	13	9.8	87	19	14	242
B Age 18-21 No written permission	141	14	8.9	623	11	9.8	764
C Underweight	496	10	3.13	4,486	2	7.02	4,982
D Anemia	1,892	2	11.93	38,005	1	59.50	39,897
E Hypertension	1,647	3	10.38	2,420	6	3.79	4,067
F Hypotension	477	11	3.01	3,698	4	5.79	4,175
G Fatty foods	94	18	5.9	193	16	3.0	287
H Pulse rate over 100 or under 60	1,460	5	9.20	3,944	3	6.17	5,404
I Temperature over 99.5	497	9	3.13	2,184	7	3.42	2,681
J Venepuncture in past 8 weeks	115	15	7.2	59	22	0.9	174
K Cold in past week	4,197	1	26.46	3,073	5	4.81	7,270
L Other recent acute illnesses or major surgery	1,031	6	6.50	988	9	1.55	2,019
M History of diabetes	64	20	4.0	51	23	0.8	115
N History of skull fracture or severe head injury and subsequent symptoms	47	22	3.0	28	24	0.4	75
O Psychoses and Psycho-neurosis	48	21	3.0	64	21	1.0	112
P Other chronic illnesses	1,511	4	9.52	1,261	8	1.97	2,772
Q General physical debility	104	16	6.6	200	15	3.1	304
R Pregnancy or childbirth within last 9 mo				395	13	6.2	395
S Malaria	257	12	1.62	127	17	2.0	384
T Infectious and indeterminate jaundice or contact with jaundice	10	24	0.6	10	26	0.2	20
U History of frequent vertigo, syncope, convulsions	73	19	4.6	387	14	6.1	460
V Donor refused venepuncture	10	24	0.6	18	25	0.3	28
W Valvular heart disease	590	8	3.71	552	12	8.6	1,142
X History of anemia	22	23	1.4	103	18	1.6	125
Y History of tuberculosis	98	17	6.2	82	20	1.3	180
Z Other causes for rejections miscellaneous	829	7	5.23	838	10	1.31	1,667

U History of frequent attacks of vertigo, syncope, or convulsions was cause for rejection

V Donor refused venepuncture Occasional donors would change their minds about donation after they entered the bleeding room

W Any donor who gave history of valvular heart disease was checked by the physician in charge Each donor was questioned about shortness of breath, swelling of feet or ankles persistent cough and pain in chest, final decision was made by physician in charge

X History of anemia If at all suspicious, donor was rejected

Y History of pulmonary tuberculosis (rejected) Questions regarding extrapulmonary tuberculosis were referred to the physician in charge and each case was decided on the extent of lesion and time elapsed since its occurrence

Z Other causes for rejections

(a) Rabies treatment within last five years

(b) Chronic sinusitis or hay fever in acute stages

(c) Donors who had had extensive or prolonged sulfa therapy

(d) Severe or septic sore throat in preceding three months

(e) Vaccinations for smallpox or other immunizations recently Smallpox may produce false positive serology

(f) Army flight personnel were not acceptable donors

(g) Filariasis

In Table I is presented the total number of donors registered and rejected

In Table II are presented the causes for the preceding rejections

#### SUMMARY

1 In our report covering a period of seventeen months of operation at the Chicago Blood Donor Center 375 768 donors reported to the fixed center and mobile units

2 This group was represented by 158 858 men (42.27 per cent) and 216,910 women (57.73 per cent)

3 The rejection or postponement rate was 9.98 per cent in men and 29.44 per cent in women

4 The greatest causes for rejections for any single condition were recent colds in men and anemia in women

5 It is hoped that this study will be of value in the future procurement of blood donors

## DISTRIBUTION OF EMETINE IN TISSUES

LEO G. PARMER, M.D., PH.D.,\* AND CHRISTY W. COTTRILL, B.S.  
WASHINGTON, D. C.

THE alkaloid emetine is obtained from ipecac or prepared synthetically by methylation of cephaelline. Ipecac has been used in the therapy of diarrheas for more than 300 years and its alkaloids were investigated more than 100 years ago. The specific usefulness of ipecac in amebic dysentery was disclosed only after the discovery in 1875 that *Endamoeba histolytica* was the causative organism of this disease. Veddei<sup>1</sup> in 1912 demonstrated that high dilutions of emetine were capable of killing *E. histolytica*. It remained for Rogers<sup>2</sup> soon thereafter to prove the value of parenteral emetine injections in the treatment of amebiasis.

In 1920 Mattei<sup>3</sup> in France reported, without disclosing his method of analysis, that emetine appeared in the urine within twenty minutes after injection and the excretion lasted for from five to nine weeks. Despite the fact that there are numerous papers dealing with the pharmacology and toxicity of emetine, no papers dealing with distribution of the alkaloid in animal tissues are reported. It is the purpose of this paper to present the data on the distribution of emetine in tissues of rabbits.

### EXPERIMENTAL

**Method**—Each of fifty-seven albino rabbits weighing about 2.5 kilograms was injected intramuscularly with 6 mg per kilogram of emetine hydrochloride in aqueous solution (Higher doses frequently resulted in the death of the animals). The animals were sacrificed, in groups of three at intervals varying from one-half hour to sixty-four days after injection, as shown in Table I. The following organs were analyzed for emetine: brain, leg muscle, heart, mesenteric lymph node, liver, spleen, kidney, lung, and a portion of large intestine freed of feces. The organs of six noninjected rabbits were analyzed to determine the range of the blank determination. Those results which fell within the blank range were considered as zero.

**Determination of Emetine**—The method used in this study was adapted with some modifications from the general method of Biodie and co-workers<sup>4</sup> for the determination of organic bases in biologic material by salt formation with methyl orange. It depends upon the extraction of emetine from an alkaline medium by benzene, combining the base with methyl orange, extracting with acid the methyl orange salt formed, and measuring photometrically the amount of color due to the salt.

**Reagents**—1 Standard solution of emetine—20 mg per 100 cubic centimeters. Twenty milligrams of emetine hydrochloride are dissolved in 100 cc 0.01N HCl. This solution is stored in a refrigerator and keeps for weeks.

2 Metaphosphoric acid 6.5 per cent

3 Saturated solution of sodium hydroxide

4 Benzene. A reagent grade is redistilled.

5 Isoamyl alcohol. A reagent grade is redistilled.

6 Methyl orange solution. Prepared according to Biodie and associates.<sup>4</sup>

From the Pharmacology Section, Army Medical Department Research and Graduate School. The assistance of M/Sgt Norman Gorin is gratefully acknowledged.

Received for publication Feb. 7, 1949.

TABLE I RECOVERY OF EMETINE AFTER ADDITION OF 5  $\mu$ G TO 0.2 GM. OF TISSUE

TISSUE	EMETINE FOUND ( $\mu$ G)	RECOVERY (%)
Brain	50	100
Lung	49	98
Lymph node	40	80
Spleen	51	102
Liver	56	112
Heart	53	106
Large intestine	53	106
Kidney	51	102
Muscle	48	96

*Procedure*—Take a known weight of tissue and grind with 20 vol of 6.5 per cent metaphosphoric acid in a Waring Blender. Grind soft tissue (brain, lung, etc.) forty five seconds and other tissue (liver, kidney, etc.) for one minute. Filter and use 3 to 6 cc of filtrate for the determination. Add 3 to 6 cc of filtrate (containing up to 20  $\mu$ g of emetine) to a 30 cc glass stoppered cylindrical separatory funnel. Add 1 cc of saturated NaOH and shake to neutralize the metaphosphoric acid and to have an alkaline solution for the extraction. Add 15 cc of benzene and shake for five minutes on a shaking apparatus, then allow the phases to separate by standing forty five minutes to one hour. Add 0.25 cc of isoamyl alcohol and mix well with only the benzene phase, taking great care not to disturb the aqueous phase. Draw off the latter and transfer all of the benzene phase to a screw capped test tube to which has been added 0.25 cc of methyl orange. Cap and shake in a shaking apparatus for five minutes and then centrifuge at 1000 rpm for ten minutes. Transfer 10 cc of the benzene phase to a glass stoppered centrifuge tube to which have been added 3 cc of 1N HCl. Shake five minutes and then centrifuge for five minutes at 1,000 rpm. Carefully remove the benzene phase by aspiration. Read the acid phase in a Beckman spectrophotometer at 510 millimicrons.

*Recovery*—To each 0.2 Gm. of various tissues from two untreated rabbits were added 5  $\mu$ g of emetine. Six cubic centimeters of tissue filtrate containing 5  $\mu$ g of emetine were then analyzed in duplicate according to the described procedure. Table I shows the amount of emetine recovered. These figures indicate that the drug can be recovered quantitatively from all tissues except possibly lymph node where only 80 per cent was recovered.

The method was used to determine as low as 0.2  $\mu$ g in 6 ml of filtrate, this being equivalent to 10 mg of emetine per kilogram of tissue. Figures below that amount were found to be within the variation of the blanks.

#### RESULTS

The tissue concentration of emetine at the various time intervals after injection are shown in Table II. Within one half hour the highest concentrations of drug were found in the lung, kidney, and spleen. The liver and heart contained much less, whereas the intestinal level was relatively very low. Emetine was found in very low amounts in striated muscle of the leg up to two hours after injection. Beyond this time the drug was not detectable. Questionable traces of emetine were found in the brain but most of these were within the limits of the blank and were recorded as negative.

In most organs the maximum concentration of drug occurred within twelve to twenty four hours after injection. This level persisted with slight change through the second day and then gradually began to decline. By the fourth day the concentration in the major organs was about half what it was at the maximum. After two weeks some of the organs were free of emetine, but the

spleen, lymph node, and kidney contained significant quantities of drug for as long as four weeks. Between six and nine weeks, the spleen, the last organ to contain emetine, became free of the drug.

TABLE II TISSUE CONCENTRATION OF EMETINE (MG/KG) AFTER AN INTRAMUSCULAR INJECTION OF 6 MG/KG, CONCENTRATIONS ARE AVERAGES OF THREE RABBITS STUDIED AT EACH TIME INTERVAL

TIME INTERVAL	MUSCLE	BRAIN	HEART	LUNG	LIVER	SPLEEN	KIDNEY	LARGE INTES TINE	LYMPH NODE
1/2 hr	0	0	12.4	46.7	12.6	18.7	39.1	3.3	2.0

#### DISCUSSION

In a preliminary report<sup>4</sup> it was suggested that the difference in efficacy of emetine in intestinal and hepatic amebiasis was due to the difference in concentration of drug in the intestine and liver. A high, sustained level in the liver probably accounts for a high percentage of cures in hepatic disease, whereas the low, transient level in the large intestine could account for the frequent relapses of dysentery in cases where emetine alone is used. With similar reasoning, it appears that amebic brain abscess would not respond to parenterally administered emetine because the drug does not enter the brain in significant amounts.

The most disastrous effects of emetine in man are due to its cardiac effects. Soon after injection in rabbits, the heart muscle level of the drug is moderately high as compared with other organs. By six hours this drops to a relatively low level at which it remains until disappearance about ten days later. In man where the drug is given in divided daily doses, electrocardiographic changes after emetine therapy usually occur several days after treatment has begun.<sup>6</sup> These repeated doses are presumably additive insofar as cardiac concentration of drug is concerned. By the fifth or sixth day there is sufficient drug and also sufficient time elapsed for the drug to act on the muscle and electrocardiographic changes become evident. It would not be safe to repeat a course of therapy with emetine until complete excretion of the drug from the heart had occurred and also after a lapse of sufficient time for the damage to the heart to be repaired. From human studies, this is probably about two months.<sup>6</sup>

Very little is known about the mechanism of action of emetine in amebiasis. It is considered a general protoplasmic poison. However, in high dilutions it is

only effective against the motile trophozoite form of *L. histolytica* and not against the encysted form. In the present experiments it was shown that the highest concentrations of drug were found in the liver, spleen, kidney, and lung, although in man few or no toxic signs and symptoms from emetine can be related to these organs as shown by Klatskin and Friedman.<sup>8</sup> In fact, they noted that some patients with hepatic amebiasis had abnormal liver function studies and that these abnormalities actually returned to normal under the influence of emetine. The lowest concentrations of drug in the rabbits were found in cardiac muscle, striated muscle, and intestinal muscle. Yet, despite the low concentration of drug in the heart, muscles and intestine, almost all toxic symptoms in man<sup>8</sup> and animals<sup>9</sup> are associated with these organs. In other words, only those organs having contractility as their most important function are affected adversely even though the concentration of drug in these organs is not inordinately high. On this basis, it is postulated that emetine interferes in some way with the chemical function of the cell (perhaps an enzyme system), which converts glycogen into contractile energy.

## SUMMARY

The tissue distribution of emetine in rabbits after a single injection has been determined. The drug is found in highest concentration in the lung, kidney, spleen, and liver. The concentration in the heart and lymph nodes is intermediate and that in the large intestine and striated muscle is very low. The drug persists for as long as four to six weeks in some organs. Significant amounts of the drug were not detectable in the brain, indicating that parenteral emetine would probably be ineffective therapy in amebic brain abscess.

On the basis of the finding that emetine is most toxic for the various muscular organs despite the low concentration of drug in these organs, it is postulated that emetine interferes with a biochemical function of those cells having contractility as their main function.

## A SPECTROPHOTOMETRIC METHOD FOR DETERMINATION OF PROCAINE AND *p*-AMINOBENZOIC ACID

KUANG S. TING, M.S., M.D., JULIUS M. COON, M.D., PH.D., AND  
ALVIN C. CONWAY, M.S.  
CHICAGO, ILL.

SINCE procaine is used widely in clinical medicine, a good method for the quantitative estimation of this drug is desirable. Acidimetric,<sup>1-5</sup> iodometric,<sup>6</sup> mercurimetric,<sup>7</sup> bromometric,<sup>8-13</sup> and gravimetric<sup>14-15</sup> methods have been proposed in the past. Vanillin,<sup>16-17</sup> sodium cuprihydrosulfite,<sup>18-19</sup> thymol,<sup>20</sup> and pyridine<sup>20</sup> have been used for the detection of procaine. It also has been analyzed by the use of its absorption spectrum.<sup>21</sup> A spectrophotometric method of determination of procaine in procaine penicillin G at the wavelength of 290 m $\mu$  was recently reported.<sup>22</sup> After the present work was completed, a spectrophotometric method for procaine and its hydrolytic products was described by Biddle and co-workers.<sup>23</sup>

The most useful methods, however, depend on the formation of a colored compound after procaine is diazotized.<sup>24-28</sup> In 1939 Bratton and Marshall<sup>29</sup> reported that *N*-(1-naphthyl) ethylene diamine dihydrochloride was the most suitable coupling reagent for sulfanilamide determinations. Since then this method has been adopted extensively for the estimation of local anesthetics of the *p*-aminobenzoic acid ester type.<sup>30-32</sup>

Because procaine and one of its decomposition products, *p*-aminobenzoic acid, give rise to similar colors in this coupling reaction, it is necessary to differentiate these two compounds in the presence of one another. Ether,<sup>24-28, 31, 37</sup> chloroform,<sup>35</sup> and isopropyl alcohol<sup>36</sup> have been used to separate the two. These procedures required repeated extractions and separations, later followed by the development of the color for procaine and for *p*-aminobenzoic acid separately. Hence the procedures were very complicated.

Legge and Duine<sup>37</sup> separated the procaine and *p*-aminobenzoic acid after the color was formed by means of hydrochloric acid. However, these workers did not describe the sensitivity and accuracy of their method. Hazard and Ravasse<sup>38</sup> separated the two azo dyes by means of ether in the presence of alkali, but they did not measure quantitatively the procaine itself.

The present study has involved the development of a modification of the foregoing methods in order to have an accurate and sensitive procedure for the determination of procaine and *p*-aminobenzoic acid in the presence of each other in blood. The procedure is simpler than any of the methods previously described.

From the Departments of Pharmacology and Surgery of the University of Chicago.

This investigation was conducted under a grant from the Office of Naval Research, N6-ori-20 task order 11.

Received for publication Feb. 14, 1949.

## EXPERIMENTAL

**Principle**—Blood protein is precipitated by trichloroacetic acid. The supernatant clear fluid is diazotized. Ammonium sulfamate is used to destroy the excess nitrous acid. The color is developed by coupling with *N* (1 naphthyl) ethylene diamine dihydrochloride.

Then the solution is treated with chloroform and alkali. The color intensity is measured in the Coleman Model 6A Junior spectrophotometer, using adapter #6-108 and cuvette #6-310B.

The orange-red color remaining in the aqueous phase represents the *p*-aminobenzoic acid azo dye, which shows maximum absorption at the wave length of 500  $\text{m}\mu$  using water for zero setting. The yellowish orange color in the chloroform represents the procaine azo dye, which shows maximum absorption at the wave length of 485  $\text{m}\mu$  using chloroform for zero setting. The optical density curves of these two products are shown as curve 1 and curve 2 in Fig. 1.

**Reagents**—

- 1% per cent trichloroacetic acid
- 0.1 per cent sodium nitrite
- 0.5 per cent ammonium sulfamate
- 0.1 per cent *N* (1 naphthyl) ethylene diamine dihydrochloride
- Chloroform
- 1*N* sodium hydroxide

**Procedure**—Pipette 0.2 ml of oxalated blood into 30 ml of water, and let stand for three minutes. Add 1.0 ml of 1% per cent trichloroacetic acid and let stand for five minutes. Centrifuge at 1500 rpm for five minutes. Pipette 3.0 ml of the supernatant

clear solution into a Maizel Gerson reaction tube. Add 0.2 ml of 0.1 per cent sodium nitrite, and let stand for three minutes. Add 0.2 ml of 0.5 per cent ammonium sulfamate, and let stand for two minutes. Add 0.2 ml of 0.1 per cent *N*-(1-naphthyl) ethylene diamine dihydrochloride, and let stand for ten minutes. Add 3.0 ml of chloroform, and shake for half a minute. Then add 0.8 ml of 12*N* sodium hydroxide. Shake vigorously for two minutes. The solution should be well mixed after each addition of reagent.

Pipette out about 2 ml of the aqueous solution for spectrophotometric determination of *p*-aminobenzoic acid at the wave length of 500  $m\mu$  using water for zero setting. Pipette out about 2 ml of the chloroform solution for spectrophotometric determination of procaine at the wave length of 485  $m\mu$  using chloroform for zero setting. Reagent blanks should be used in each series of determinations.

**Effect of Order of Reagents**—The shaking with chloroform before the addition of alkali is important. If the chloroform is added after the alkali, the extraction of procaine azo dye will be incomplete and a part of the dye will remain in the aqueous solution. For instance, a sample containing 30  $\mu$ g of procaine hydrochloride and 30  $\mu$ g of *p*-aminobenzoic acid was analyzed according to the procedure except that the sodium hydroxide was added ten minutes after *N*-(1-naphthyl) ethylene diamine dihydrochloride, then chloroform was added. The spectrophotometric reading of the chloroform solution gave an optical density of 0.271, which corresponded to about 21  $\mu$ g of procaine hydrochloride. Therefore the extraction was only two thirds complete. The spectrophotometric reading of the aqueous solution gave an optical density of 0.587, corresponding to about 36  $\mu$ g of *p*-aminobenzoic acid.

This phenomenon may be explained by means of polarity. When the procaine azo dye solution is first shaken with chloroform, the ester portion of the dye goes into

the chloroform phase while the  $\text{—N—HCl}$  part remains in the aqueous phase. The subsequent addition of alkali neutralizes the  $\text{HCl}$ , freeing the amino group. Hence the whole molecule of the procaine azo dye goes into the chloroform. On the other hand, if the alkali is first added prior to the chloroform, the ester group may be hydrolyzed in the following manner:

This sodium salt thus produced is less soluble in chloroform.

**Effect of Amount of Alkali**—The amount of alkali added is important in the determination of *p*-aminobenzoic acid. The sodium hydroxide solution was tested in volumes of 0.2, 0.4, 0.5, 0.7, 0.8, and 1.0 milliliter. It was found that 0.8 ml of sodium hydroxide gave the best result. The amount of alkali is, however, not so important in the determination of procaine. The same results were obtained using 0.2 ml and 0.8 ml of sodium hydroxide.

**Stability of Color**—The color of the procaine azo dye is remarkably stable. There was no significant fading of the color even after the chloroform solution was stored in the refrigerator for eight weeks. The color of the *p*-aminobenzoic acid azo dye is much less stable. About 25 per cent of the color intensity of the latter dye will fade in four hours, and this color will bleach out almost completely after one day. For this reason, the measurement of the *p*-aminobenzoic acid should be carried out as quickly as possible.

**Prevention of *in Vitro* Hydrolysis of Procaine in Blood**—Since blood contains procaine esterase, highest in the human being,<sup>31</sup> the procaine disappears rapidly from a drawn

sample of oxalated blood. When sodium fluoride (about 4 mg per milliliter) was added to the blood sample or if the blood sample was kept in ice the hydrolysis was greatly retarded. When combined fluoride and low temperature were used immediately after the blood was drawn, the procaine hydrolysis was completely inhibited, as shown in Table I.

Fig 1—Spectrophotometric absorption curves. Curve 1 *p* aminobenzoic acid azo dye in aqueous phase; curve 2 procaine azo dye in chloroform; curve 3 sulfanilamide azo dye in aqueous phase.

TABLE I HYDROLYSIS OF PROCAINE ADDED TO FRESH HUMAN BLOOD

	μG PROCAINE AT ZERO TIME	μG PROCAINE AFTER 1 HR	PER CENT LOSS
Oxalated blood (25 C)	37.0	13.5	64
Oxalated blood (0.5 C)	69.0	65.4	5
Oxalated blood + NaF (25 C)	50.0	48.0	4
Oxalated blood + NaF (0.5 C)	42.5	42.5	0

**Results of Analysis**—Different amounts of procaine hydrochloride were added to 0.2 ml of fresh oxalated dog or human blood to which sodium fluoride was added 4 mg per milliliter, and the tubes were kept in ice. Analysis for procaine was done according to the foregoing procedure and the results were obtained as illustrated by line 1 in Fig 2. When different amounts of *p* aminobenzoic acid were added to the blood and analyzed, the plotted results gave line B in Fig 2. When the blood was added to different amounts of procaine hydrochloride containing 50 μg of *p* aminobenzoic acid in each sample, the results of the analysis for procaine still gave line 1. When the blood was added to different amounts of *p* aminobenzoic acid containing 50 μg of procaine hydrochloride in each sample and analyzed the results of the analysis for *p* aminobenzoic acid still gave line B. The deviation of individual determinations from the line for procaine was usually less than that for *p* aminobenzoic acid.

Six 0.2 ml samples of human blood each containing 50 μg of procaine hydrochloride and various amounts of *p* aminobenzoic acid in each were analyzed. The spectrophotometric readings of the chloroform solution for the determination of procaine are shown in Table II.

*Determination of Sulfanilamide*—According to this method, sulfanilamide formed an azo dye which remained in the aqueous solution and gave a maximum absorption at the wave length of 500 mμ as shown by curve 3 in Fig 1. Sulfanilamide, in the absence of p-aminobenzoic acid, could be determined by this method in a manner similar to that employed for p-aminobenzoic acid. Since

hydrolysis of sulfanilamide does not occur in blood, sodium fluoride and low temperature are not necessary. The result of analysis was quite similar to that of *p* aminobenzoic acid.

## DISCUSSION

Blood samples containing less than 25  $\mu\text{g}$  of procaine hydrochloride *p* aminobenzoic acid, or sulfanilamide in 0.2 ml will give a reading below optical density 0.05, which represents more than 10 per cent effective error.

Fig 3—Diagram of calculation by internal standard

of the instrument used (Coleman Model 6A Junior spectrophotometer). Samples containing more than 5 to 7  $\mu\text{g}$  will give an optical density above 0.10, which represents less than 5 per cent instrument error. The effective instrument error in the range of optical density between 0.30 and 0.70 is below 2 per cent.

A reagent blank might be used for zero setting. However, this was less constant than when water or chloroform was used. The reagent blank usually gave an optical density below 0.010. If the optical density becomes too high (e.g., the coupling reagent solution turns to a pinkish color) the reagents should be changed.

Citrate was tested as an anticoagulant instead of oxalate and was found to give similar results. The coupling reagent *N* (1 naphthyl) ethylene diamine dihydrochloride, should be stored in the refrigerator and must be colorless when used.

Sulfanilamide as predicted from the closer similarity of its chemical structure to *p* aminobenzoic acid than to procaine interferes with the determination of *p* aminobenzoic acid but not with that of procaine.

Blood samples of the mouse, rat, dog, and man were analyzed with satisfactory results. This method is also applicable to any kind of biological materials. A specific reference line should be prepared in each case.

For each series of determinations, a reference line should be made from the blank and from the blank with a known amount of standard added. If a reference line is not available, a simple calculation of results based on the principle of "internal standard" may be used. This can be done in the following manner. Divide the sample into two equal parts, part A and part B. To part B add a suitable amount,  $M$ , (Fig 3) of procaine hydrochloride and *p*-aminobenzoic acid. Then perform the analysis of these two parts separately according to the method outlined. Let the spectrophotometric readings be  $R_A$  and  $R_B$  for part A and part B respectively. Locate the  $R_A$  and  $R_B$  on the ordinate, and draw two horizontal lines as  $R_A R_A'$  and  $R_B R_B'$ . Locate  $M$  on the abscissa and draw a vertical line which intersects  $R_B R_B'$  at  $S$ . Now draw a sloping line passing through the reagent blank reading 1 and parallel to  $R_A S$ . This line intersects  $R_A R_A'$  at  $U$ . The abscissa of the point  $U$ , or  $OU'$ , represents the amount of procaine hydrochloride or *p*-aminobenzoic acid present in the unknown sample part A.

#### SUMMARY

A simple spectrophotometric method for determination of procaine and *p*-aminobenzoic acid in blood in the presence of one another is presented. The sensitivity is 2.5 micrograms.

Fluoride and low temperature should be used *in vitro* to inhibit hydrolysis of procaine in the blood sample.

Sulfanilamide, in the absence of *p*-aminobenzoic acid, also can be determined by this method. Sulfanilamide interferes with the determination of *p*-aminobenzoic acid but not with that of procaine.

A simple method of calculation by means of "internal standard" is described.

We are very grateful to Dr. K. P. DuBois and Dr. H. M. Livingstone for reading the manuscript.

# THE KEPLER WATER TEST IN TABES DORSALIS

FEDERICO DIEZ-RIVAS, M D

ANN ARBOR, MICH

IN 1941 Robinson, Power, and Kepler<sup>1</sup> devised the water test as an aid in the diagnosis of Addison's disease. Soon other unrelated conditions were found to result in a positive test. According to Kepler, Power, and Levy,<sup>2</sup> these included chronic nervous exhaustion, cachexia, hyperthyroidism, liver disease, pituitary insufficiency, and renal disease.

The present report deals with nine patients having tabes dorsalis who were observed to give a positive result to the water test. Some of these had symptoms suggestive of adrenal hypofunction. None had any of the conditions previously reported as responsible for a positive test. Seven of these patients had a positive Kahn reaction in the spinal fluid and blood.

Table I summarizes the clinical and laboratory data, including the results of the water test on these nine patients with syphilis of the central nervous system. Some of these patients had been treated for neurosyphilis with penicillin and fever therapy. Neurological findings were minimal in a few instances (Patients 1, 7, and 8). All the nine patients were found to have orthostatic hypotension. The urine analyses done prior to the tests were normal in all the nine cases. Cystometric studies were performed in each patient to eliminate the possibility of a neurogenic bladder. Patient 8 with a positive Wilder test did have an early neurogenic bladder, but no residual urine could be found by catheterization. The state of hydration in all the patients was satisfactory by clinical observations, i.e., normal turgor of the skin, normal blood pressure, and normal daily urine output.

During the performance of this test the patients remained in bed and were observed carefully to insure proper ingestion of the calculated volume of water. The last urine specimen was collected by catheterization.

## RESULTS

The results show that five patients had a positive value for factor A, two were borderline, and one was negative. The volumetric part of the test was positive in all patients. There was a slight increase of the blood urea nitrogen values in five instances. Only Patients 5 and 6 had plasma chloride ion values below normal levels.

Table II shows a comparison of the individual items in the water test between the normal individual patients with Addison's disease (average values in twenty-four untreated cases)<sup>3</sup> and patients with tabes dorsalis (average in the nine cases). It is clear that the variation from normal tests was due to an abnormal volumetric part (delayed water diuresis). The average values of the plasma and urine chloride ion and urine urea nitrogen were within normal limits. As previously mentioned, there was a slight increase in the blood urea nitrogen in five out of the nine patients.

Factor A =			
$\frac{Cl_B}{Cl_{Ur}} \times \frac{Urea_{Ur}}{Urea_B} \times \frac{\text{Largest fraction (c c)}}{\text{Night volume (c c)}}$	30	25	24

\*Average values obtained by Cutler Power and Wilder in twenty four untreated patients with Addison's disease

## DISCUSSION

The explanation of the abnormal changes in the test in these patients is not clear. There are several possibilities which will be considered. (1) *Abnormal gastrointestinal motility*. In tabes dorsalis there may be episodes of pylorospasm, as well as increased or decreased gastrointestinal activity. Pyloro spasm or decreased gastrointestinal motility would result in gastric retention of the water ingested for the performance of the test. Consequently, intestinal absorption would be decreased and water diuresis delayed, resulting in a positive volumetric part of the test. (2) *Disturbed innervation (decreased tone) of the renal efferent arterioles* may reduce the rate of glomerular filtration and thus produce a delayed diuresis. (3) *Abnormal innervation of the adrenals or actual syphilitic involvement of these glands* is unlikely since normal chloride ion values were obtained in six out of the nine cases. (4) *Impaired intestinal absorption of water* seems unlikely in the absence of diarrhea or dehydration. Nevertheless the rates of absorption may have been decreased. (5) *An abnormal distribution of water in the body* as a cause for delayed diuresis is unlikely in view of the preponderance of normal plasma chloride ion values. It is known that in Addison's disease a positive water test is usually associated with a low plasma concentration of chloride. (6) *Overactivity of the pituitary gland* with excessive production of antidiuretic hormone has been suggested in Addison's disease by Gaunt<sup>4</sup>. It has not been determined, however, that this suggestion holds for Addison's disease or tabes dorsalis. (7) *Morphologic renal changes* with resultant delay in diuresis seem unlikely in the presence of a normal urine analysis in all nine patients. Of course, abnormal variations in the hemodynamics of the kidney may play a role.

Whatever the correct explanation may be for the present findings, it is advisable in performing a Kepler water test, to evaluate the individual values

necessary to compute the factor A from the formula devised by Kepler, Power, and Levy,<sup>2</sup>

$$A = \frac{\text{Blood chloride ion (mg \%)} \times \text{Urine urea nitrogen (mg \%)}}{\text{Urine chloride ion (mg \%)} \times \text{Blood urea nitrogen (mg \%)}} \times \frac{\text{Largest functional specimen (cc)}}{\text{Night volume (cc)}}$$

before accepting the results of the test as an indication of Addison's disease (or adrenal hypofunction)

Fig. 2.—The effect of heated and unheated hyaluronidase on the hematocrit of the albino rat.

Suitable control experiments were performed. The testicular extract was heated at 70° C for thirty minutes which completely inactivated the hyaluronidase. A volume of this material equivalent to 7,500 units of hyaluronidase, was administered to thirty five rats. No significant elevation of hematocrit occurred as compared with the eighty five control animals. Striking differences between the effects of heated and unheated testicular extract were evident (Fig 2).

Several other animals were given bovine plasma albumin or histamine intravenously. No equivalent change of the hematocrit was demonstrated.

*Plasma Proteins*—The mean plasma protein level of fifty three control animals was 5.64 Gm per cent. A significant reduction in the plasma proteins occurred in thirty rats receiving 7,500 turbidimetric reducing units of hyaluronidase (Table II). The maximum decrease was noted in fifteen to thirty minutes and thereafter the level of proteins slowly returned to normal. Thirty three animals, to whom were administered heat inactivated hyaluronidase, failed to reveal a similar reduction in the level of the plasma proteins.

Fractionation of the proteins was performed on several samples, but the results failed to demonstrate any significant alteration of the albumin globulin ratio.

† includes standard deviation

#### DISCUSSION

Following the intravenous administration of adequate amounts of testicular extract a prompt direct rise occurred in the hematocrit of the albino rat and the level of plasma proteins was significantly reduced. These changes paralleled the findings of edema, contraction of blood vessels and diffusion of dye described previously,<sup>1</sup> and were further evidence of an increase in capillary permeability.

The disparity between these results and those reported by Chambers<sup>7</sup> as to the effect of hyaluronidase on capillary permeability may possibly be resolved if the amounts of enzyme injected are compared. In order to alter the

Tryptophane was determined microbiologically by the method of Wooley and Sebrell.<sup>1</sup> The term "tryptophane" includes the microbiologically available compounds, such as peptides, closely related to tryptophane that may stimulate the growth of the organisms used. Urine was diluted with water and assayed without further treatment. Samples extracted with ethyl ether to remove indole gave essentially the same values as untreated samples. Storage of samples for one week has no effect on assay values. Food samples were digested enzymatically by pepsin, trypsin, and erepsin. Ba(OH)<sub>2</sub> hydrolysis gave satisfactory checks. Fecal tryptophane determinations were made for a few weeks but showed no consistent results. Nitrogen data were based on the Kjeldahl method.

TABLE II DIET SUPPLEMENTATION SCHEDULE

Period 1	Experimental restricted diet started
Full supplement	B complex supplementation, biotin, 60 $\mu$ g, nicotinamide, 12 mg, pteroylglutamic acid, 90 $\mu$ g, pantothenic acid, 6 mg, riboflavin, 15 mg, paminobenzoic acid, 300 $\mu$ g, pyridoxine, 3 mg, choline 0.5 Gm added
Supplement 3	Thiamine 1.2 mg added
Supplement 4	Protein 45 Gm calcium caseinate added
Supplement 5	Nicotinamide 12 mg, riboflavin 15 mg added
Supplement 6	1 egg for breakfast, 100 Gm (raw weight) ground beef for lunch, $\frac{1}{2}$ pint whole milk for dinner, in order to keep the caloric and protein content similar to that of the other subjects, the calcium caseinate, sugar, and oleo margarine were approximately reduced

## RESULTS

In Fig. 1 are given values for the daily urinary excretion and daily dietary intake of tryptophane. It is apparent that in the case of the five restricted subjects there was no decrease in the amounts of free tryptophane excreted during the periods of restricted dietary intake of proteins and B complex vitamins. This result is in contrast to the excretion of B vitamins which decreased sharply when the dietary intake was reduced.<sup>2</sup> Furthermore no decrease in tryptophane excretion occurred during the period of restricted protein intake despite the intake of large amounts of corn which is deficient in tryptophane.

Fig 1—Dietary intake and urinary excretion of tryptophane

Ordinates Excretion of tryptophane milligrams per twenty four hours

Abscissas Time on experimental diet weeks. Body weights of subjects pounds C 1 169 C 2 144 E 157 E 6 137 E 150 E 7 183 E 3 146 Dietary intakes as shown Diets and supplements described in text, Table II

During the period of the control diet, the urinary excretion of tryptophane varied from 1 to 3 per cent of the ingested dietary tryptophane. On the restricted dietary intake of tryptophane, the urinary excretion was approximately 3 to 15 per cent of the ingested tryptophane. Actually there was a slight increase in the excretion levels of free tryptophane. The two control subjects showed approximately 5 milligrams increase in daily excretion during the period of supplemented dietary intake as compared with their control period on a normal diet. Perhaps the excretion of metabolic derivatives of tryptophane not microbiologically available was altered by the conditions of the diet and physical activity of the subjects, but these were not studied.

No important differences existed between control and restricted subjects despite the wide difference in protein intake. Variation between individuals is wide as evidenced by the differences between subjects E-3 and E-5. There was no significant loss of body weight during the experimental period nor was any correlation demonstrated between body weight and tryptophane excretion (Fig 1). Nitrogen balance was maintained by all subjects during the period studied (Fig 2). When protein was added to the diet at various intervals each of the subjects receiving this supplement showed an immediate increase in nitrogen excretion over the preceding period of restricted intake.

Fig 2—Nitrogen balance of subjects on control and experimental diets From top to bottom two control subjects and five experimental subjects

Ordinates Nitrogen intake grams per day, dotted lines nitrogen excretion grams per day solid lines

Abscissas Time on experimental diet weeks

#### SUMMARY

Seven healthy young men excreted daily in the urine from 8 to 22 mg of free *L*-tryptophane, approximately 1 to 3 per cent of the ingested tryptophane, while on a normal dietary intake of 70 Gm of protein containing 813 mg of free *L*-tryptophane. During twenty-one and twenty-seven week periods on an experimental diet restricted in B complex vitamins and containing 40 Gm of protein (94 per cent nonanimal) and 241 mg of free *L*-tryptophane, five of these same subjects excreted slightly greater amounts of tryptophane than in the control period amounting to a ratio approximately 3 to 15 per cent of the ingested tryptophane. Still greater urinary excretion occurred on a diet supplemented liberally with B complex vitamins and animal protein. Control subjects did not excrete more tryptophane than the subjects on the restricted diet. Nitrogen balance was maintained on levels as low as 0.24 Gm of free tryptophane per day, indicating that the minimum tryptophane requirement of normal adults can be met by a dietary intake of 0.24 Gm daily. No correlation was found between body weight, minimum tryptophane requirement, and excretion of free *L*-tryptophane.

# ALCOHOL AND PANCREATITIS SERUM AMYLASE DETERMINATIONS IN NORMAL INDIVIDUALS FOLLOWING INGESTION OF ALCOHOL

JAMES MYHRE, M D , AND SAMUEL NESBITT, M D , PH D  
MINNEAPOLIS, MINN

ALCOHOLISM has often been indicted as a possible etiological agent or predisposing factor in pancreatitis, but its actual importance in the production of the disease never has been determined definitely. There is considerable clinical and pathological indirect evidence,<sup>1</sup> however, of such a relationship.

Siegel and Krautman<sup>2</sup> and Gray and co-workers<sup>3</sup> reported lowered serum amylase in patients with acute alcoholism. Domzalski and Wedge<sup>1</sup> in 1948 found that 48 per cent of fifty chronic alcoholic patients admitted to a neuropsychiatric hospital within forty-eight hours after their last drink had an elevated serum amylase. They postulated a subclinical pancreatitis that might easily be considered clinically to be alcoholic gastritis.

## EXPERIMENT

In an attempt to evaluate further the role of alcohol in relation to pancreatitis or at least as an agent which may affect the values of the serum amylase,<sup>4</sup> an experiment was designed utilizing as subjects fourteen normal, healthy males ranging in age from 27 to 40 years. These men drank habitually only in moderation. After a control serum amylase was determined, from 2 to 12 ounces of a good grade of 86 proof whiskey were ingested within a period of one and one-half hours before a substantial meal. In certain instances of higher alcoholic intake, a serum amylase was determined at this interval. Following the meal, quantities of whiskey varying from 0 to 12 ounces were ingested over a period of four hours. Total amounts of whiskey consumed varied from 7½ to 24 ounces. Determinations of serum amylase values were made following the period (approximately six hours after the beginning of the experiment) and again on the following day (approximately sixteen hours after the beginning of the experiment). The results are shown in Table I. Subject 4 lost some alcohol through emesis approximately seven hours after starting the experiment. In no instance was there a significant change in the value of the serum amylase.

## SUMMARY AND CONCLUSIONS

Some investigators have noted an increase and others have noted a decrease in the values of the serum amylase in patients suffering from alcoholism. A controlled experiment is described utilizing as subjects fourteen healthy men

subsisting on well balanced diets. No significant alterations of the values of the serum amylase were noted during or after the ingestion of alcohol. It would appear that alcohol per se at least in the quantities consumed in the present study, does not affect the level of the serum amylase in the normal individual. It may be that alcohol ingested in the amounts of this controlled experiment are not sufficiently great to affect the serum amylase values or that some other complicating factor present in chronic alcoholic subjects studied by other workers accounted for abnormal values in those instances.

# STUDIES ON THE DEPRESSION OF BRAIN OXIDATIONS

## I BIOPSY TECHNIQUE AND ANALYSIS OF VARIANCE IN THE SELECTION OF A PENTOBARBITAL CONCENTRATION<sup>1</sup>

D S WILKINS, M D, R M FEATHERSTONE, PH D, C E GRAY, M D,\*  
J T SCHWIDDE, M D, AND M BROTMAN, M D  
IOWA CITY, IOWA

WE ARE pursuing a study of sodium pentobarbital depression of oxygen consumption at various levels in the dog brain. Recently reported spectrophotometric determinations of barbiturates in blood and tissues<sup>2,4</sup> have not established concentrations of such drugs suitable for *in vivo* experiments. The present investigation was designed to find a concentration of sodium pentobarbital which would significantly, but not completely, depress the oxygen uptake of dog cortex. The experimental design comprises a technique for dog brain biopsy and the application of analysis of variance to standard manometric procedures in a manner which may prove useful in additional experiments with barbiturates and other depressant drugs.

### TECHNIQUE

A cortical biopsy was taken from each of five dogs by a method devised for this experiment. During Nembutal nitrous oxide oxygen anesthesia the temporal muscles were partially excised and the calvarium was removed. The dura was excised and replaced without suturing, which procedure was found necessary to permit access to the cortex at subsequent biopsy without evoking pain and struggling. Number 32 stainless steel wire was employed to close the scalp. Approximately seven days later the incision was reopened during 1 per cent procaine local anesthesia injected into the scalp. The dural flaps and granulations at the periphery were removed. The cortex appeared normal to gross and microscopic examination. A block of cortex approximately 5 by 15 by 20 mm was excised from each hemisphere and placed in a refrigerator.

Slices were prepared for use according to standard manometric practices. The elapsed time from biopsy to oxygenation and equilibration was thirty five minutes. The flasks contained Krebs Ringer phosphate buffer in which the calcium chloride content had been reduced to prevent the precipitation of calcium pentobarbiturate. The treatments comprised duplicate flasks of (1) 0.00, (2) 0.04, (3) 0.08, and (4) 0.12 per cent sodium pentobarbital, as pentobarbital, added to the solution before the flasks were filled. The pH was determined by a Beckman pH meter and was adjusted to  $7.4$  with 1 per cent HCl. Glucose was added from the side arm at the end of ninety minutes to produce a final concentration of 0.025 per cent. Readings were taken for eight thirty minute periods.

### RESULTS

1, B, and C, Fig 1, are photomicrographs of a section from the biopsy of Dog 2. The section is a representative one and is interpreted as showing no evidence of inflammation, unusual cellular degeneration, or other abnormalities.<sup>6</sup>

From the Divisions of Anesthesiology and Neurosurgery of the Department of Surgery and the Department of Pharmacology, College of Medicine, State University of Iowa.

The authors wish to thank Mrs Dorothy Baldwin for her technical assistance during certain phases of the experiment.

Received for publication March 14 1949

\*Present address 1940 Center Street, Salem, Ore.

Fig 2 is a graphic representation of the results on Dog 5. Each bar on the graph represents cubic millimeters of oxygen consumed per milligram of tissue dry weight during the preceding thirty minute period. Attention is called to the fact that this is the only expression of the results in terms of dry weight. Fig 2 is derived from Table I by the application of the wet to dry weight ratio which was found to be 5.62. The control for Dog 5 consumed 1.846 cmm of oxygen per milligram of tissue (mean of duplicate samples), wet weight, during the first ninety minutes. Quastel and Whentley<sup>7</sup> reported 0.780 cmm in comparable terms for dog cortex.

Table I presents the data from duplicate samples for four treatments observed through eight thirty minute periods on five dogs. Tables II to VIII are the statistical analysis which is presented in toto to clarify the method. Subsequent statistical analyses from this laboratory will contain a table comparable to Table VII only.

#### DISCUSSION

The dog brain was used as its own control for the *in vitro* addition of the desired drug. This method also allows the dog brain to serve as its own control for *in vivo* administration of a compound. For example it has proved successful at this laboratory to remove tissue from one side controlling the hemorrhage with Gelfoam after which the drug is introduced by the intravenous route before taking a second biopsy from the other hemisphere. Moreover if a small amount of cortex is removed the animal will remain healthy for another procedure upon a different brain level at a later date.

In a departure from custom an analysis of variance<sup>8\*</sup> a statistical method appropriate for small samples has been applied to the data from this experiment.\* Inasmuch as it is felt that this method of statistical treatment long used in the field of agronomy could find expedient application in many medical researches it will be discussed in detail.

Table II is a two way table for the purpose of calculating the dogs times periods ( $D \times P$ ) mean square in Table VII. It is made up from Table I, for example the figure 1.104 is the total oxygen consumption for all treatments of Dog 1 during Period 1. Likewise Table III for the  $D \times T$  mean square of Table VII contains the figure 3.050 the total oxygen consumption of Dog 1 Treatment 1 for all periods. Table IV referring to  $T \times P$  in Table VII is constructed in similar fashion.

Table VIII traces the calculations. Numbers from the preceding tables have been substituted for algebraic terms so that they may be followed more easily.

The summary of the analysis of variance Table VII contains the deductions which may be drawn from the experiment. The main sources of variation are dogs, periods and treatments. The mean square for each is a representation of the variance in oxygen consumption attributable to its respective source. The first order interaction,  $T \times P$  found to be highly significant, is the appropriate error term for estimating the significance of either treatments or periods.  $D \times T$

\*For his guidance in the analysis the authors are indebted to G. F. Sprague, Senior Agronomist, United States Department of Agriculture in charge of the cooperative corn breeding investigations at Iowa State College, Ames, Iowa. They also gratefully acknowledge the help of L. A. Knowler, Chairman of the Department of Mathematics, State University of Iowa.

is the error term for dogs. The error terms represent experimental error. Each  $F$  value listed is the ratio of the appropriate mean square to the error term.  $F$  values for significance at the 0.05 and 0.01 levels are included.<sup>8b</sup>

It is of note that the selection of first order interactions ( $T \times P$  and  $D \times T$ ) as measures of experimental error makes the conclusions from this experiment on five dogs applicable to the general dog population, based upon the assumption that the dogs used were a representative random sample of that population. However, use of  $D \times P \times T$  would limit any conclusions to the particular five dogs in the experiment.

It is seen that there is a highly significant difference among the control and other treatments and that the variance among periods is probably significant, as would be expected. The variance among dogs, which approaches significance, is certainly higher than desirable. This fact will be discussed later.

Comparing the control with 0.04 per cent sodium pentobarbital\* (Treatments 1 and 2 in Table VII), one finds the oxygen consumption significantly reduced by that concentration. Furthermore, in comparing 0.04 with 0.08 per cent (Treatments 2 and 3), one may conclude that the inhibition by the former is significantly less than that of the latter. In addition, there is no difference between 0.08 and 0.12 per cent (Treatments 3 and 4). Sodium pentobarbital 0.16 per cent was used on three of the dogs. This oxygen uptake, not shown, was statistically identical with the uptakes of 0.08 and 0.12 per cent. It seems logical to conclude, on the basis of the foregoing facts, that 0.08 and 0.12 per cent sodium pentobarbital cause essentially complete inhibition of dog cortex oxygen consumption.

Quastel's work upon the various substrates inhibited by di-alkyl barbituric acid derivatives was done with a 0.12 per cent concentration of those barbiturates.<sup>9</sup>

Returning to the substantial variance among the five dogs, it is discerned from Table III that the total oxygen consumed by samples from each dog was greater for each succeeding dog used. The linear increase was apparently associated with the improving technique of the experimenters. For example, successively larger sample sizes were used (from 50 to 60 mg. on Dog 1 to 115 to 130 mg. on Dog 5), due to successively larger biopsies. In other words, variation for a form of experimental error has been included with the mean square for a main source of variation, dogs. Deviation from linearity is an appropriate measure of the "actual" variance among the dogs. The mean square (Dogs, Deviation), 0.001117, for this so-called actual variance, that is, the variance inherent in the dogs and uninfluenced by technique, is calculated in Tables V, VI, and VIII<sup>10, 11</sup>. This mean square was found not to be significant when compared with its error term ( $D \times T$ , Deviation).

One more conclusion may be drawn from Table VII. Duplicate samples were sufficient, as indicated by the fact that the mean square for sampling error is of the same magnitude as that for  $D \times T \times P$ †.

\*In each instance per cent sodium pentobarbital indicates the concentration present as pentobarbital.

†It will be seen from Table I that a particular pair of flasks was used for each given treatment throughout the experiments. Any differences among flask pairs are thus confounded with treatment effects. It is technically inconceivable that flask pair differences could have been important relative to the large treatment differences so that conclusions concerning treatments are considered valid. In subsequent experiments the samples will be randomized as to placement in flask pairs.

It is perhaps pertinent to point out those things which have been accomplished through analysis of variance and which would have been less clear or less easily attained by other statistical methods. Had Fisher's "T" or the difference of means, both of which are commonly used in medical literature, been employed, the comparison of the full lengths of the curves would have been laborious. Therefore those portions of the curves following the addition of glucose would probably have been totaled, the totals being compared by the alternate methods. Thus the value existing in the varying shapes of the curves would have been lost.

The statistical conclusion regarding the sufficiency of duplicate samples would have been replaced by a merely arbitrary limit of error, such as 10 per cent. Such arbitrary treatment might well have required the use of triplicate samples, which would have unnecessarily reduced the scope of the experiment as delimited by the size of the biopsies.

Moreover, by the other methods mentioned the main sources of variation could not have been simultaneously ascribed their proper proportions in respect to the experiment as a whole. In other words a figure representing variation among dogs could have been computed (for example, a mean and standard deviation of the dog totals). Another figure for the variation among treatments could have been computed and still a third for periods. However one would be left with no clear evaluation of what each might have been while uninfluenced by the others. That evaluation has been accomplished through use of the analysis of variance.

We feel that an even more valid concentration of the drug for *in vitro* use would be that found to occur in the dog brain during hypnosis by the compound. However, sodium pentobarbital in a concentration of the magnitude of 0.04 per cent should prove satisfactory for testing depression of dog brain oxygen consumption at various levels.

#### SUMMARY

A method of dog brain biopsy and an analysis of variance, a statistical method appropriate for small samples, were combined with standard manometric technique in selecting a sodium pentobarbital concentration satisfactory for testing oxygen consumption at various brain levels. The biopsy procedure allows the dog brain to serve as its own control for either *in vitro* or *in vivo* administration of drugs and seems well adapted to this type of experimentation.

An analysis of variance, which permitted the drawing of more conclusions than would otherwise have been available from the data presented, disclosed the following facts:

- 1 Sodium pentobarbital 0.04 per cent, as pentobarbital, significantly depresses the oxygen consumption of dog cortex without completely inhibiting such consumption.
- 2 Sodium pentobarbital 0.08 and 0.12 per cent are quantitatively identical in their almost total abolition of dog cortex oxidations.
- 3 The variation among randomly selected healthy dogs is shown to be statistically nonsignificant for experiments of this type.

4 Duplicate samples were sufficient in the hands of these investigators

Conclusions 3 and 4 would not have been readily deduced without this method of statistical analysis. Conclusions 1 and 2 are much more accessible by this technique than by those more frequently used in the medical literature

The experiment does not show which substrates were depressed

## STUDIES ON SERUM ESTERASE

### THE SERUM ESTERASE IN LIVER DISEASE

MARTIN G. GOLDNFR, M.D., AND MARGARET MORSE, B.S.  
FORT LOGAN, COLO.

GOMORI'S recently described micromethod for the determination of blood esterase<sup>1</sup> gave occasion to examine this enzyme in human sera under various clinical conditions. The principle of this method is that phenyl benzoate is hydrolyzed into phenol and benzoic acid when incubated with an esterase containing material. The phenol is then linked to a chromogen—Red B Salt—which permits quantitative colorimetric estimation. The amount of enzymatic activity of the substrate is expressed in micromoles of phenol per cubic centimeter material. The details of the procedure are described in Gomori's original publication.<sup>1</sup> The method can be carried out easily in a clinical laboratory.

Our series consists of more than 400 estimations performed with sera from 150 unselected patients of this hospital. The blood was withdrawn in the morning before breakfast and was permitted to clot; the serum was separated and used either immediately or after storage in the refrigerator for twenty-four hours. Many of the patients were examined on several occasions.

Fig. 1 shows graphically the values obtained. The patients are enumerated on the abscissa, the esterase values indicated on the ordinate. Each dot represents one estimation. Where more than one estimation was done on the same patient, the individual values are connected by a vertical line. From this graph it is evident that

- 1 Most of the values fall within a range between 12 and 25 micromoles, with an average of 16 micromoles.

- 2 The fluctuations of serial estimations in the same individual are extremely wide in many instances.

- 3 There are a number of estimations, individual and serial, which are far below the average range.

The wide spread of the values of the same individual may suggest that the blood esterase fluctuates rapidly and widely under physiologic conditions and therefore may have little clinical significance. Since this survey was done on hospital patients, the alternative possibility had to be considered that the fluctuation of the values paralleled in some way the change in the patients' illnesses. Thus it became advisable to determine the blood esterase level in

Received for publication March 15, 1949.

FIG 1

healthy control persons. This was done in five individuals who were followed with serial estimations over periods up to thirty days. It was found that each test person maintained a rather constant serum esterase level, although the different individuals showed different degrees of enzymatic activity in their serum, all of them were, however, well within the average range. Fig 2 demonstrates the serum esterase levels of three normal individuals during a ten-day period. In another series the effect of absorption

Fig 2

and digestion of a fatty meal upon the normal serum esterase level was determined by hourly estimations over an eight-hour period. No significant fluctuations were found. Thus the stability of the serum esterase in health appeared to be established.

We proceeded to correlate the clinical diagnoses of our patients with their blood esterase values. At the same time all those patients were selected who showed an enzymatic activity of less than 10 micromoles phenol. This level was set arbitrarily in the hope that an analysis of values far below the average might yield positive results and reveal some clinical condition associated with or even responsible for such decrease of enzymatic activity of the serum.

A tabulation of the clinical diagnoses of our 150 patients is given in Table I. The pathologic conditions represented in this series represent cardiovascular disturbances, gastrointestinal diseases, tumors, chronic pulmonary

diseases such as tuberculosis, pulmonary fibrosis, and bronchiectasis, acute inflammatory conditions, liver diseases, chronic pancreatitis, diabetes, thyroid diseases, arthritis, and a few miscellaneous conditions as fractures severe burns, bilateral polycystic kidneys and pyelitis with the differential diagnosis of amyloidosis. Twenty seven of these patients showed a serum esterase value below 10 micromoles at a single determination or several determinations. Fifteen low values were found in the group of liver diseases, that is, more than half of this group was in the low range. Twelve more low values occurred in other pathologic conditions: four in chronic pulmonary diseases, two in gastrointestinal diseases, and one each in the tumor group, in the cardiovascular group, and in the diabetic group. The three remaining low values were found in the patients with severe burns, bilateral polycystic kidneys and chronic pyelitis with possible amyloidosis.

TABLE I. THE DIAGNOSES AND THE DISTRIBUTION OF LOW SERUM ESTERASE VALUES IN 150 UNSELECTED PATIENTS

DIAGNOSIS	NUMBER OF PATIENTS		
	TOTAL	SERUM ESTERASE	
		ABOVE 10 MICROMOLES	BELOW 10 MICROMOLES
Liver disease	28	13	15
Cardiovascular disease	14	13	1
Chronic pulmonary disease	30	26	4
Gastrointestinal disease	18	16	2
Acute inflammatory condition	8	8	0
Malignant tumor	10	9	1
Neuropsychiatric condition	11	11	0
Chronic pancreatitis	5	5	0
Diabetes mellitus	11	10	1
Thyroid disease	4	4	0
Arthritis	5	5	0
Miscellaneous (fractures severe burns, bilateral polycystic kid- neys, amyloidosis?)	6	3	3
	150	123	27

An analysis of the case histories of these thirteen patients with extra hepatic diseases showed the following: the four pulmonary patients had far advanced bronchiectases (two) or pulmonary tuberculosis, three of them had just undergone chest surgery when the low values were obtained, all four were in poor nutritional state. The two gastrointestinal patients had peptic ulcers with acute complications due to pyloric obstruction in one and perforation with peritonitis in the other. Both patients had serum esterase values above 10 micromoles in the postoperative recovery phase. The cardiovascular and the diabetic patient had enlarged livers but the usual liver function tests had failed to show any abnormality. The patient with tumor was suffering from Hodgkin's disease and was under treatment with nitrogen mustard when his serum esterase was determined. Only one single estimation had been done in this patient. In these patients as well as in the one with extensive burns and the other with the differential diagnosis of amyloidosis, it seems doubtful whether the low serum esterase levels can be ascribed to

then organ disease or are due to some general metabolic involvement. The great majority of patients with cardiovascular diseases, pulmonary conditions, tumors, ulcer disease, and diabetes mellitus had serum esterase levels well above 10 micromoles. It should be noted also that none of the five patients with chronic pancreatitis had shown a low serum esterase activity, one patient in this group had undergone a subtotal pancreatectomy.

Thus, it appeared that only the group with liver diseases was characterized in the majority of cases by a low level of serum esterase. A differential diagnostic breakdown of this group showed sixteen cases of portal cirrhosis, five cases of infectious hepatitis, six cases of cholangitis, cholecystitis, and cholelithiasis, and one case of biliary xanthomatosis (Table II). The low values were confined to cirrhosis of the liver and to the one case of biliary xanthomatosis. In two instances of liver cirrhosis, where the diagnosis had

TABLE II THE DIFFERENTIAL DIAGNOSIS AND DISTRIBUTION OF LOW SERUM ESTERASE VALUES IN 28 PATIENTS WITH LIVER DISEASE

DIAGNOSIS	NUMBER OF PATIENTS		
	TOTAL	SERUM ESTERASE	
		ABOVE 10 MICROMOLES	BELOW 10 MICROMOLES
Portal cirrhosis	16	2	14
Biliary xanthomatosis	1	0	1
Infectious hepatitis	5	5	0
Cholangitis / cholecystitis	6	6	0
	28	13	15

been established by history, clinical findings, and the usual liver function tests, the serum esterase levels were above 10—in one instance 12, in the other 16.2 and 18. Out of the fifteen cases with low levels, the usual liver function tests such as cephalin flocculation, thymol turbidity, total serum proteins, and albumin-globulin ratio had been done and had confirmed the diagnosis in thirteen instances. In one patient the differential diagnosis of infectious hepatitis had been entertained for some time but while the jaundice was clearing he developed ascites, low blood proteins, and a reversal of the albumin-globulin ratio and there could be little doubt that the infectious hepatitis was superimposed upon a cirrhotic process. The serum esterase level had been low since his admission to the hospital. The second patient was in cardiac failure, the liver was large and hard, no liver function tests had been done, the serum esterase level was low and decreased progressively. The day prior to his death we found an activity of only 0.96 micromole phenol in his serum, the lowest of all our values. The autopsy revealed in addition to other findings a far-advanced cirrhosis of the liver. Fig 3, b demonstrates the individual values obtained in all patients with liver disease.

A direct relationship between course of the disease and the serum esterase level was found in several other patients. Two other patients with cirrhosis died during the period of our investigation, both showed progressively decreasing esterase values and again the lowest levels were found shortly prior to death.

On the other hand, in patients who improved under medical management, the serum esterase increased gradually and paralleled the improvement of the usual liver function tests and the general condition of the patient

The average value for all levels obtained in cirrhosis of the liver is 9.5 micromoles phenol. Such average may be of little importance for differential diagnostic clinical purposes because of the spread of the individual values

Fig

It demonstrates, however, a significant difference from the average value for healthy persons, diabetic subjects, or patients with chronic pancreatitis in whom it lies between 16 and 19 micromoles

#### COMMENT

Gomori<sup>1</sup> found the serum esterase activity ranging between 14.5 and 41.2 micromoles per cubic centimeter in his series of fifty one unselected patients. The majority of our values is well within these limits. Gomori did not give a list of the clinical diagnoses of his patients nor did he indicate the range of fluctuations of enzymatic activity in the serum of the same individual at repeated examinations. While these variations have been extremely wide in many of our patients we have found that in health the serum esterase level tends to be rather constant.

A markedly low esterase activity in the serum of patients with chronic liver disease has been reported by a number of other investigators.<sup>2,3</sup> These studies were done with different methods, the stalagmometric or the acid titration procedure. Further investigations will have to show whether the esterases determined by these procedures are identical. Lagerloef found that the level of the serum esterase is not altered by pancreatectomy and postulated that this enzyme originates in the liver. Our own observations are in

agreement with his findings. While chronic pancreatic disease such as chronic pancreatitis and pancreatic sclerosis with steatorrhea was not associated with low serum esterase values, such decreased enzymatic activity was present in almost all of our patients with chronic and extended parenchymatous liver damage.

Our series is too small to offer the serum esterase estimation as another liver function test or as a diagnostic test for cirrhosis of the liver. Most of our patients had far-advanced disease and we do not know yet whether significant changes in the serum esterase can be detected early enough to be of diagnostic help and to supplement the already large battery of liver function tests.

In view of our observations of low serum esterase levels in a few patients with chronic pulmonary disease, it is of interest that Paraf and associates,<sup>6</sup> working with the stalagmometric method, reported a direct relationship between serum esterase levels and the severity of pulmonary tuberculosis. An analysis of the values of all our pulmonary cases, however, did not reveal such relation. We found low values in only four out of thirty patients, three of them had just undergone severe thoracic surgery. It seems that their general condition, possibly an involvement of liver metabolism, was responsible for the decrease in the serum esterase activity and not the underlying pulmonary disease.

Nothing is known about the physiologic function of the serum esterase determined with the described method. Our observations, however, seem to indicate that this enzyme is present in the blood of healthy individuals at a rather constant level that it is not involved in the process of absorption or digestion of fatty nutrients and that it is not related to the fat splitting enzyme of the pancreas.

#### SUMMARY

1 The Gomori method for estimation of the serum esterase was used for the examination of the serum of 150 unselected patients and a group of normal individuals.

2 Under physiologic conditions this esterase seems to be present in the serum at a rather constant level.

3 Under pathologic conditions, mainly in advanced cirrhosis of the liver, this serum esterase is significantly decreased.

## LABORATORY METHODS

### THE CONVERSION OF A STANDARD INCUBATOR TO A CARBON DIOXIDE INCUBATOR

ARONIAN M. REFSO MS, JANET F. MORRIS MS AND  
D. J. SUNKES MS, DR PH  
ATLANTA, GA

AN ATMOSPHERE of increased CO<sub>2</sub> concentration has been proved many times to be an important factor in stimulating the growth of a number of bacteria. The use of candle jars is one of the simplest means of obtaining additional CO<sub>2</sub> and was the method employed for several years by the Georgia Department of Public Health. This method had many disadvantages which were especially evident in the cultivation of blood specimens for *Brucella* organisms. These specimens were examined weekly and the negative cultures incubated for four weeks. The long incubation period necessitated the use of many jars the handling of which was time consuming and the additional moisture from the candles encouraged fungous contaminants. A concentration of 5 to 10 per cent CO<sub>2</sub> has been shown to produce optimum growth of *Brucella abortus*<sup>1</sup>. Since the CO<sub>2</sub> concentrations in the candle jars were usually less than this level and also quite variable, some device was needed to simplify and improve this method. The device had to be simple to operate, efficient and large enough to accommodate both the *Brucella* cultures and those of other organisms requiring increased CO<sub>2</sub> atmosphere.

Various methods have been used by other laboratories. Large air tight cans or jars have been fitted with special outlets so that the desired percentage of air could be removed and replaced with CO<sub>2</sub>. After adding the CO<sub>2</sub>, these cans or jars were incubated in an ordinary air incubator. Special incubators have been constructed such as the nonventilated "capnic" incubator. This incubator is filled by means of a rotameter, with a measured mixture of gases producing the desired atmosphere. Another procedure is the use of a regular air incubator into which a very small amount of CO<sub>2</sub> is allowed to flow constantly. This latter method is very inaccurate as the percentage of CO<sub>2</sub> in the incubator is unknown. Our plan was to pass a measured amount of CO<sub>2</sub> into an ordinary air incubator once a day and then by testing samples of the incubator air at hourly intervals to determine the decrease in CO<sub>2</sub> over a twenty four hour period. By this method we hoped to arrive at the amount of CO<sub>2</sub> which should be added once a day to give an atmosphere of 5 to 10 per cent during most of the following twenty four hours.

From the Georgia Department of Public Health Laboratories.

Presented before the Laboratory Section of the Southern Branch American Public Health Association at the Annual Meeting in New Orleans La. April 13 1948

Received for publication April 13 1949

## CONSTRUCTION AND OPERATION

An air incubator\* was selected. The two lower ventilation outlets on each side were closed from the inside with cork stoppers and a two-hole rubber stopper was placed in each of the two top outlets. One hole in each of the stoppers was left open for ventilation, and in the other two holes were placed glass tubes for the addition of  $\text{CO}_2$  (Fig 1, *A*) and for sampling the incubator air (Fig 2, *L*).

We use the Liquid Carbonic Corporation's Medical Carbon Dioxide cylinder with a regulator made by the same company, but presumably any type  $\text{CO}_2$  cylinder with a screw valve regulator would be satisfactory. The usual dial gauge found on these regulators is not shown in Fig 1. Such an indicator is unnecessary as it does not register less than 5 pounds pressure. Valve *E* is also unnecessary except in the initial opening and checking of the regulator, in routine use it is kept open at all times.

When  $\text{CO}_2$  is to be added, the cylinder valve (*B*) is opened all the way and the screw valve (*C*) is carefully closed until the desired pressure is obtained. This pressure is measured by mercury in a U tube (*D*), the open side of which is marked in fractions of an inch. This U tube is connected to the regulator by a T tube, the other side of which is connected with the glass tube (*A*) that takes  $\text{CO}_2$  into the incubator. The U tube is supported in a large plugged test tube that is clamped to the regulator. (This clamp is not shown in Fig 1).

The apparatus for measuring the percentage of  $\text{CO}_2$  in the incubator is a homemade modification of an Orsat gas apparatus (Fig 2). Samples of gas are taken through a tube (*L*) at various levels in the incubator, the quantity of the samples being controlled by clamp *H*. With clamp *H* open and clamp *K* closed, the gas is brought into the burette (*Y*). This burette is made from the bulb of a 50 ml pipette attached to a long glass tube. The tube is calibrated in milliliters and the total measurable capacity of the burette is determined (in this apparatus from *X* to *Y* is 58 ml). By means of a leveling bottle (*N*), the burette is filled with distilled water, to which has been added 2 drops of concentrated  $\text{H}_2\text{SO}_4$  and sufficient methyl red to show that the water is acid at all times. The absorption gas pipette (*M*) is made by attaching the bulbs from two 100 ml pipettes and filling the absorption compartment with pieces of glass tubing. To the crooked neck of the expansion compartment is attached a gas expansion bag, in this case made from a small funnel covered with rubber from a rubber glove (*R*). The pipette is filled with approximately 80 ml of 50 per cent KOH.

To make a reading of percentage  $\text{CO}_2$  with this apparatus, the KOH is first brought up to *W* by lowering the leveling bottle below the table top with *H* closed and *K* open. When the KOH is at *W* (a point about midway between the bulb and the rubber tubing) *K* is closed. Then by opening *H*, the burette is filled and emptied twice with gas from the incubator, to remove any gas left from previous tests. About five minutes is allowed after each of these fillings,

\*Theleo Precision No 6 Electric incubator No 1485 large

then the sample (58 ml) of  $m$  is carefully taken by lowering the water from  $X$  to  $I$ . The tube is allowed to drain for one minute, then the water in the bottle and that in the tube are leveled at  $I$ , and  $II$  is closed.  $K$  is opened

Fig 1 Apparatus for adding carbon dioxide to the incubator  
(As used routinely)

Fig 2 Apparatus for testing carbon dioxide content of the incubator  
(Used only while determining amount of CO<sub>2</sub> required)

and the gas is forced into the gas pipette ( $M$ ) by raising the leveling bottle until water reaches  $X$ . This forcing of the gas into the pipette is repeated six times, with care taken not to force bubbles through the KOH. After the sixth

absorption the KOH is brought again to the point W, and K is closed. The tube is allowed to drain one minute, then the water in the bottle is leveled with that in the tube and a reading is made. The number of cubic centimeters of water above the mark Y represents the quantity of CO<sub>2</sub> absorbed from the sample of gas. This is transcribed from milliliters of CO<sub>2</sub> in 58 ml of gas to percentage of CO<sub>2</sub> in the incubator at the level and time tested.

As in working with any Oisat gas apparatus, several precautions should be observed. When fresh water or fresh KOH is added, air is forced through the apparatus several times so that all dissolvable air will be dissolved by the liquids before any test is made. Periodically the absorption of the gas by KOH is checked by forcing the gas being tested into the pipette seven to eight times and comparing that reading with the reading made after six absorptions. In no instance was this higher than the reading after six absorptions.

#### ADDITION OF CO<sub>2</sub>

The gas-measuring apparatus was used to determine the amount of CO<sub>2</sub> required to give an atmosphere of approximately 5 to 10 per cent in the incubator over the longest practical period. One hundred and thirty-nine readings were made. The first few determined what percentage of CO<sub>2</sub> would be obtained by holding the mercury column at different heights for varying lengths of time. Then several tests were made to determine the approximate drop in CO<sub>2</sub> during the first few hours. These tests showed that if approximately 20 per cent is added there will be a drop to approximately 12 per cent in three hours, and then the decrease will be markedly less and more constant. With this tentative information it was decided to add 1 in mercury of CO<sub>2</sub> for four and a fourth minutes. Several series of hourly readings were made starting fifteen minutes after the addition of CO<sub>2</sub> and extending for twenty-four hours. The average percentages obtained are shown in Fig. 3. In thirteen series the average initial percentage of CO<sub>2</sub> was 19, and hourly readings for the next three hours were 14.6, 13.1, and 11.7 per cent respectively. At this point the rate of decrease level to only 0.35 per cent per hour for the next twenty-one hours tested, leaving 4.4 per cent CO<sub>2</sub> in the incubator at the end of twenty-four hours. Variations from these averages were small. In all the readings for the last twenty-one hours, the highest decrease in CO<sub>2</sub> per hour was 0.5 per cent and the lowest, 0.2 per cent. Although there was considerable fluctuation of the mercury column at various times while adding the CO<sub>2</sub>, in no instance was there a variation of over 1.7 per cent in the incubator fifteen minutes after the addition, and at the end of three hours the variation was never over 0.5 per cent. From these readings it may be concluded that after adding 1 in mercury of CO<sub>2</sub> for four and one-fourth minutes the incubator tested will contain approximately 11.7 to 4.4 per cent CO<sub>2</sub> for twenty-one hours. This concentration range is apparently favorable to the growth of *Brucella abortus* and to most of the other organisms that require increased CO<sub>2</sub> tension.

The readings, as recorded in Fig 3, were of samples of air taken from the middle shelf of the incubator. Two series were observed hourly on samples from the lowest shelf and they showed approximately the same percentage as the middle shelf. Air from the top shelf also was tested in the same manner, the initial readings, fifteen minutes after addition of  $\text{CO}_2$ , were approximately 4 per cent lower than those of the middle and lowest shelves, but after one hour the percentages were the same. Three series also were done on a candle jar, the initial readings, five minutes after the candle stopped burning, were

Fig 3 --Rate of  $\text{CO}_2$  decrease in the incubator after adding 1 in mercury of  $\text{CO}_2$  for four and a fourth minutes (incubator kept closed). These are the averages from thirteen series of hourly readings.

31, 31, and 28 per cent. The percentage of  $\text{CO}_2$  in the jar showed a steady decrease to a fraction of 1 per cent at the end of twenty four hours but work was not done to show what the decrease in the jar would be in the presence of *Brucella* organisms or contaminants.

Routinely,  $\text{CO}_2$  is added at about 4:00 PM and the incubator doors are kept closed until 2:00 PM the following day, at which time the transplants and examinations are made. If for any reason the doors must be opened in the morning a small amount of  $\text{CO}_2$  may be added so that the incubator will not be without  $\text{CO}_2$  for the remainder of the day. Before each addition of  $\text{CO}_2$  the incubator doors should be opened to remove any  $\text{CO}_2$  left from the previous addition. Addition of  $\text{CO}_2$  does not alter the incubation temperature.

## CULTURES

Eight strains of *B. abortus* were used and twenty eight comparisons made to show the difference in growth in candle jars and the CO<sub>2</sub> incubator. Some of these strains were recently isolated and others had been on artificial media for several months. Bottles of Tryptose broth were inoculated and incubated for forty-eight to seventy-two hours, then two sets of decimal dilutions were made through twenty tubes on each culture. One set was incubated in the CO<sub>2</sub> incubator and the other in candle jars. Observations for turbidity were recorded at the end of forty-eight hours. After that time, accurate comparisons could not be made because in most instances tubes in the incubator showed heavy growth through the twentieth dilution. In seventeen of the twenty eight comparisons the candle jars were used as in routine Brucella culturing, that is, the candles were lighted when the tubes were first placed in the jars and the jars were not opened until after forty eight hours of incubation (Fig 4). A second group of eleven comparisons was made in which the candles were relighted at twenty-four hours (Fig 5).

In both groups the incubator apparently gave better growth than the candle jars, but the differences were much more evident when the candles were not relighted. The average difference in growth in the incubator and the jar as used routinely (Fig 4) was approximately nine decimal dilutions more in the incubator, with the greatest difference being nineteen tubes and the least four tubes. When the candles were relighted at twenty-four hours, the average difference in eleven comparisons was four decimal dilutions more in the incubator. In four instances the comparative growth did not differ more than one tube, and in two instances the incubator produced growth in ten decimal dilutions higher than the candle jar (Fig 5).

For seventeen months all cultures for Brucella and then transplants have been grown in the CO<sub>2</sub> incubator. During this time Brucella organisms have been isolated from fifty-six specimens. From one hundred and eight blood clots cultured from ninety three patients having positive agglutination reactions with Brucella antigen twenty positive cultures were obtained. Ten of these were *B. abortus*, nine, *B. suis*, and 1, unclassified. From seventy six special bottles containing culture media<sup>3</sup> sent to physicians for whole blood specimens, fifteen *B. abortus* and twenty-one *B. suis* cultures were isolated. During this routine use of the incubator, mold contaminants were observed very rarely. These contaminants had been quite prevalent in cultures kept in candle jars for several weeks.

Before using the CO<sub>2</sub> incubator for routine cultivation of gonococci, several series of duplicate plantings were made from cervical specimens in order to compare growth (number and size of colonies) obtained in the CO<sub>2</sub> incubator with that in candle jars. Growth was approximately the same, and in no instance was a culture positive in the candle jar and negative in the CO<sub>2</sub> incubator. Since these comparisons proved satisfactory the CO<sub>2</sub> incubator was put into routine use for growing all gonococcus cultures and has been used satisfactorily for seven months. Other miscellaneous cultures (streptococci, *Hemophilus m-*

*fluenzae*, and *Streptobacillus moniliformis*) have been grown successfully in the incubator. For routine culture work it has proved to be convenient and inexpensive to operate.

Fig. 4—Comparative growth of *Br. abortus* in broth incubated in the CO<sub>2</sub> incubator and in candle jars (Jars not opened until after forty eight hours). Growth is recorded at forty eight hours.

Fig. 5—Comparative growth of *Br. abortus* in broth incubated in the CO<sub>2</sub> incubator and in candle jars (candles relighted after twenty four hours). Growth is recorded at forty eight hours.

## SUMMARY

The conversion of an ordinary air incubator to an incubator with a measured increased  $\text{CO}_2$  atmosphere has been described. The conversion and standardization were simple and required only materials found in the usual bacteriologic laboratory. After adding 1 in. mercury of  $\text{CO}_2$  for four and a fourth minutes, this incubator maintains an approximate percentage of 11.7 to 14.4 per cent of  $\text{CO}_2$  for twenty one hours and has proved to be more efficient than candle jars for growing *Br. abortus* and other organisms requiring an increased  $\text{CO}_2$  atmosphere. It is efficient, easy to operate, and practical for daily use in diagnostic laboratories.

## A PHOTOMETRIC MODIFICATION OF THE HYPOBROMITE METHOD FOR NONPROTEIN NITROGEN

D. A. FEE, M.D., DOLORES CRUGER, B.A., AND H. B. COLLIER, PH.D.  
SASKATOON, SASKATCHEWAN, CANADA

RAPPAPORT and Eichhorn<sup>1</sup> have recently published a rapid titrimetric micromethod for the determination of nonprotein nitrogen, based upon the hypobromite reaction. They claim excellent agreement with the results of micro-Kjeldahl analyses. The application of the hypobromite method to the determination of urea in blood and urine has been discussed by Peters and Van Slyke,<sup>2</sup> who pointed out that urea does not react quantitatively with the reagent, and that ammonia, uric acid, and creatinine do react to some extent. Thus good results in the determination of urea depended upon a balancing of errors.

In a preliminary examination of the Rappaport and Eichhorn method for nonprotein nitrogen in blood filtrates, we found that urea reacted quantitatively, amino acids gave considerably greater than 100 per cent recovery, and creatinine, uric acid, or adenine much less than theoretical recovery of total nitrogen. Titration of actual blood filtrates gave values corresponding to 93 to 94 per cent of the total nitrogen, as compared with micro-Kjeldahl analyses.

The present report describes a modified procedure in which the liberated iodine is estimated photometrically, and in which reliable and precise results are conveniently obtained.

### METHOD

The reagents were those described by Rappaport and Eichhorn, unless modified as indicated below. All reagent solutions were made up in redistilled water or Vacoliter water in order to avoid the possibility of turbidity in the photometric analysis. Accurate volumetric flasks and pipettes were used throughout.

#### Reagents—

*A. Deproteinizing Solution* Modified Abraham's reagent

*1. Deaminating Reagent* Nineteen parts of boron acid fluoride mixture mixed with 1 part of bromine solution

*C. Reagents for Liberation of Iodine*

1. Potassium iodide 10 per cent solution

2. Hydrochloric acid, 6N (18 per cent) equal volumes of concentrated hydrochloric acid and distilled water

**NOTES** Potassium bromate was found most convenient for making up bromine solution B<sub>4</sub>, as suggested by Rappaport and Eichhorn. The deaminating reagent was found to keep for about three hours after which it should be made up fresh. The strength of this reagent should be adjusted by varying the proportion of bromine solution B<sub>4</sub> to boron fluoride solution B<sub>3</sub> so that the blank reading lies within the most sensitive range of the photometer, i.e., in the range 30 to 40 per cent transmittance.

From the Saskatchewan Cancer Commission, the Saskatoon City Hospital, and the Department of Biochemistry, University of Saskatchewan.  
Received for publication Feb. 1, 1949.

*Procedure—*

- 1 Pipette 0.100 ml of finger tip or venous blood into 5.00 ml of Aldrich's deproteinizing fluid. Mix thoroughly and filter (or centrifuge).
- 2 Into a 25 ml volumetric flask containing about 10 ml of water, pipette exactly 3.00 ml of the clear filtrate and 5.00 ml of deaminating reagent.
- 3 Wait exactly two minutes after the addition of the deaminating reagent and then add 0.2 ml of 10 per cent KI and 3 ml of 18 per cent HCl.

Fig. 1—Calibration curve for photometric nonprotein nitrogen estimation. The vertical axis represents differences between optical density of blank and of unknown. Coleman Junior spectrophotometer at 475 millimicrons.

- 4 Dilute to the mark with distilled water, invert to mix, and read at once in the photometer.
- 5 Prepare a reagent blank, substituting 3 ml of deproteinizing solution for the blood filtrate in (2), and proceed as described.
- 6 Subtract the optical density reading of the blood filtrate from that of the reagent blank, and, using the difference, read off the concentration of nonprotein nitrogen from the calibration curve.

**NOTES.** In procedure (2) a tube calibrated at 25 ml, such as the Fohn Malmros blood sugar tube, may be substituted for the volumetric flask, a Fohn Wu sugar tube is not suitable.

(3) In adding the HCl, the technician must avoid transferring KI from the mouth of the flask or tube back into the HCl stock bottle on the tip of the pipette. This will turn the acid yellow.

(4) Filter photometers such as the Lumetron and Fisher have been used, with the blue filters supplied. We used a Coleman Junior spectrophotometer, with 19 mm cuvettes set at 475 millimicrons. The wave length setting is not critical, as free iodine does not give a sharp absorption band.

(5) As the calibration curve is not linear above 100 mg per cent, blood filtrates giving a value above this must be diluted as necessary, and the determination repeated.

*Calibration*—A calibration curve was obtained by using a series of blood specimens with nonprotein nitrogen values up to 100 mg per cent. Readings were made upon these as described and the actual nonprotein nitrogen was accurately determined by a micro Kjeldahl procedure. For the various specimens, the difference in optical density between blank and blood filtrate was plotted against the nonprotein nitrogen of the whole blood in milligrams per 100 milliliters.

The calibration curve obtained with the Coleman Junior Spectrophotometer is illustrated in Fig. 1. The precision of the method is indicated by the results of replicate determinations upon separate filtrates of the same blood, as presented in Table I.

TABLE I. PHOTOMETRIC DETERMINATION OF NONPROTEIN NITROGEN IN WHOLE BLOOD  
(Optical density readings in Coleman Junior spectrophotometer at 4.5  $m\mu$ )

Constant by method of least squares				0.00249

If a reliable micro Kjeldahl method is not available the procedure may be calibrated with a standard urea solution although urea gives readings about 5 per cent higher than blood filtrates with equivalent nitrogen contents. Weigh out accurately 200 mg. of chemically pure urea and dissolve in distilled water to 100 ml. giving a solution with nonprotein nitrogen concentration of 93.3 mg per 100 milliliters. Using this solution carry out the steps of the procedure as with whole blood. Prepare a calibration curve by making serial dilutions of this standard urea solution.

## CONCLUSION

The hypobromite method for nonprotein nitrogen in whole blood has been modified in that the liberated iodine is estimated photometrically, rather than by titration. The method is standardized by micro-Kjeldahl. It affords readily reproducible results, and is much more rapid and convenient than the conventional Folin-Wu determination.

## STANDARDIZED REAGENT FOR THYMOL TURBIDITY TEST

J DE LA HUELGA, M D, AND HANS POPLER, M D, PH D  
CHICAGO, ILL.

THE thymol turbidity of Maelagan<sup>1, 2</sup> has been widely accepted as an hepatic test, however, the normal range recorded by different investigators varies.<sup>1, 3</sup> The thymol reagent is a supersaturated solution. This causes a variation of the thymol concentration in different reagents prepared. This is significant since the reagent becomes turbid after a few days of standing at room temperature. In the following, the error resulting from the use of different thymol reagents is evaluated and then thymol concentration is determined. In addition, the preparation of a uniform thymol reagent is described which is not subject to the mentioned error.

### METHODS

The thymol turbidity was determined following the original description,<sup>1, 2</sup> the calibration being done with barium sulfate according to Shank and Hoagland.<sup>9</sup> The units recorded with this calibration are twice as high as those with the standard of Maelagan, since the barium sulfate suspension is wrongly based on a 0.962 normal instead of molar barium chloride solution.<sup>10</sup> Inasmuch as the values can be converted into each other by simple multiplication or division by two the units are easily comparable if reference is made to the standard used.

For determination of the thymol concentration in thymol reagents, the following method was adapted.

#### *Reagents —*

- 1 Fohn and Ciocalteu phenol reagent.<sup>11</sup>
- 2 2.5N NaOH
- 3 Thymol standard solution containing 60 mg of pure thymol per liter

#### *Standard Curve —*

Exactly 1, 2, 3, 4 and 5 ml of the standard solution are transferred to 50 ml volumetric flasks. Another flask is reserved for the blank. Water is added to all flasks to make approximately a total volume of 25 milliliters. Then 4 ml of 2.5N NaOH solution, and slowly, while shaking 3 ml of the Fohn-Ciocalteu reagent are added. The volume is made up to the mark with water and the readings are made after fifteen minutes, using a wave length of 620 millimicrons. The blue color is stable for at least twenty five minutes. The curve follows Beer-Lambert's law.

#### *Results —*

*For Determination of the Thymol Concentration in Maelagan's Reagent* The reagent was diluted 5 ml to 100 ml and from this dilution 5 ml were pipetted into a 50 ml volumetric flask and the color was developed as in the standard curve simultaneously with a blank and 5 ml of the standard solution. In twenty even thymol reagents prepared according to Maelagan on the same or different days, the thymol concentration varied from 89.5 to 117

Received for publication, April 9, 1949.

mg per 100 ml of reagent. The mean of the thymol concentration was 102 mg per 100 ml with a standard deviation of  $\pm 2$ . Therefore, in the following experiments a concentration of 100 mg per 100 ml of reagent was selected.

The influence of the thymol concentration of the reagent upon turbidity readings was determined by measuring the turbidity resulting from using seven different Maelagin reagents of varying thymol concentration for four sera. In general, the turbidity was proportional to the concentration of the thymol in the reagent (Fig 1). In addition, the thymol reagent with the highest thymol concentration was diluted with the barbital buffer to produce concentrations of 95, 90 and 85 per cent of the reagent. The turbidities were proportionate to the thymol concentration.

Fig 1—Relation between the thymol turbidity of four sera and the thymol concentration of the reagents

*A Thymol Reagent With Constant Thymol Concentration Was Prepared as Follows*  
Because USP thymol may contain impurities which are not soluble in ethyl alcohol, a bulk amount of thymol was dissolved in 95 per cent ethyl alcohol, and the insoluble material was removed by filtration. Cold water was added to the filtrate to precipitate the thymol. The crystals were dried on a desiccator under anhydrous calcium chloride for two or three days. Then, an exactly 10 per cent solution of the dried thymol in 95 per cent alcohol was prepared which serves as permanent stock solution. The thymol reagent is prepared by transferring about 80 ml of the barbital buffer (prepared according to Maelagin 2 but without thymol) to a 100 ml glass stoppered volumetric flask, and adding exactly 10 ml of the 10 per cent alcoholic thymol solution the thin oily layer of thymol is dissolved by shaking the flask vigorously for thirty to sixty seconds and then more buffer is added to make to the mark. No oily droplets must be seen in the neck of the flask. In eighteen different lots prepared from three different stock solutions on different days, the concentration of thymol was  $100 \text{ mg} \pm 1$ . If necessary, a large volume of reagent may be prepared accordingly.

Since in barbital buffers without thymol an amorphous precipitate may eventually form, probably because of the growth of mold or bacteria, a stock barbital buffer solution with half concentration of thymol which does not permit bacterial growth and which is not super saturated was prepared as follows. About 800 ml of the barbital buffer solution were transferred to a 1 liter volumetric flask, and 50 ml of the 10 per cent alcoholic thymol

solution were added. The flask was then shaken as before and filled with buffer to the mark. To prepare the thymol reagent 0.5 ml of the 10 per cent thymol stock solution is diluted as described to 100 ml with the buffer thymol solution. The reagents prepared by either method can be kept at room temperature and used until turbidity develops.

To ascertain whether the presence of 1 ml of ethyl alcohol per 100 ml interferes with the thymol turbidity test to different aliquots of MacLagan's thymol reagent 9.9 per cent ethyl alcohol was added to produce an alcohol concentration of 1, 2, and 3 per cent respectively. The turbidity readings of different sera by use of the reagent with 1 and 2 per cent alcohol did not differ from those obtained with the original reagent, while in a few sera a slight aberration was noticed with the 3 per cent alcohol reagent.

Using the alcoholic thymol stock solution a thymol reagent with thymol concentration of 120 mg per 100 ml was prepared which is about 20 per cent more concentrated than most of MacLagan's reagent. As expected with this reagent the turbidity readings of normal and pathologic sera were higher than with the original reagent. However no additional diagnostic benefit was observed from using this modification.

#### DISCUSSION

The thymol turbidity readings depend upon the thymol concentration of the reagent used. Since the latter varies in view of the slight supersaturation of the reagent it was not surprising that different lots produced different readings with the same serum. Alcohol increases the solubility of thymol in water and thus permits the preparation of uniformly supersaturated thymol reagents. Since the thymol reagent is not stable for more than two weeks and has to be prepared repeatedly it appears advantageous to use the presented modification by using a stable alcoholic stock solution and a stable buffer with half concentration of thymol which will give a uniform thymol concentration in any batch prepared.

In addition to the necessary standardization of the calibration (which takes into account the double unitage reading if the published standard of Shank and Hoagland<sup>1</sup> is used) standardization of the thymol reagent should assist in producing uniform results in the same laboratory and in different institutions.

#### SUMMARY

A modification in the preparation of the thymol reagent in MacLagan's thymol turbidity test is proposed by using a stable 10 per cent alcoholic thymol stock solution and a stable barbital buffer with one half thymol concentration. Using this modified reagent the variations in the results due to different thymol concentrations in various batches of the original thymol reagent of MacLagan's are avoided.

## VACUUM SAMPLING TUBE FOR RESPIRATORY GASES

C. A. FORSSANDER, M.D.  
PHILADELPHIA, PA.

RAPID repetitive sampling of respiratory gases is often necessary and in our own case it has been needed for estimation of cardiac output. For accurate estimations a tube has been devised which will in quick succession wash out the instrumental dead space and collect the sample. The tube was designed for use

Fig. 1

with the Scholander gas analysis apparatus and has been found very suitable, for the sample can be transferred directly without the necessity of using the conventional transfer pipette thus eliminating a possible source of contamination. By increasing the dimensions of the tube it is suitable for use with the Haldane gas analysis apparatus.

From the Department of Physiology, University of Pennsylvania Medical School.  
Received for publication March 11, 1949.

*Construction* —The tube is made of glass and consists of two barrels, one of half-inch internal diameter and 10 c.c. capacity to receive the sample and the other of quarter-inch internal diameter and 5 c.c. capacity to receive the dead-space air from the supply lines. A twoway cock connects the lower end of either barrel to a length of Tygon tubing (superior to rubber since it does not leak under pressure) which leads to the mercury reservoir. Another cock at the upper end connects either barrel with the intake, which is fitted with a short length of stainless steel tubing, to which may be fitted the small-bore polyvinyl tubing leading to the point from which it is desired to sample. A piece of similar tubing, six inches long with conventional rubber tip fixed at the end of a short piece of narrow-bore glass tubing, is used for transferring the sample to the Scholander apparatus. The sampling tube, with its fellows, is supported in a stand rather like a large test tube rack and is nine inches high.

*Mode of Use* —Before use, each barrel is evacuated separately in the ordinary way, and the volume of the smaller barrel evacuated can be varied with the length of line to be cleared. Sampling is then carried out when desired by turning the upper cock through a complete rotation.

The vacuum sampling tube described has been devised for operations in which rapidly obtained uncontaminated samples of gas are required, it also provides a simplified and accurate method of transfer of gases to the Scholander gas analysis apparatus.

The tube was made up in the Department of Physiology, University of Pennsylvania, by Mr J. D. Graham.

# THE HEMATOLOGIC CHANGES INDUCED IN GUINEA PIGS BY THE PROLONGED ADMINISTRATION OF PTEROYL GLUTAMIC ACID ANTAGONISTS

JAMES INNES, M.D.,\* ELIZABETH M. INNES, M.B.,† AND CARL V. MOORE, M.D.  
ST. LOUIS, MO

ANTAGONISTS of pteroyl glutamic acid (folic acid) are currently being evaluated as therapeutic agents for the treatment of leukemia and are being used experimentally in attempts to study the physiologic relationship between pteroyl glutamic acid (PGA) and the antipernicious anemia principle of liver. Detailed information about the hematologic effects produced by PGA antagonists is needed as a background for these observations. The experiments reported in this paper define the hematologic changes induced in guinea pigs by the prolonged administration of four different antagonists. An earlier report described the effects of relatively large doses of 4-amino pteroyl glutamic acid (4-amino PGA) and emphasized the striking difference in the susceptibility of different species of animals to the drug.<sup>1</sup> In the present study, small doses of the various antagonists were used in order that chronic rather than acute changes might be induced. Guinea pigs were selected because they occupy an intermediate position with respect to species susceptibility, and because the cytology of their peripheral blood and bone marrow is remarkably similar to that of the human being.

## I. MATERIALS AND METHODS

Except where otherwise specified adult guinea pigs weighing about 500 grams were used. Since the effects of PGA antagonists per se were being studied no attempt was made to influence the amount of PGA available to the animals either through diet or intestinal synthesis. Lettuce and Purina Rabbit Chow were fed throughout the experiments. Antagonists were administered by subcutaneous injection at intervals of twenty four hours.

Before injection of an antagonist was started each animal was observed during a control period of two to five days to establish its normal range of weight and its peripheral blood values. Throughout the time of drug administration, frequent determinations were made of the red blood cell count, hemoglobin value, reticulocyte percentage, total and differential white blood cell counts and the platelet level. For the reticulocyte and platelet estimations, Dameshek's platelet solution was used.<sup>2</sup> Hemoglobin was estimated by the Evelyn method.<sup>3</sup>

Bone marrow was aspirated from the iliac crest of guinea pigs in quantities sufficient to allow the preparation of satisfactory marrow films. A 20 gauge spinal puncture needle, complete with stylet, was cut to a length of one and one half inches. The animals were firmly held, face down, with the hind legs fully extended after shaving and cleansing the skin over the ilium, a small cut was made in the tough skin and the sterile needle introduced.

This investigation was supported by a research grant from the National Heart Institute, United States Public Health Service.

through the muscle until contact was made with the crest of the bone. A boring movement allowed the tip of the needle to enter the marrow cavity, so that on withdrawal of the stylette a small quantity of marrow blood and flecks could be aspirated into a 5 cc syringe. The flecks were spread on slides and stained with Wright's stain. In about 75 per cent of aspirations attempted in this manner enough marrow was obtained for satisfactory examination. The operation appeared to cause little lasting discomfort to the animals and although it was not felt desirable to repeat the procedure on the same side until at least ten days had elapsed, aspiration from the opposite ilium was carried out on the next day in some animals where rapid changes in the marrow cytology were anticipated.

No guinea pigs were sacrificed during the investigation, though several died from the effects of the drugs. Autopsy was then performed as soon as possible and the weight and gross appearances of the organs were noted. Fixed sections of liver, spleen, kidney, suprarenal heart, and lung were made for microscopic examination.

(a) *The Peripheral Blood and Bone Marrow of Normal Guinea Pigs*—Normal values for the cellular elements in the peripheral blood of guinea pigs are summarized in Table I. The tabulation includes data obtained by other workers as well as those from the present investigation.

The marrow in healthy guinea pigs is cytologically similar to normal human marrow (Fig. 1). It has been described in detail by Epstein and Tompkins<sup>7</sup> figures given by them for the differential counts agree essentially with those found for the normal animals in the present study. Instead of reporting results in terms of differential counts however, it was decided to describe the alterations induced by the PGA antagonists. This was done for two reasons: (1) careful descriptions of the appearance and distribution of the cell types probably convey a more accurate impression of any cytologic changes, and (2) in the treated animals, primitive cells were often encountered which were difficult to classify with conviction.

(b) *The Pteroyl Glutamic Acid Antagonists Used*—The chemical names of the four antagonists employed in this investigation and the symbols which will be used to identify them are tabulated below.

NAME	SYMBOL
Pteroyl aspartic acid—racemic form	As Fol R†
Pteroyl aspartic acid—active form	As Fol A†
7 methyl pterotic acid	Met Fol B†
4 amino pteroyl glutamic acid	Aminopterin 4 amino PGA

Each of the first three antagonists was given alone to some of the animals and in combination with 4 amino PGA to others.

## II. RESULTS

A *Pteroyl Aspartic Acid—R*—This compound was given to four guinea pigs. One animal (Guinea pig 1) received a daily dose of 20 mg, another (Guinea pig 3) 10 mg, and the other two (Guinea pigs 2 and 4) 5 mg each. These dosages were continued for seventy four, seventy two, sixty two, and fifty three days respectively. No general ill effects were noted throughout the experiment; the animals maintained their weight, appetite, and normal activity.

In all four animals a mild, prolonged reticulocytosis, ranging from 4 to 13 per cent, developed after about ten days and continued for twenty to thirty days. In three animals (Guinea pigs 1, 3, and 4) this reticulocytosis was pre-

Supplied by the Lederle Laboratories Division of the American Cyanamid Company to whom the authors express their appreciation.  
†Names used by the Lederle Laboratories to identify these compounds.

ceded by a fall in the erythrocytes to approximately 4 million per cubic millimeter, followed by a spontaneous return to normal levels. Otherwise, no changes

Fig 1—Marrow of a normal guinea pig (X850)

Fig 2

were noted in the peripheral blood of any of the animals, the white blood cell, differential and platelet counts remained within normal limits throughout. Hematologic data for Guinea pig 3 are graphically recorded in Fig 2.

Bone marrow aspiration was successful in three of these animals (Guinea pigs 1, 2 and 4) at the completion of the experiment. Apart from a slight increase in the orthochromatic and polychromatic normoblasts, no morphologic change was observed.

*B Pteroyl Aspartic Acid—4*—This optically active form of pteroyl aspartic acid was administered to one animal (Guinea pig 5) in daily dosage of 20 mg for sixty seven days. No general ill effects were observed and the only hematologic change observed in the peripheral blood was an intermittent polymorphonuclear leucocytosis rising to levels as high as 28,000 cells per cubic millimeter. Marrow aspiration at the end of the experiment showed no abnormality other than an increase in metamyelocytes, band forms and polymorphonuclear neutrophils.

*C 7 Methyl Pteric Acid*—Two animals (Guinea pigs 6 and 7) were given daily doses of 5 mg and 10 mg of this drug respectively. After forty days the dosage was increased to 10 mg and 20 mg daily and continued for an additional twenty two days. No general ill effects were noted.

On the lower dosage both pigs showed a mild reticulocytosis, ranging from 5 to 8 per cent, which appeared after seven days and continued for approximately twenty five days. The red corpuscles remained within normal limits during the experiment. The total leucocyte count in both animals rose within ten days from control levels of 10,000 to 15,000 per cubic millimeter to around 20,000 per cubic millimeter and remained thus while the drug was being given. This slight increase affected both the granular and nongranular forms. The platelet values showed no striking change.

Marrow aspiration was unsuccessful in these animals.

*D 4 Amino Pteroyl Glutamic Acid—4* amino PGA was given to eight animals (Guinea pigs 8 to 15) in six of which (Guinea pigs 8 to 13) the effects of prolonged daily administration were observed.

Three animals (Guinea pigs 8 to 10) received 0.25 mg daily for ninety two, sixty five, and sixty three days respectively. Guinea pigs 9 and 10 maintained their weight and appetite throughout. In Guinea pig 9 the red blood count had fallen gradually to 3.5 million per cubic millimeter after sixty five days, but otherwise neither of these two animals showed any hematologic changes. Guinea pig 8 maintained its weight for sixty four days on the 0.25 mg dose but thereafter lost weight steadily and died on the ninety second day. During this whole period the red blood cells remained essentially normal. About the fiftieth day a leucocytosis of 23,000 cells per cubic millimeter developed because of an increase in both neutrophils and lymphocytes. The elevated white blood cell count continued until the ninetyeth day though after the eightieth day it was accounted for entirely by a granulocyte increase, the lymphocytes falling sharply at this time. In the terminal two days a dramatic fall occurred in the total white blood cells (from 24,250 to 2,350 cells per cubic millimeter) and in the platelets (Fig 3).

Marrow studies were made in the latter animal eight days before death and post mortem. At the time of the peripheral leucocytosis, the marrow showed a marked increase in metamyelocytes, band and segmented neutrophils (Fig

4,A), although the red blood count at this time was normal, there was a definite increase in pronormoblasts and basophilic normoblasts. Megakaryocytes of normal appearance were seen. There was also present a number of large cells, of irregular outline with nongranular, pale blue-staining cytoplasm and large nuclei with an open chromatin network and occasional nucleoli. For reasons to be discussed later, these cells were considered to be "reticulum cells."

Fig. 3

In the post-mortem marrow of the same animal (Guinea pig 8, Fig 4,B), myelocytes were still present in considerable numbers but there was an almost total absence of metamyelocytes and polymorphonuclear granulocytes. The number of reticulum cells had definitely increased, their wide distribution and the general cellularity of the marrow could best be appreciated in fixed section (Fig 4,C).

No abnormalities of the viscera were noted grossly at autopsy and no hemorrhages were observed macroscopically. On microscopic examination the liver showed extreme fatty change affecting the central and mid-zonal cells of the lobules (Fig 4,D). An area of recent hemorrhage was seen in the medulla of one suprarenal. In the splenic pulp the endothelial elements were prominent, but apart from these findings the organs showed no changes.

Three animals (Guinea pigs 11, 12, and 13) were given prolonged daily dosage of 0.5 mg 4-amino PGA.

Fig 4.—Culnea pig 8. *A* Bone marrow during peripheral leucocytosis ( $\times 80$ ). *B* Bone marrow film after terminal leucopenia (post mortem) ( $\times 80$ ). *C* Bone marrow section after terminal leucopenia (post mortem) ( $\times 80$ ). *D* Liver ( $\times 10$ ).

The first of these lost weight and died in thirty-two days. During this time its red blood cell count fell to 3.7 million per cubic millimeter and its leucocytes to 3,250 per cubic millimeter, the differential count showed a reduction in both granulocytes and lymphocytes. There was also a terminal drop in platelets. At the time of death, the marrow was very cellular and contained a large number of reticulum cells. The red cell precursors were decreased, and in the granulocytic series there was an almost complete absence of segmented and band forms. Myelocytes, however, were numerous, with basophile and eosinophile forms especially prominent. Megakaryocytes were scanty. Microscopic study of tissue sections showed areas of recent hemorrhage and edema in the lungs and an increase in the endothelial cells in the spleen. No fatty change was observed in the liver, and other organs examined showed no significant abnormalities.

The second animal (Guinea pig 12) was given 0.5 mg 4-amino PGA for forty-eight days, at the end of which time it appeared to have suffered no general ill effects. No changes were observed in the peripheral blood other than a very gradual decline in the erythrocyte level to 4.22 million per cubic millimeter.

The third animal (Guinea pig 13) received the daily 0.5 mg dosage for 144 days with no apparent change in its general condition. In the peripheral blood, a fall in erythrocytes to 3.03 million per cubic millimeter in thirty-six days was partly corrected by a subsequent reticulocytosis which continued for thirty days and attained a maximum of 15 per cent. Thereafter, the red blood cell level remained between 3.5 million and 4.0 million per cubic millimeter until the one hundred sixteenth day. While administration of 4-amino PGA was continued, 10 mg PGA were then injected daily for fourteen days, followed by 5 USP units of liver extract daily for an additional two weeks. These supplements caused no increase in reticulocytes, and the red blood cell count fell gradually to 2.9 million per cubic millimeter. Up to this time (one hundred forty-fourth day) no change had occurred in the total or differential leucocyte count or in the number of platelets. Marrow aspiration studies were made on the one hundred sixteenth day and one hundred forty-fourth day, i.e. before and after the PGA and liver extract. On the one hundred sixteenth day the marrow was very cellular and showed erythroid hyperplasia with a large number of pronormoblasts and basophilic and polychromatic normoblasts. The granulocytic precursors and megakaryocytes appeared normal. A considerable number of reticulum cells was present. On the one hundred forty-fourth day, the marrow cytology was essentially unchanged (Fig 5, A and B).

In two animals (Guinea pigs 14 and 15) the effects of giving a large single dose of 4-amino PGA were investigated.

Guinea pig 14, weighing 510 grams, received an injection of 20 mg of the compound. No changes were observed in its general condition or in its peripheral blood during the succeeding fourteen days, aspirated marrow examined on the tenth day following the injection showed no abnormality. A second injection of 20 mg produced the same negative result. Doses of 2 mg were then administered daily for ten days, the white blood cell count fell to 5,500 per cubic millimeter but there was little change in the red blood cell and hemoglobin levels. The dosage was next reduced to 1 mg daily for thirty-two days.

Fig 5—Guinea pig 13. *A* Bone marrow after 0.5 mg. 4 amino PGA had been given daily for 116 days ( $\times 1400$ ). *B* Bone marrow after PGA and liver extract (one hundred forty fourth day) ( $\times 1400$ ). *C* Bone marrow five days after stopping 4 amino PGA ( $\times 1400$ ).

During this time, the red blood cells decreased to 2 68 million per cubic millimeter and the hemoglobin level fell to 7 8 Gm per cent, no further depression occurred in the leucocytes, and the differential and platelet counts remained normal. Marrow examination at the end of the period showed an increase in

Fig 6—Guinea pig 14. A Bone marrow before stopping 4-amino PGA ( $\times 1400$ ) B Bone marrow twenty-four hours after stopping 4-amino PGA ( $\times 1400$ )

the number of pronormoblasts and basophilic and polychromatic normoblasts, with no change in the white cell precursors or megakaryocytes. Reticulum cells and plasma cells were prominent (Fig 6,A).

The second animal (Guinea pig 15, 830 grams) was given a single injection of 40 mg of 4-amino PGA. Observations over the next fourteen days revealed no general or hematologic effects. Doses of 4 mg daily were then given for ten days, and while no changes were found in the peripheral blood, the marrow at the end of this time showed a decrease in the proportion of erythroid precursors with pronormoblasts and basophilic normoblasts outnumbering the later forms

In the granulocytic series all stages of precursors were present, though the proportion of early myelocytes was increased. Reticulum cells, plasma cells, and lymphocytes were numerous.

*E 4 Amino PGA and Pteroyl Aspartic Acid—R*—The combined effects of these two antagonists were studied in five animals (Guinea pigs 16 to 20). Table II indicates the daily dosage of each drug, the duration of administration,

GP 16 Effects of Combined Doses of 4 Amino PGA and Pteroyl Aspartic Acid (R) on Peripheral Blood

Fig 7

and the findings in the peripheral blood before and after the experiments. In all cases a general depression of erythrocytes, leucocytes, and platelets resulted. A severe anemia developed in animals 16 and 19 and marked leucopenia in Guinea pigs 16 and 18. In both of the latter differential counts showed an almost equal reduction in granulocytes and lymphocytes. Weight loss occurred in Guinea pigs 16 and 18 though animal 16 was the only animal in the series to die (Fig 7).

Marrow examined at the end of dosage in Guinea pigs 16, 17, 19, and 20 was cellular in each instance. There was an increase in pronormoblasts and basophilic and polychromatic normoblasts with a diminution in orthochromatic normoblasts. In the anemic Guinea pig 16 the total erythroid elements were reduced with pronormoblasts as the predominating type. The granulocytic

precursors appeared normal except for a marked decrease in polymorphonuclear leucocytes and band forms in Guinea pig 16. All four marrows showed megakaryocytes of normal appearance. Reticulum cells were numerous in every instance.

Post mortem examination in animal 16 showed a large, pale liver weighing 24 grams and splenic enlargement to about three times the normal size. There were no signs of hemorrhage. Microscopically there was a marked degree of fatty change in the liver with vacuolation of the central and mid zonal cells of the lobules. Endothelial elements in the spleen were prominent. Other organs showed no significant changes.

*F 1 Amino PGA and Pteroyl Aspartic Acid—Active Form*—Two animals (Guinea pigs 21 and 22) were given daily injections of 0.25 mg of 4 amino PGA and 20 mg An Fol A.

Both lost weight, Guinea pig 21 died after twenty four days and Guinea pig 22, at the end of forty six days. Peripheral blood examinations showed a gradual decline in erythrocytes and in hemoglobin though at the time of death neither animal was severely anemic (3.67 million and 3.39 million per cubic millimeter). The white blood cell count for Guinea pig 21 fell from an initial value of 18,000 per cubic millimeter to 7,500 two days before death; the absolute number of lymphocytes decreased from 15,000 to 600 per cubic millimeter. Unfortunately, no terminal white blood count was obtained. Guinea pig 22 developed a leucopenia (1.450 per cubic millimeter) before death, the differential count showing a parallel fall in neutrophils and lymphocytes. Platelets remained virtually unchanged.

Marrow examination at the time of death showed in both guinea pigs a decided increase in the number of pronormoblasts and early myelocytes. The more mature granulocytic precursors were considerably reduced and megakaryocytes were present though scanty. Reticulum cells were numerous; plasma cells and lymphocytes were found in more than normal numbers.

Necropsy revealed no macroscopic signs of hemorrhage in either animal. The liver was large in Guinea pig 21 (weight 23 grams), but showed no histologic abnormality. There was increased endothelial activity in the splenic pulp of Guinea pig 22. No other abnormalities were observed in either animal.

*G 1 Amino PGA and 7 Methyl Pteric Acid*—These two antagonists were administered simultaneously to three animals (Guinea pigs 23, 24 and 25). The amounts, duration and effects on the peripheral blood are shown in Table III.

All three animals died. Guinea pigs 23 and 25 showing marked loss of weight. Leucopenia and thrombocytopenia developed terminally and there was some depression of erythrocytes in each pig, the anemia in Guinea pig 24 was severe. Changes in the leucocytes followed a general pattern: first there was an increase in the neutrophils and monocytes with no change in the lymphocytes; then a sharp fall occurred in all three white cell types (Fig. 8).

In Guinea pigs 23 and 25 the bone marrow became uniformly hypoplastic for erythrocytic granulocytic and megakaryocytic elements; the most prominent cells were reticulum cells, plasma cells, and lymphocytes. Of the erythroid and

myeloid series, the majority were early forms pronormoblasts and young myelocytes. The marrow of the severely anemic animal (Guinea pig 24) was actively cellular and showed an increase in the pronormoblasts and basophilic normoblasts with relatively few more mature forms. Considerable numbers of very early myelocytes were seen together with bands and segmented neutrophils,

GP 23 Development of Leucopenia on Combined Dosage With 4 Amino PGA and Methyl Pteric Acid

Fig 8

but the intermediate myelocyte and metamyelocyte stages were largely missing. Megakaryocytes were of normal appearance. In this marrow also, reticulum and plasma cells were numerous.

Macroscopic and microscopic examination of the tissues of these three animals showed little of note except for endothelial proliferation in the splenic pulp and a moderate degree of fatty change toward the center of the liver lobules in Guinea pigs 24 and 25.

*H Hematologic Recovery From Effects of Antagonists*—The peripheral blood and marrow changes which occurred when administration of the antagonist compounds was discontinued were observed in six of the animals in Guinea pigs 13 and 14 after 4-amino PGA alone, and in Guinea pigs 17, 18, 19, and 20 after combined dosage with 4-amino PGA and An-Fol-R.

Hematologic recovery occurred with striking rapidity in each instance (Table IV). Figs 9 and 10 show the detailed course of recovery from anemia and leucopenia in Guinea pigs 14 and 18 respectively. In every animal a reticulocytosis was evident within forty-eight hours after the last injection and reached a maximum (amounting to over 40 per cent in Guinea pigs 14 and 19)

within three to five days. There was a rapid return of the red blood cell count toward normal, with a noticeable lag in the rate of hemoglobin recovery in some instances. In all the animals, cessation of the drug was followed also by a rise in leucocytes. Lymphocytes were the first cells to increase in number in every instance (Fig 10).

Marrow was studied in three animals at different stages of the recovery phase. In Guinea pig 14, marrow was obtained twenty-four hours after the last dose of 4-amino PGA. Compared with the marrow of the previous day, there were definite signs of increased maturity of the erythrocytic precursors, with polychromatic and orthochromatic normoblasts more numerous although large numbers of pronormoblasts still remained (Fig 5, B and C). A complete return to normal erythropoiesis was evident in the marrow of Guinea pig 19 obtained ten days after the last administration of 4-amino PGA and An-Fol-R.

### III. DISCUSSION

The purpose of this discussion is to examine the experimental results obtained and to determine whether they indicate the mode of action of the PGA antagonists.

*4-Amino PGA*—Of the four compounds employed in this investigation, 4-amino PGA was obviously the most active hematologically. The smallest dose (0.25 mg daily) produced recognizable effects only when given over a very long period (nine to thirteen weeks), but when 0.5 mg was administered daily, marrow and blood changes appeared much earlier.

In the bone marrow the effects of 4-amino PGA were characterized by an increasing number of early erythrocytic and/or granulocytic precursors. The general cellularity tended to be increased rather than decreased. In all instances the change toward immaturity was accompanied by the appearance of a great many large, primitive-looking cells with pale, nongranular cytoplasm and large nuclei with an open chromatin meshwork. The cytoplasm of these cells was sometimes vacuolated, their nuclei usually showed nucleoli and were not infrequently divided. These cells were seen only occasionally in normal guinea

pig marrow. It was decided that they were most probably reticulum cells since their morphologic characteristics corresponded with the description of the latter given by Jaffe<sup>8</sup> and other workers. The earlier red blood cell precursors were studied with a view to ascertaining whether dosage with a PGA antagonist would produce a maturation arrest of the type seen in pernicious anemia. Whereas large numbers of pronormoblasts were found, no cells were seen which possessed all of the cytologic features of the megakaryoblasts of pernicious anemia.

The changes in the peripheral blood reflected those in the bone marrow. In general, when the erythroid elements in the marrow were retarded in maturation, a slowly developing anemia became evident. Repeated examination of blood films indicated this anemia to be normocytic and normochromic in type. In two instances when the red cells appeared macrocytic, determination of absolute cellular constants yielded normal values. Leucopenia in the peripheral blood accompanied a diminution in the more mature granulocytic precursors in the marrow. Thrombocytopenia occurred as a terminal event in two animals, in both of which evidence of tissue hemorrhage was found post mortem. Although the marrow of these latter pigs contained a few megakaryocytes, it seemed possible that some of the large double nucleated reticulum cells, also present in considerable number, might represent very early forms of platelet precursors.

In the animals which developed leucopenia, there was a marked diminution in the number of circulating lymphocytes as well as neutrophils. This finding, together with the histologic evidence of proliferation of the endothelial elements in the splenic pulp, suggests that 4-amino PGA may exert a general effect on reticuloendothelial tissue. The advanced degree of fatty change in the liver cells observed in one of the animals which died from the effects of the drug suggests that it also may have a systemic toxic action.

It was found in two animals (Guinea pigs 14 and 15) that a large single dose of as much as 20 to 40 mg. could be administered without producing any hematologic abnormality in the peripheral blood. Moreover, in animals in which prolonged daily dosage had brought about a marked retardation of hematopoietic output, signs of a return toward normal blood formation were evident in the marrow within twenty-four hours after administration was stopped. These two results suggest that in guinea pigs 4-amino PGA is excreted rapidly and that its action is dependent upon the maintenance of a sufficient concentration in the body tissues. Furthermore, unless the animals were moribund, hematologic effects produced by the drug appeared to be completely reversible merely by stopping dosage. In one animal a previous attempt to reverse the changes by the administration of PGA and liver extract was unsuccessful.

*An Fol R, An Fol A, and 7 Methyl Pterioic Acid*—These three compounds were all given over prolonged periods in doses as large as 20 mg. daily, with remarkably little hematologic effect. Apart from a mild continued reticuloctosis in all instances and a persistent elevation of the leucocyte count in the two animals given 7-methyl pterioic acid and the one given An Fol A, no general or hematologic changes were observed.

*Combined Dosage With 4-Amino PGA and Other Antagonists*—In the series of animals in which the effects of combined dosage were investigated, the amount of 4-amino PGA given was chosen as 0.25 mg daily, a dose which had been shown previously to produce minimal changes over a long period. To this were added the same amounts of An-Fol-R, An-Fol-A, and 7-methyl pterioic acid which had appeared relatively inactive when given alone. The object was to determine whether these three compounds would have any potentiating effect on the action of 4-amino PGA.

4-amino PGA and An-Fol-R, given simultaneously to five animals, produced anemia and leucopenia in all of them, with one death. 4-amino PGA and An-Fol-A caused a moderate degree of anemia and leucopenia in two animals, both of which died. 4-amino PGA and 7-methyl pterioic acid produced anemia with profound leucopenia and terminal thrombocytopenia, killing all three animals observed. In general, these changes occurred in a distinctly shorter period than was required to produce demonstrable effects by the use of 4-amino PGA alone, but the resulting marrow changes were in every way similar to those observed with the latter drug. While this series of experiments is too small to allow definite conclusions to be drawn, it does suggest that An-Fol-R, An-Fol-A, and 7-methyl pterioic acid are themselves true, though weak, depressants of hematopoiesis.

The nature of this investigation does not permit speculation as to the biochemical action of the PGA antagonist compounds. However, on the basis of the cytologic effects, it seems permissible to consider briefly the mechanism whereby the hematologic changes were brought about. The actions of the four antagonists studied are probably similar, though 4-amino PGA is by far the most powerful agent.

The action in guinea pigs would seem to be a generalized slowing of maturation of all blood cell precursors found in normal marrow. The effects may be manifested mainly on one or more of the series of precursors and tend to result in the production of an ever-increasing number of early forms and reticulum cells. Thus, while the marrow becomes more and more filled with primitive cells, anemia, leucopenia, or thrombocytopenia may develop in the peripheral blood before a terminal pancytopenia occurs. These changes are quickly and spontaneously reversible unless dosage with the drugs is maintained.

#### IV. SUMMARY

1. The hematologic effects of prolonged administration of pteroyl aspartic acid (R and A), 7-methyl pterioic acid, and 4-amino pteroyl glutamic acid to a group of twenty-five guinea pigs are described in detail.

2. 4-amino PGA was found to be the most active compound in depressing hematopoiesis with the production of immature cell types in the bone marrow, and anemia and/or leucopenia in the peripheral blood.

3. The other antagonists studied produced little hematologic effect when administered alone, but each appeared capable of potentiating the action of minimal dosage of 4-amino PGA when given simultaneously.

4 The marrow changes produced were found to be rapidly and spontaneously reversible unless dosage with the compounds was maintained

# THE EFFECTS OF NITROGEN MUSTARD ON INDUCED ERYTHROBLASTIC HYPERPLASIA IN RABBITS

LEON O JACOBSON, M D, EDNA K MARKS, EVELYN GASION, AND  
MATTHEW H BLOCK, M D \*  
CHICAGO, ILL

## INTRODUCTION

THE successful therapy of various benign or neoplastic disease processes with ionizing radiation or chemicals depends to some extent on the selective sensitivity of certain offending cell types. Occasionally, as in the treatment of Hodgkin's disease with the nitrogen mustards, no unusual sensitivity of the Hodgkin's tissue appears to obtain as compared with the normal hematopoietic marrow<sup>1</sup>. It would appear that a significant clinical effect is related to a comparable destruction or depression of normal and neoplastic hematopoietic processes but with a more rapid recovery in the former. This problem of selective and sustained depression of one cell type as opposed to others in the hematopoietic system is well demonstrated in polycythemia rubra vera where hematologic remissions of several years may be induced by a single dose of radiophosphorus<sup>2</sup> or a single course of nitrogen mustards<sup>3</sup>. A serious limitation in the use of a drug such as the nitrogen mustards (methyl-bis-( $\beta$ -chloroethyl) amine hydrochloride) is related to the fact that in some instances the neoplastic process recurs more rapidly than the recovery of the normal hematopoietic tissue, thus making further adequate therapy dangerous or impossible<sup>4</sup>. Likewise the failure of the skin or other normal structures of the body to recover rapidly enough if at all from the absorption of ionizing radiation primarily directed to underlying or adjacent neoplasm imposes the same restriction. These remarks only serve to indicate the importance of determining ways and means of rendering normal cells of the body temporarily more resistant to the therapeutic agent than the cell population of the neoplasm. It was reported recently by Jacobson and associates<sup>5, 7</sup> that the erythropoietic tissue of the rabbit could be protected from the destruction of  $\gamma$ -radiation if the erythropoietic tissue were previously stimulated by the withdrawal of blood or the administration of phenylhydrazine. Since the biologic effects of ionizing radiations and methyl bis-( $\beta$ -chloroethyl) amine hydrochloride† are so similar, especially as they effect the hematopoietic system,<sup>2, 8</sup> it was decided to determine whether stimulation of erythropoiesis would similarly reduce the degree of destruction produced by the latter chemical agent. This communication relates these studies. Certain studies with  $\gamma$ -radiation carried on simultaneously are included for comparative purposes.

†Hereafter referred to as HN<sub>2</sub> or nitrogen mustard

## MATERIALS AND METHODS

Swift's snuffle free rabbits of uniform age and weight (2½ to 3 kilograms) were used exclusively in this study. The rabbits were divided into four groups (Table I). Group 1 consisted of normal, untreated animals. Group 2 received 3 mg of nitrogen mustard intravenously per kilogram of body weight. Group 3 consisted of rabbits with a phenylhydrazine induced anemia and Group 4 received 3 mg of nitrogen mustard intravenously after an anemia had been induced by phenylhydrazine.

TABLE I. NUMBER OF ANIMALS AND TREATMENT OF VARIOUS GROUPS. HEMATOLOGIC STUDIES

GROUP	PHENYLHYDRAZINE	NITROGEN MUSTARD	NUMBER OF ANIMALS
1	-	-	17
2	-	3 mg/kg	19
3	40 mg	-	10
4	40 mg	3 mg/kg	37

In preliminary experiments it was found that 30 mg of nitrogen mustard per kilogram of body weight was approximately the LD<sub>50</sub>/14 day dose for rabbits. This means that 3 mg per kilogram were sufficient to kill 50 per cent of the rabbits within fourteen days. On the other hand 800 r of x radiation is the LD<sub>50</sub>/30 day dose in our laboratory for this strain of rabbit.<sup>9</sup> No adequate criterion exists on which to base the comparability of these totally different agents. Since the histologic damage in the marrow present at three days was more or less comparable after 3 mg per kilogram of nitrogen mustard or 800 r whole body x irradiation these doses were arbitrarily chosen as equivalent doses for the purposes of this study.

*Technique of Nitrogen Mustard Administration*—Three milligrams of nitrogen mustard per kilogram of body weight were slowly injected into the marginal ear vein of the rabbit immediately after the chemical had been dissolved in physiologic saline. A concentration of 1 mg of the drug per 1 cc of saline was used since this concentration produced no sloughing at the site of injection and did not obliterate the ear vein.

*Technique of X Irradiation*—The x rays administered in these experiments were generated on a 200 kVP machine operating at 15 milliamperes. A 0.5 mm. copper filter and a 1 mm. aluminum filter were used. The half value layer in copper of the filtered beam was 0.98 millimeter. The exposure was measured with a Victoreen condenser meter equipped with a 100 r chamber. Measurements were made in air within a treatment box at a position occupied by the center of the animal's body. The exposure distance was approximately 30.5 inches. Victoreen chambers of 250 r full scale readings were used as monitors.

*Hematologic Studies*—The studies on the peripheral blood taken from the rabbit, using standard techniques included the following:

- Erythrocytes per cubic millimeter
- Hemoglobin in grams per 100 cubic centimeters
- Reticulocytes in per cent of erythrocytes
- Total leucocytes per cubic millimeter
- Differential leucocytes

Studies on blood obtained by cardiocentesis (venous or arterial blood) included

- Platelet counts
- Whole blood clotting time (Lee White)
- Prothrombin determinations
- Heparin tolerance test
- Fibrinogen and calcium determinations

These latter studies on the effect of nitrogen mustard on coagulation of blood have been reported in detail elsewhere<sup>10</sup> and will therefore not be related here.

*Histopathologic Studies*—Histologic studies were made in order to study the blood forming tissues for the proper correlation with the peripheral blood on control animals, animals given HN, only, animals given phenylhydrazine, and animals given phenylhydrazine

followed by nitrogen mustard. Animals were sacrificed at frequent intervals the first nine days and at less frequent intervals thereafter, the tissues were fixed in Zenker formol, embedded in nitrocellulose, cut at 8 or 6  $\mu$ , and stained with hematoxylin eosin azure II (Table II).

\*Two days after phenylhydrazine withdrawal

## RESULTS

*Mortality Studies*—The mortality rate of the animals in Group 4 which received nitrogen mustard and phenylhydrazine was slightly higher than that of the animals of Group 2 which received mustard alone. The survival data indicate that 3 mg of nitrogen mustard injected intravenously kills approximately 50 per cent of the animals in fourteen days. The most critical period appears to be the fourth day. However, no experiments involving large numbers of animals were undertaken to determine the LD<sub>50</sub> dose and, therefore, the 3 mg per kilogram dose can be considered only a tentative and approximate LD<sub>50</sub> value.

### *Hematologic Findings*—

*Erythrocyte Values* The erythrocyte values of the animals in Groups 3 and 4 that received phenylhydrazine were reduced to  $3.3 \times 10^6$  and  $3.5 \times 10^6$  respectively at time 0 (Fig 1). The animals in Group 3 which received phenylhydrazine alone recovered from the anemia in twelve days. The erythrocyte values of the rabbits which received nitrogen mustard after the anemia had been produced (Group 4) continued to fall, reaching a mean minimum value of  $2.8 \times 10^6$  by the third day after the mustard injection, they remained thus depressed through five days, then gradually reached normal values by the twelfth day and remained within normal limits throughout the balance of the experimental period (thirty-five days). Between the sixth and twenty-second day a decrease (circa 15 per cent) in the erythrocyte values occurred in the Group 2 rabbits which received nitrogen mustard alone.

Fig 1—The effect of nitrogen mustard in a single intravenous dose of 3 mg per kilogram on the erythrocyte values of control rabbits and rabbits injected with phenylhydrazine prior to the administration of nitrogen mustard

Fig 2—The effect of nitrogen mustard in a single intravenous dose of 3 mg per kilogram on the hemoglobin values of control rabbits and rabbits injected with phenylhydrazine prior to the administration of nitrogen mustard

*Hemoglobin* The hemoglobin values (Fig 2) of the various groups followed a pattern of response comparable with that described for the erythrocytes

*Reticulocytes* The mean reticulocyte value in the control group (Group 1) varied between 3.2 and 4.2 per cent (Fig 3). The mean reticulocyte value of Groups 3 and 4 rose as a result of the phenylhydrazine administration to 22.6 and 25.4 per cent respectively. The mean reticulocyte value of Group 3 fell rapidly after the phenylhydrazine was discontinued from a maximum of 22.6 to 4.3 per cent and remained essentially in the normal range thereafter. The reticulocyte values of Group 2 which received nitrogen mustard only fell to 0.2 per cent in three days, remained below these values through the fifth day, then gradually rose to the normal range by the ninth day. The reticulocytes of the Group 4 animals, on the other hand, which received mustard after the phenylhydrazine-induced anemia fell abruptly to a minimum of 1.6 per cent by the third day, rose rapidly to 15.6 per cent by the sixth day, then gradually fell to normal by the sixteenth day.

*Leucocytes* The mean leucocyte value of the rabbits which received nitrogen mustard only (Group 2) and those that received mustard after the phenylhydrazine-induced anemia (Group 4) fell to circa 600 per cubic millimeter by the third day (Fig 4). The mean leucocyte value of the animals that received mustard alone (Group 2) continued to fall, reaching a minimum by the sixth day, after which recovery occurred by the ninth day. The leucocyte value of the animals that received nitrogen mustard after the phenylhydrazine-induced anemia (Group 4) gradually rose after the third day to an essentially normal value by the ninth day. An initial rise in the absolute heterophil value above the normal occurred in twenty-four hours in both Groups 2 and 4. In three days the heterophil value fell maximally in Group 4 animals which had received phenylhydrazine and nitrogen mustard, whereas the heterophils in the Group 2 rabbits that received mustard alone reached a minimum value in five days (Fig 5). An abortive rise occurred in both groups on the fifth and sixth days respectively. Both groups returned to normal values by the ninth day and remained essentially normal thereafter.

The absolute number of lymphocytes per cubic millimeter in Groups 2 and 4 paralleled the leucocyte curve closely (Fig 6). Partial recovery had occurred by the ninth day, but complete recovery had not occurred in thirty-five days.

The leucocyte values, including the heterophil and lymphocyte values of the animals with the phenylhydrazine-induced anemia only (Group 3), were slightly depressed by the fifth day, remained thus depressed for circa six days, rose above normal values by the sixteenth day, returned to normal values by the eighteenth day, and remained within normal limits thereafter (Figs 4, 5, and 6).

#### *Histologic Studies —*

*General Observations on Ectopic Blood Formation in Lymphatic Tissue*  
Scattered about the red pulp in the spleen of normal animals a few small islands

Fig. 3—The effect of nitrogen mustard in a single intravenous dose of 3 mg per kilogram on the reticulocyte values of control rabbits and rabbits injected with phenylhydrazine prior to the administration of nitrogen mustard

Fig. 4—The effect of nitrogen mustard in a single intravenous dose of 3 mg per kilogram on the leucocyte values of control rabbits and rabbits injected with phenylhydrazine prior to the administration of nitrogen mustard

Fig 5—The effect of nitrogen mustard in a single intravenous dose of 3 mg per kilogram on the heterophil values of control rabbits injected with phenylhydrazine prior to the administration of nitrogen mustard

Fig 6—The effect of nitrogen mustard in a single intravenous dose of 3 mg per kilogram on the lymphocyte values of control rabbits and rabbits injected with phenylhydrazine prior to the administration of nitrogen mustard

of ectopic erythrocytopoiesis and granulocytopoiesis and an occasional megakaryocyte can be found. At the height of the hyperplastic reaction in the bone marrow (two days after last dose of phenylhydrazine) the amount of this ectopic blood formation in the spleen is increased by at least 100 per cent. These islands gradually decrease in extent over a period of three weeks following the last dose of phenylhydrazine leaving only the normal amount seen in most of the young adult rabbits. Ectopic blood formation in lymphatic tissue elsewhere in the body was not increased appreciably by phenylhydrazine.

*Effect of Nitrogen Mustard on Lymphatic Tissue*—The effect of HN on the dose employed on the lymphatic tissue of the thymus, mesenteric node, and spleen will only be summarized. An intense degeneration of lymphocytes was apparent within the first twenty-four hour period. In fact, six hours after injection of HN<sub>2</sub> lymphocytes were in all stages of disintegration in the lymph nodes, thymus and spleen. By the twelfth hour the degeneration phase was very marked and many macrophages within the nodules and sinuses were filled with particulate debris. Mitosis in lymphocytes was not seen at the twenty-four hour stage. Twenty-four hours after injection the debris-laden phagocytes were almost entirely gone except in the nodules of the spleen, lymph nodes and thymus, and only minimal evidence of continued cell death was evident. At the twenty-four hour stage however, there was a marked heterophil invasion of the lymph node red pulp of the spleen and of the thymus to a lesser degree. Two days after HN<sub>2</sub> injection the lymphocytes of the spleen had practically disappeared except for a few small to medium lymphocytes about the central arterioles of the nodules. The lymphocyte population of the lymph nodes and thymus, though markedly depleted, was so to a lesser degree than that of the spleens. Only a few granulocytes scattered throughout the red pulp were found in these lymphatic structures at this stage. The atrophic phase lasted through the fifth day in these lymphatic tissues. During this period little evidence of regeneration was evident. Only occasional mitoses were seen in the lymphocytes. From the sixth day stage on however the amount of lymphatic tissue in the spleen, lymph node and thymus slowly increased. Mitoses were again more prominent. Not until about the fourteenth day had the histologic reconstitution of lymphatic tissue reached the state which made differentiation from the normal control difficult if not impossible.

The effect of a single injection of nitrogen mustard on ectopic erythrocytopoiesis and granulocytopoiesis in the spleen was difficult to assess in terms of any differential sensitivity or insensitivity because of the small amount of such tissue present in the spleen. There was however a definite decrease in amount of ectopic erythrocytopoiesis and granulocytopoiesis following HN<sub>2</sub> injection.

#### *Bone Marrow*—

(a) *Femoral Bone Marrow of Normal Rabbit (Group 1) and Rabbits With Hyperplastic Marrow (Two Days After Last Phenylhydrazine Injection)*—The femoral marrow of the normal control rabbits (Group 1) used in this study was composed of roughly 60 per cent fat. The balance of the marrow was composed of hematopoietic tissue. The free cells were predominantly granulo and erythrocytopoietic but contained scattered hemocytoblasts, megakaryocytes and

C, Two days after intravenous injection of nitrogen mustard in a dose of 3 mg per kilogram. The space normally occupied by marrow cells is filled with a homogeneous basophilic staining material and the general cellularity is drastically reduced

D, Two days after intravenous injection of nitrogen mustard (3 mg per kilogram) and four days after phenylhydrazine withdrawal. Note that fat spaces are small, the general cellularity is greater than normal, hemocytoblasts and basophilic erythroblasts are abundant and larger than normal

plasma cells. Only relatively few proerythroblasts (basophilic erythroblasts) were found. Mitoses were seen in granulocytes, erythrocytes, and megakaryocytes but were not prominent. In general this active hematopoietic tissue was largely concentrated in the metaphysis and along the endosteum of the entire diaphysis, diminishing toward the center of the diaphysis. The variation in the activity of the normal marrow is shown in Figs 7, 8, and 9.

The femoral marrow of rabbits two days after the last dose of phenylhydrazine (Group 3) was extremely hyperplastic. The hematopoietic marrow occupied from 85 to 95 per cent of the marrow space. Fat was correspondingly decreased. This hyperplastic marrow consisted chiefly of an increase in hemocytoblasts (Downey's myeloblast) and erythroblasts in all stages of maturation. The increase in basophilic erythroblasts was particularly conspicuous. Mitoses in these latter cells were numerous. A modest increase of granulocyte precursors and megakaryocytes was also apparent. The marrow was replete with all stages of transformation of reticular cells to erythroblasts or hemocytoblasts. The marrow hyperplasia reached its maximum two days after withdrawal of phenylhydrazine, paralleling the maximum reticulocyte response in the peripheral blood of this group (Fig. 3). Only gradually over a period of approximately two weeks did the bone marrow return to a normal state of activity after withdrawal of phenylhydrazine. Figs 7, 8, 9, and 10 illustrate the marrow hyperplasia and the lessening of hyperplasia following phenylhydrazine withdrawal. As the erythroblastic hyperplasia in the bone marrow increased the amount of phagocytized iron increased but was evident also in the later intervals after phenylhydrazine withdrawal as the marrow returned to a normal state. As indicated previously, it was at the height of the hyperplasia (two days after last injection of phenylhydrazine) that  $\text{HN}_2$  was given to the rabbits in Group 4. Animals in Group 2 (normal, previously untreated animals) were given  $\text{HN}_2$  simultaneously.

(b) *Effect of  $\text{HN}_2$  on Normal Animals (Group 2) and Animals With Hyperplastic Marrow (Group 1): Period of Degeneration (Zero to Twenty-four Hours Following  $\text{HN}_2$  Injection)* Degeneration (pyknosis, karyorrhexis, and phagocytosis) was apparent in both the granulopoietic and erythropoietic cells as early as six hours after the injection of  $\text{HN}_2$  in both Group 2 (normal animals which received  $\text{HN}_2$ ) and Group 4 (animals which received  $\text{HN}_2$  after a phenylhydrazine induced anemia), but the intensity of this degeneration was increased at the twelve hour stage. Phagocytosis of debris in the marrow was marked at the twelve hour stage. Destruction of megakaryocytes was not as obvious. Some megakaryocytes were in a stage of disintegration in twenty-four hours. The destruction of the more mature erythroblasts was more rapid than the destruction of granulocytes. In twenty-four hours the cells of the marrow of the normal rabbits which received  $\text{HN}_2$  (Group 2) were largely granulopoietic with a few scattered erythroblasts (mostly basophilic), hemocytoblasts and megakaryocytes.

The marrow of the animals whose marrow was hyperplastic when  $\text{HN}_2$  was given (Group 4) contained granulocytes, scattered megakaryocytes and numerous hemocytoblasts and basophilic erythroblasts at this twenty-four hour

stage. Again transformation of reticular cells to erythroblasts and hemocytoblasts was conspicuous. Mitoses were absent in the marrow of the animals which received  $\text{HN}_2$  only (Group 2) in six hours and none were seen at subsequent intervals studied through twenty-four hours. Mitoses were present in all the intervals studied during this destructive phase in the animals which had phenylhydrazine and  $\text{HN}_2$  (Group 4). Mitoses were largely confined to the erythroblasts. They were fewer in number than in the animals that received phenylhydrazine only (Group 3) at a comparable stage, but at least 200 per cent higher than in normal untreated controls (Group 1). Little basophilic-staining "gelatinous" marrow was evident in animals which received  $\text{HN}_2$  only (Group 2) at the twenty-four hour interval. In the phenylhydrazine and  $\text{HN}_2$  animals (Group 4), however, gelatinous marrow as well as dilated vessels were prominent, but the residual cellularity of the latter was much greater.

*Period of Atrophy (Twenty-Four Hours Through Four Days)*—The marrow of animals which received  $\text{HN}_2$  only (Group 2) was almost completely devoid of cells on the second, third, and fourth day intervals and consisted of dilated vessels, some gelatinous material, scattered reticular cells, unidentified mononuclear cells, occasional normal or giant erythroblasts, hemocytoblasts, megakaryocytes, normal or giant myelocytes, plasma cells, and fat cells. Only rarely were mitotic figures observed during this period. This extreme atrophy is illustrated in Figs 7 and 8.

The marrow of animals which received phenylhydrazine and  $\text{HN}_2$  (Group 4) contained a large amount of basophilic-staining gelatinous material, dilated vessels and phagocytized debris. Large islands of hyperplastic marrow were scattered about and were composed almost exclusively of hemocytoblasts and basophilic erythroblasts two days after  $\text{HN}_2$  injection. Other areas contained many of these precursors as well as more mature erythroblasts (Fig 7, D). The amount of residual granulopoietic and megakaryocytopoietic cells was greater than in the marrow of animals at a corresponding interval which received  $\text{HN}_2$  only (Group 2). Many giant myelocytes and erythroblasts were seen scattered about as were clover-leaf patterns in the erythroblasts. There was a questionable increase in the number of plasma cells. The surviving hemocytoblasts and basophilic erythroblasts overwhelmed the other cell types in numbers and many parts of the marrow were composed exclusively of one or the other or both. The size of these cells as compared with similar cells in the marrow of the other groups (1, 2, and 3) is illustrated in Figs 7, 8, and 9. The amount of erythrocytopoietic marrow on the second day was estimated to be at least 200 per cent greater than normal marrow (Group 1), 200 to 300 per cent greater on the third day, and 300 to 400 per cent greater on the fourth day. Mitoses were very prominent in the erythroblasts at these intervals. Granulopoietic and megakaryocytopoietic cells and the mitotic activity of these cells increased slowly at first but were relatively quite prominent by the fourth day. As was evident during the period of destruction (zero to twenty-four hours), transformation of reticular cells to erythroblasts and hemocytoblasts was prominent. In fact, direct transformation of reticular cells to giant myelocytes was becoming decidedly more prominent during the third and fourth days after  $\text{HN}_2$  in this group (Group 4).

*Period of Regeneration (Five Days Through Fourteen Days)*—The marrow of animals which received HN only (Group 2) contained scattered islands of hemocytoblasts and myelocytes and erythroblasts in various stages of maturation on the fifth day after the HN injection and increasingly greater numbers on the sixth and seventh day intervals. On the eighth and ninth day intervals granulocytes and megakaryocytes became more conspicuous. This more or less orderly regeneration continued by the fourteenth day the marrow was essentially similar to that of the untreated controls of Group 1. This period of active regeneration is illustrated in Figs 9 and 10. In the marrow of animals which received phenylhydrazine prior to the HN<sub>2</sub> injection (Group 4), erythroblastic hyperplasia continued to be active far in excess of Group 2 (HN only) or Group 1 (normal) and only gradually returned to a normal state. Whereas evidence of granulo- and megakaryocytopoietic regeneration was conspicuous on the eighth day in the animals that received HN only (Group 2) active regeneration of granulo- and megakaryocytopoietic cells was evident beginning on the fourth day and increased through the ninth day in the animals which received phenylhydrazine and HN<sub>2</sub> (Group 4). The intense erythroblastic proliferation seen at previous intervals continued with only slight diminution during this period.

*Comparison of X ray and HN on Phenylhydrazine Induced Anemia and Hyperplastic Marrow*—In a previous series of papers<sup>9</sup> the effects of 800 r whole body x irradiation on the peripheral blood and bone marrow of normal rabbits and rabbits with a phenylhydrazine induced anemia have been described in detail. The conditions of these experiments were identical with those of the experiments described in this paper except that a physical agent (800 r x ray) was given instead of a chemical agent (HN). Although the main findings in the x ray experiments are essentially the same as in the HN experiment, certain gross differences make a brief comparison worthwhile. As was demonstrated in Figs 1 and 2 nitrogen mustard alone produced an anemia which was on the borderline of significance some two weeks or more after the HN administration. Animals which had a phenylhydrazine induced regenerative anemia developed further anemia within the first five days after HN<sub>2</sub> administration. A dose of 800 r whole body x irradiation produced an anemia in rabbits which reached a maximum on about the fourteenth day (Fig. 11). On the other hand, the administration of 800 r to animals with a phenylhydrazine induced regenerative anemia produced neither an early nor a latent anemia and recovery proceeded rapidly but not as rapidly as occurred in the phenylhydrazine and HN animals (Fig. 12). This difference in the early effect of phenylhydrazine followed by HN on the one hand and phenylhydrazine followed by x irradiation on the other was not apparent in the bone marrow since in neither was erythrocytopoiesis seriously interrupted.

Nitrogen mustard alone and x ray alone produced a comparable degree of cellular depletion in the marrow of normal rabbits but bone marrow recovery was more rapid in the HN series than in the x ray series (Compare Fig 9, C with Fig 13 1). Similarly the degree of cellular depletion in the marrow

 B, Six days after 800 r whole body x-irradiation and eight days after last injection of phenylhydrazine. This shows the marked hyperplasia which is found scattered about in the marrow.

of animals which received both phenylhydrazine and HN was comparable with the cellular depletion in the bone marrow of animals which received both phenylhydrazine and x ray in the early stages (one day after HN or x ray respectively). However, the marrow of the phenylhydrazine HN<sub>2</sub> animals underwent a more rapid regeneration than that of the phenylhydrazine x ray animals.

#### DISCUSSION

It is interesting that the production of a regenerative anemia with phenylhydrazine or bleeding protects against the usual latent radiation induced anemia in rabbits by virtue of the survival of sufficient hematopoietic tissue to insure an almost immediate hyperplastic reaction.<sup>6,7</sup> Stimulation of erythropoiesis likewise protects the marrow from the destruction regularly produced in rabbits by the chemical agent methyl bis ( $\beta$  chloroethyl) amine hydrochloride. The degree of destruction of the marrow which regularly follows the administration of a single intravenous dose of 3 mg of HN<sub>2</sub> or 800 r whole body x irradiation is comparable from the histologic point of view through the fourth day after exposure to either of these agents. A significant anemia follows the latter (800 r) which reaches its maximum on the fourteenth day after exposure whereas an anemia of only borderline significance is apparent after the former (HN). As is evident in the data presented, the histologic recovery of the marrow from intoxication with HN<sub>2</sub> only is so rapid that the brief but complete cessation of erythropoiesis is essentially masked.

The further fall of the erythrocyte values and hemoglobin, after HN<sub>2</sub> injection in animals already made anemic with phenylhydrazine (Group 4), is very likely due to continued hemolysis as a result of the combination of phenylhydrazine and HN. No evidence of significant hemolysis was apparent during this initial period in animals which received HN<sub>2</sub> only (Group 2), nor did further significant anemia develop in animals which had received only phenylhydrazine (Group 3). In previous experiments in which phenylhydrazine administration was followed by 800 r whole body x irradiation, no further anemia developed immediately following x ray (one to five days). It is therefore suggested that phenylhydrazine plus HN exerts a synergistic hemolytic effect on circulating erythrocytes. After reaching a minimum of less than  $2.8 \times 10^6$  per cubic millimeter, the erythrocytes of the animals which had phenylhydrazine and HN<sub>2</sub> rose so rapidly that a normal value was evident as rapidly as in the animals which received phenylhydrazine only (Group 3) and before the value of the group which received HN only had fallen to its lowest point. The histologic findings indicate that a sufficient number of erythroblasts and hemocytoblasts survive the insult of the HN<sub>2</sub> in the latter group to immediately carry on normal erythropoietic activity and subsequently proceed to an intense hyperplasia and rapid recovery. In the group which received HN<sub>2</sub> only (Group 2) on the other hand erythropoietic tissue was essentially destroyed and compensatory hyperplasia and recovery were comparatively slow. In previous reports<sup>2,3</sup> it was pointed out that whereas mitotic activity stopped in the bone marrow of normal rabbits during the first twenty four hours after 800 r whole

body  $\gamma$ -radiation, mitotic activity in the marrow of animals with an erythroblastic hyperplasia continued at a normal or greater than normal rate after this dose of  $\gamma$ -radiation. The findings in the present study with  $\text{HN}_2$  are identical in this respect with the  $\gamma$ -ray studies. The free cells of the hematopoietic marrow which survive the insult of  $\text{HN}_2$  are largely hemocytoblasts and basophilic erythroblasts. This fact is good evidence for support of the concept that the less mature cells are more resistant than more mature cells of the erythroblast series. If the more mature forms were less sensitive or of equal sensitivity to their precursors, one would expect to find a proportionate number of various maturation phases surviving at the early intervals after  $\text{HN}_2$  particularly. In other words, one would expect surviving erythroblasts in each maturation phase to be in a proportion or ratio to one another more nearly like that of the hyperplastic marrow at the time of  $\text{HN}_2$  administration if the sensitivity were equal. If the sensitivity of various maturation phases differs, then a predominance of the more resistant forms would be found in the early intervals after exposure to the noxious agent. Since the surviving free cells were predominantly basophilic erythroblasts and hemocytoblasts, one must conclude that under the conditions of this experiment these immature cells are less sensitive to  $\text{HN}_2$  than the more mature forms in the marrow. It is further apparent that reticular cells not only retain their function of transformation to the free precursors of the marrow but also that the stimulation provided by the phenylhydrazine administration has probably increased this transformation to an extent which is significant in the development of the rapid hyperplasia and recovery.

Of interest is the fact that after  $\text{HN}_2$  only (Group 2), granulocytopoietic, megakaryocytopoietic, and erythrocytopoietic tissue in the marrow is more completely destroyed than lymphatic tissue in the spleen, lymph node, and thymus. Recovery of the bone marrow and return of the circulating granulocytes, erythrocytes, and platelets to normal values, however, precede the complete histologic recovery of lymphatic tissue and the return of lymphocyte values of the peripheral blood to normal.

It is of even greater interest that recovery of the bone marrow from the insult of  $\text{HN}_2$  (3 mg per kilogram) is more rapid than the recovery from  $\gamma$ -ray (800 r) even though the degree of destruction and atrophy is entirely comparable during the early phases (one to four days). If one assumes that this difference in recovery rate is on the basis of the fact that  $\text{HN}_2$  has a more selective action than total body  $\gamma$ -radiation, then one is assuming that irradiation can produce an indirect suppression of marrow hematopoiesis or that irradiation produces greater effects on reticular cells which retard heteroplastic blood formation than does  $\text{HN}_2$ . The latter possibility seems more likely.

Significant regeneration of granulocytopoiesis and megakaryocytopoiesis in the marrow of animals which received phenylhydrazine and  $\text{HN}_2$  (Group 4) occurred at a distinctly earlier stage than in the animals which received  $\text{HN}_2$  only (Group 2). This regeneration occurs homoplastically from a few surviving myelocytes and heteroplastically from reticular cells and hemocytoblasts. This

histologic evidence of in earlier regeneration of granulocytes in the animals which received both phenylhydrazine and HN (Group 4) correlates well with the studies on the peripheral blood as illustrated in Fig 5

The degree of destruction and time required for recovery of lymphatic tissue after the administration of HN only (Group 2) appear to be entirely comparable with the destruction and recovery of lymphatic tissue after phenylhydrazine and HN (Group 4)

These observations suggest that the production of a hyperplastic marrow prior to the use of a irradiation or HN might be useful as a means of protecting the normal hematopoietic tissue when these agents are used in therapy of such neoplastic disorders as the lymphomas. The fact that the persistent hyperplasia after HN<sub>2</sub> or a ray is dependent in part on heteroplastic formation of the free marrow precursors from reticular cells suggests that venesection almost immediately before HN or a ray administration might effect a more rapid regeneration of the marrow from the destructive action of these agents. Phenylhydrazine administration would not seem particularly desirable under these conditions but perhaps adequate and controlled stimulation could be achieved by exposure to a low atmosphere of oxygen or venesection

#### SUMMARY

The effect of intravenous administration of a nitrogen mustard (methyl bis ( $\beta$  chloroethyl) amine hydrochloride) in a dose of 3 mg per kilogram was studied in normal rabbits and in rabbits with an anemia and erythroblastic hyperplasia produced by phenylhydrazine hydrochloride. Controls consisted of normal untreated rabbits and rabbits given phenylhydrazine alone. Histopathologic studies were made of animals from each group which were sacrificed at frequent intervals. Hematologic observations likewise were made at frequent intervals.

A single intravenous injection of HN produced only a modest anemia of questionable significance in normal rabbits which was maximal at approximately three weeks. Leucopenia and a marked reduction in the number of circulating reticulocytes also were produced. A rapid destruction of hematopoietic tissue in the spleen, thymus, lymph nodes and bone marrow occurred within twenty-four hours. The virtual absence of mitoses during the first twenty-four hours after the injection of HN was striking; in stages up to the fifth day mitoses were seen only rarely. During the second, third and fourth days after HN the bone marrow was practically devoid of cells. Only a few scattered hemierythroblasts, erythroblasts, plasma cells and giant myelocytes were seen. Erythropoietic, granulopoietic and megakaryocytopoietic recovery in the group occurred more or less simultaneously. Regeneration evidence of which was first apparent on the fifth day progressed to an essentially normal marrow by the tenth day. Lymphatic tissue though severely damaged by HN<sub>2</sub> was less atrophic than the bone marrow but regeneration was slower and reconstruction was not apparent until after the fourteenth day. The appearance of leucopenia and reticulocytopenia correlated closely with the hematopoietic destruction, atrophy, and eventual reconstitution. The anemia which developed was modest, probably because of the rapid reconstitution of erythropoiesis in the marrow.

Phenylhydrazine alone in a dose totaling 40 mg produced an approximate 50 per cent reduction in erythrocyte and hemoglobin values with a simultaneous reticulocytosis and erythroblastic hyperplasia in the bone marrow. These hematologic values of the peripheral blood returned to normal by the twelfth day after phenylhydrazine withdrawal, but increased erythrocytopoiesis in the marrow persisted for about two weeks.

Animals to which 3 mg per kilogram of  $\text{HN}_2$  were given after an anemia and an erythroblastic hyperplasia of the bone marrow had been produced by phenylhydrazine developed further anemia within the first five days after the  $\text{HN}_2$  administration, but recovery was complete by the twelfth day. *In fact, the hemoglobin and erythrocyte values of this group returned to normal as quickly as in animals which were given phenylhydrazine only.* The reticulocyte value of the animals which received phenylhydrazine prior to the  $\text{HN}_2$  fell from a value of circa 25 per cent to 2 per cent by the third day after  $\text{HN}_2$ , but rose rapidly to 15 per cent by the sixth day and slowly fell to normal by about the fourteenth day. The marrow of these animals was extremely hyperplastic at the time at which the  $\text{HN}_2$  was given. The usual evidence of destruction followed the  $\text{HN}_2$  administration, but large numbers of cells in the bone marrow survived as compared with animals which were given  $\text{HN}_2$  only. *The surviving cells were predominantly basophilic erythroblasts and hemocytoblasts and were present in an appreciably larger number than normally present in controls.* Heteroplastic regeneration from reticular cells was conspicuous throughout the first six days after  $\text{HN}_2$  administration. Mitoses were present in large numbers even in the early stages after the  $\text{HN}_2$  administration and increased rapidly to a maximum by about the fourth day. The more mature forms of the erythroblast series were progressively increased in the second, third, fourth, fifth, and sixth day stages after  $\text{HN}_2$ . A significant recovery of granulopoiesis and megakaryocytopoiesis in the marrow was apparent beginning on the fourth and fifth day after  $\text{HN}_2$  in these animals. Hyperplasia in the marrow of these animals continued for about two weeks.

The fact that further anemia followed immediately after  $\text{HN}_2$  administration in the group of animals which received phenylhydrazine and  $\text{HN}_2$  cannot be interpreted as related to bone marrow destruction since a normal or greater than normal amount of erythrocytopoiesis was present during this period as evidenced by the histologic studies and the increased number of reticulocytes in the peripheral blood. It seems likely that this was a hemolytic effect due to a synergistic action of phenylhydrazine and  $\text{HN}_2$  under the conditions of this experiment.

The initial effects of 800 r whole body x-radiation on the hematopoietic system of normal animals and animals with a regenerative anemia and hyperplastic bone marrow are largely comparable with the initial effects produced by  $\text{HN}_2$  insofar as the destruction of the bone marrow is concerned. The latter agent ( $\text{HN}_2$ ), however, apparently intensifies the hemolytic action of phenylhydrazine on circulating erythrocytes, whereas x-ray does not. Regeneration of the bone marrow after  $\text{HN}_2$  alone or phenylhydrazine plus  $\text{HN}_2$  is more rapid than after x-ray alone or after phenylhydrazine plus x-ray.

It is suggested that stimulation of the hematopoietic system of the human being with disorders such as lymphomata might be feasible as a means of partial protection of or hastening the recovery of normal hematopoiesis from such destructive therapeutic agents as x ray or HN

#### CONCLUSIONS

1 In normal rabbits the intravenous injection of nitrogen mustard (methyl bis ( $\beta$  chloroethyl) amine hydrochloride) in a dose of 3 mg per kilogram body weight produces a modest anemia and a severe leucopenia and reticulocytopenia

2 Nitrogen mustard in a dose of 3 mg per kilogram when given to animals in which an anemia, reticulocytosis and hyperplastic marrow are already present by virtue of prior phenylhydrazine hydrochloride administration produces

(a) Further anemia within the first five days after the HN administration which is presumed to be due to an apparent synergistic hemolytic action of phenylhydrazine and HN on the circulating erythrocytes. No latent anemia is produced under these circumstances such as is produced by  $\text{HN}_2$  alone. Recovery from the anemia induced by phenylhydrazine and HN is as rapid as from the anemia produced by phenylhydrazine alone and faster than the recovery from the modest anemia produced by HN alone

(b) A leucopenia comparable with that produced by HN only. Recovery from the leucopenia induced by phenylhydrazine and HN is more rapid than the recovery after HN only

(c) A reduction of the reticulocyte value from circa 25 per cent to the normal value by the third day followed by immediate recurrence of the reticulocytosis.  $\text{HN}_2$  alone, on the other hand, produces a marked reduction below normal values with a gradual return to a normal value

3 In the normal rabbit  $\text{HN}_2$  alone produces a marked depletion of lymphatic tissue recovery from which requires more than two weeks. Bone marrow becomes extremely atrophic but regeneration begins by the fifth day. Mitotic activity which is virtually absent in these tissues for the first twenty four to forty eight hours after HN administration is only gradually resumed

In rabbits with an anemia, reticulocytosis and hyperplastic marrow induced by phenylhydrazine hydrochloride the intravenous injection of 3 mg of nitrogen mustard per kilogram of body weight produces the usual evidence of destructive effects in the hematopoietic tissue but large numbers of hemocytoblasts and erythroblasts in the bone marrow especially survive which are immediately capable of proliferation. Mitotic activity continues at a normal or greater than normal rate under these conditions

4 The production of a hyperplastic (erythroblastic) marrow protects the marrow from the destructive effects of HN by virtue of increasing the population of hemocytoblasts and basophilic erythroblasts which are less sensitive to this chemical agent than the more mature derivatives of these cells. Heteroplastic regeneration from reticular cells likewise probably plays a significant role in the rapidity of recovery

5 More immature forms of the erythroblast series and hemocytoblasts are less sensitive to either a physical agent (X-ray) or a chemical agent (HN<sub>2</sub>) than are the more mature forms of the same maturation series

6 Prior stimulation of hematopoiesis in the human being as a means of partially protecting the hematopoietic tissue from such therapeutic agents as nitrogen mustard or irradiation may be feasible

The authors wish to thank Lorena Allen, Jessie Brown, and Robert Hardy for their technical assistance. The photomicrographs were made by Jean M. Crunelle of the Photography Department of Billings Hospital of the University of Chicago.

## DIETARY AND HORMONAL INFLUENCES IN EXPERIMENTAL UREMIA

GEORGES MASSON, M D, A C CORCORAN M D, AND IRVINE H PAGE, M D  
CLEVELAND, OHIO

THE mechanism of uremia has not been defined in precise chemical terms. Still, on general grounds treatment is directed toward control of azotemia and hyperpotassemia. The most obvious means to these ends are dietary and consist in restriction of exogenous protein and potassium and in the administration of high caloric diets consisting of carbohydrate and fat. Such diets slow the rate of endogenous protein catabolism and also inhibit the release of potassium from the cell stores. The advantages of such a regime supplemented with blood transfusion and by antibiotics has been demonstrated recently by Boist.<sup>1</sup>

In addition theoretical and experimental considerations suggest that advantage might be taken of the actions of certain hormones. Thus desoxy corticosterone acetate (DCA) prolongs life when given to animals prior to bilateral nephrectomy,<sup>2,3</sup> and an antiuremic property probably dependent on increased protein anabolism<sup>4</sup> has been ascribed to testosterone.<sup>5</sup> Lastly, insulin since it decreases potassemia and tends to slow the conversion of protein to glucose, might be of some value.<sup>6</sup>

While the general considerations underlying the treatment of uremia by high caloric nonprotein diets are entirely clear and valid a survey of the field indicated a dearth of critically controlled experimental comparisons in significantly large groups of animals. The present study was therefore designed for the evaluation of the comparative effects of isocaloric diets of protein fat and carbohydrate on the survival time of rats subjected to bilateral nephrectomy and of the effect of hormones under controlled conditions of diet and fluid intake.

The first series of observations were made in normal animals and the second in animals in which infection was simulated by formation of turpentine abscesses. The distinction is important since infection with its acceleration of protein catabolism and discharge of protein metal oxides and potassium into the blood is a frequent complication in uremic patients.

### SERIES I NORMAL ANIMALS, BILATERALLY NEPHRECTOMIZED EFFECTS OF DIET AND HORMONES

(a) *Method*—The animals used were male albino rats weighing 200 to 350 grams. The experimental groups were selected for equal weights in each because age is a determinant of survival after nephrectomy.<sup>7,10</sup> Nephrectomy was done in two stages at intervals of

From the Research Division and the Frank E. Bunts Institute of the Cleveland Clinic Foundation.

This investigation was supported in part by a research grant from the Division of Research Grants and Fellowships, National Institutes of Health, U. S. Public Health Service.

Received for publication March 3, 1949.

seven days Treatment was begun immediately after removal of the second kidney Effects of each of the diets and of concurrent hormonal treatments were tested separately and, in each of the comparative series, a reference group given either protein or carbohydrate was used The carbohydrate and fat diets were prepared in the manner of Reinecke, Ball, and Samuels<sup>11</sup> but without salt mixture and vitamins, the protein diet used was isocaloric and consisted of egg albumin, casein, and a protein digest The diets were given twice daily by gavage in a daily volume of 3 cc per 100 sq cm of body surface In each of the diets, this volume contained 10 calories Body surface was calculated from the formula  $S = KW^{.66}$  where  $S$  is body surface in square centimeters,  $K$  a constant of 9.1, and  $W$  the weight in grams The potassium contents of the diets were measured by the method of Shohl and Bennett<sup>12</sup> and found to be 1.1, 0.29, and 0.84 mg per cubic centimeter respectively for protein, fat, and carbohydrate rations

Steroid hormones were given subcutaneously in daily doses of 10 mg of 0.4 cc hydro alcoholic suspension Blood samples of 0.2 cc were taken from the tail at thirty and forty eight hours after nephrectomy for determination of urea nitrogen by the method of Archibald<sup>13</sup>

(b) *Results*—The effects of treatment on survival time and on the level of blood urea nitrogen are summarized in Table I

Inspection of the data shows first that survival decreases as azotemia increases Second, comparison of Groups 1 (fasting) and 2 (protein-fed) shows that fasting, contrary to some impressions, is as deleterious as protein feeding Third, comparisons of Groups 3 and 7, 8 and 12, and 13 and 17 indicate that survival is longer and azotemia less in carbohydrate- and fat-fed than in protein-fed animals Last, survival is somewhat shorter and azotemia greater in animals given fat instead of carbohydrate, a difference which can be attributed to the diarrhea caused by a pure fat diet

Treatment with hormones, singly or in combination, had no significant effect on survival and azotemia in animals fed either protein or fat However, in animals fed only carbohydrate, blood urea nitrogen levels at thirty hours after nephrectomy were somewhat lower during treatment with DCA (Group 9) and testosterone (Group 10) than in the controls The difference was even greater in animals given combined treatment of the two steroids (Group 11) Mean survival time was somewhat prolonged by hormonal treatment To confirm this observation, the experiments were repeated on four groups (8a, 9a, 10a, and 11a) of ten animals each, which were treated exactly as were animals in Groups 8, 9, 10, and 11 In these groups blood urea nitrogen concentrations at thirty hours after nephrectomy were as follows: group 8a, 129 (range, 94 to 150) mg per 100 cc, group 9a, 92 (71 to 100), group 10a, 112 (78 to 150), and group 11a, 70 (57 to 87) Thus, these observations establish the facts that testosterone and, curiously, DCA both tend to suppress azotemia in carbohydrate-fed, nephrectomized animals

#### SERIES II ANIMALS WITH SIMULATED INFECTION (TURPENTINE ABSCESS)

The purpose of this series of experiments was to test the effects of carbohydrate feeding as such and of the same diet when combined with steroid hormones and insulin under conditions of catabolic stress

TABLE I MEAN SURVIVAL TIME AND BLOOD UREA NITROGEN LEVEL IN BILATERALLY NEPHRECTOMIZED RATS

GROUP	DIET	TREATMENT	NUMBER OF RATS	SURVIVAL TIME (HF)	BLOOD UREA NITROGEN (MG %)	
					AT 30 HF	AT 48 HF
1	--	--	16	38 (41 64)	297 (200-75)	388 (337-430)
2	Protein	--	10	60 (44 82)	154 (140 192)	300 (240 320)

4	Protein	Testosterone	10	44 (34 57)	263 (216 294)	543 (460 605)
5	Protein	DCA and testosterone	10	44 (31 57)	240 (194 30)	461 (400 512)
6	Protein	--	10	52 (38 60)	281 (253 312)	510 (460 562)
7	Carbohydrate	--	10	86 (60 108)	167 (140 185)	237 (206 262)
8	Carbohydrate	DCA	20	93 (59 128)	112 (74 152)	134 (80 157)
9	Carbohydrate	Testosterone	9	127 (83 179)	89 (69 106)	131 (103 146)
10	Carbohydrate	DCA and testosterone	9	118 (60 156)	100 (73 152)	130 (95 173)
11	Carbohydrate	--	9	116 (70 156)	60 (46 88)	90 (67 110)
12	Protein	--	9	53 (44 68)	219 (162 284)	--
13	Fat	DCA	20	77 (52 98)	175 (150 200)	208 (218 322)
14	Fat	Testosterone	18	76 (50 100)	167 (112 28)	210 (172 284)
15	Fat	DCA and testosterone	18	74 (57 103)	173 (158 193)	208 (282 343)
16	Fat	--	18	75 (39 100)	166 (147 191)	247 (238 250)
17	Protein	--	10	30 (41 53)	39 (167 285)	455 (438-468)

(a) *Method*—Thirty rats were divided into five groups. Following a two stage nephrectomy, all the animals were fed a high carbohydrate diet by stomach tube. Supplementary treatment was started as indicated in Table II and turpentine was injected once subcutaneously into the prepectoral region in a dose of 0.5 cc in four of the groups. Prothamine zinc insulin was given in a dose of 1 unit daily in two groups and the steroid hormones were given in doses of 5 mg twice a day in another two groups. Blood urea nitrogen was determined thirty and forty eight hours after nephrectomy. At forty eight hours the animals were anesthetized and blood was collected for potassium determination.<sup>18</sup> Data are collected in Table II.

TABLE II. INFLUENCE OF INSULIN AND STEROID HORMONES ON THE MORTALITY AND BLOOD UREA NITROGEN OF NEPHRECTOMIZED RATS INJECTED WITH TURPENTINE AND FED CARBOHYDRATE

TREATMENT	BLOOD UREA NITROGEN (MG PER 100 CC)		SERUM POTASSIUM (MG PER 100 CC)	NUMBER OF DEATHS AT 48 HR
	AT 30 HR	AT 48 HR		
--	111 (74-142)	156 (125-186)	35	0
Turpentine	156 (127-172)	242 (202-275)	45	1
Turpentine and insulin	182 (157-204)	241 (210-280)	42	1
Turpentine and insulin and DCA and testosterone	179 (167-215)	252 (217-277)	43	3
Turpentine and DCA and testosterone	174 (147-202)	238 (210-272)	46	1

(b) *Results*—The increased azotemia and mortality at forty-eight hours consequent on turpentine abscesses were not influenced by hormonal treatment. Furthermore, animals which were not given turpentine (group 1) remained in good condition (temperature, muscular tone, reactivity), while those with turpentine abscesses were apathetic, asthenic, cold, and had buccal hemorrhages. Morbidity and mortality corresponded roughly with the serum potassium contents. Therefore, under the present experimental conditions, neither steroid hormones nor insulin proved to be of any advantage over feeding a high carbohydrate high caloric diet alone, and the diet did not prevent the deleterious effects of simulated infection.

#### DISCUSSION

In earlier studies, Lyon<sup>1</sup> and Lyon, Shatton, and Ivy<sup>16</sup> showed that the mean survival time of nephrectomized dogs fed on bread, milk, and lactose was 137.6 hours as compared with 105.6 hours for dogs fed on a meat diet. In contrast Wintermiz, Mylon, Waters, and Katzenstem<sup>17</sup> reported no beneficial effects of a carbohydrate feeding to nephrectomized dogs, taking as criteria of benefit blood urea and survival time. Their animals, however, were treated with fluids and alkalis, in order to maintain normal blood volume and alkaline reserve. There is no proof that such procedures are of real benefit, while it is well recognized that anuric animals do not withstand excess fluid or electrolytes. Such treatment might therefore obscure any effect of diet. The harmful effects of water have been demonstrated by Beigman and Drury<sup>9</sup> and by Burne, Eversole, and Gaunt.<sup>10</sup> Beigman and Drury<sup>9</sup> also showed that preoperative fasting does not influence significantly the survival time, and that meat is definitely toxic while glucose improves the condition of the rats.

They obtained a definite prolongation of survival time by daily administration of as little as 5 cc of a 20 per cent glucose solution. Since this represents only 45 calories in contrast to the average daily intake of about 50 calories given in our experiments it seems carbohydrate is beneficial even though it does not meet the caloric requirements. Mylon and Goldstein<sup>18</sup> found also that preoperative feeding of a carbohydrate diet to dogs subjected to nephrectomy or renal artery ligation prolongs the survival time and delays the blood nonprotein nitrogen rise which occurs with preoperative meat feeding. The toxic effects of protein in experimental uremia produced by ligation of the vena cava above the renal veins have also been demonstrated by Addis and Lew.<sup>19</sup> More recently Addis<sup>20</sup> showed that protein diet has a deleterious influence in animals subjected to sudden loss of three fourths of the renal tissue.

These results and our own confirm the well established principles that high caloric carbohydrate and fat diets have an inhibitory effect on protein catabolism which in turn delays or diminishes uremia.

DCA given preoperatively has been shown to prolong the survival time of nephrectomized rats and mice.<sup>2, 3, 4</sup> However Winkler, Smith and Hoff<sup>21</sup> were unable to demonstrate any beneficial effect from DCA or adrenocortical extract given postoperatively to dogs made uraemic by ureteral ligation. They suggested that the probable protective mechanism of DCA pretreatment lies in its depletion of the body stores of potassium. That this may be so is shown by the increased survival of nephrectomized animals preoperatively depleted of potassium by diet alone.<sup>2, 3</sup> Rodbard<sup>5</sup> has confirmed the fact that the life of nephrectomized dogs can be prolonged by preoperative treatment with DCA. He also observed some beneficial effect from DCA given postoperatively which was unrelated to the level of serum potassium. Our data also indicate a slight effect on survival and a more definite decrease in azotemia from post operative treatment with DCA and testosterone in rats fed only on carbohydrate and thus confirm Selye and Nielsen.<sup>4</sup> As concerns DCA, Selye<sup>6</sup> has also observed a beneficial effect of testosterone given pre and postoperatively to nephrectomized mice. Since the effect cannot be ascribed to renal potassium depletion,<sup>5</sup> it must depend on the protein anabolic property of the steroid.

Our data emphasize the importance of diet in experiments on uraemic animals. They also suggest that some of the contradictory results of post operative treatment with hormones as to survival time and blood nonprotein nitrogen can be attributed to differences in the diets on which the different groups of animals were maintained in the several laboratories. While the dietary data form a basis for clinical treatment the hormonal effects obtained during treatment with massive doses can hardly serve as recommendations for a clinical trial.

Finally although high carbohydrate and fat diets can prolong survival and diminish the rate of increase of azotemia in nephrectomized animals they are ineffective in countering the protein catabolic impulse caused by turpentine abscess. This is a confirmation of Boist's observation<sup>1</sup> that the effective

ness of dietary treatment depends on the control of infection. These and other aspects of the treatment of uremia have been reviewed editorially<sup>6</sup> and the recommendation has been made that Boist's protein-free regime has more theoretical merit than the low protein ration of Black and Stanbury.<sup>27</sup>

#### SUMMARY

Effects of fasting and various high isocaloric diets consisting of carbohydrate, fat, or protein were tested in bilaterally nephrectomized rats.

Fasting is not more advantageous than protein feeding. Carbohydrate and fat are definitely more beneficial in terms of survival and azotemia than protein diet and, of the two, carbohydrate feeding is better tolerated.

Desoxycorticosterone acetate and testosterone alone or in combination were somewhat effective only in rats fed a carbohydrate diet, the most significant change was a decrease of azotemia following combined treatment with both steroids.

High carbohydrate diet alone or in combination with DCA, testosterone, or insulin did not influence the course of uremia in nephrectomized rats subjected to turpentine abscess.

The authors are indebted to Dr. E. Henderson of the Schering Corporation, Bloomfield, N. J., for the steroids used in this investigation. The valuable technical assistance of Lucille Hunter is gratefully acknowledged.

## EFFECT OF AN ACID AND ALKALINE SALT ON THE URINARY EXCRETION OF IRON

ADELAIDE P. BARER, PH.D., AND WILLIS M. FOWLER, M.D.  
IOWA CITY, IOWA

MUCH work has been done on the absorption, utilization, and excretion of iron, and although new information is accumulating there is still confusion in respect to many of the metabolic processes concerned. The amount of iron ordinarily excreted in the urine is small,<sup>1-3</sup> although a study on 100 men and 100 women<sup>4</sup> showed a greater excretion than had many of the previous investigations and also revealed a higher urinary iron excretion in women than in men, 0.489 mg. per day as compared with 0.395 milligram. The urinary iron excretion was found to be fairly constant in the same individual from day to day. There is a marked and prompt increase in the urinary iron excretion following intravenous administration of iron<sup>5-6</sup> although no appreciable increase occurs in the iron content of the feces under these circumstances. Little, Power, and Wakefield<sup>5</sup> thought that this was due to the marked and rapid increase in the serum iron concentration, and that it probably did not occur with normal iron absorption from the intestine. Our previous investigation<sup>4</sup> did not show an increase in the urinary iron excretion when large amounts of iron were given by mouth or with intramuscular iron injections given to the point of tolerance. Although previous extensive studies have failed to clarify all phases of iron metabolism, it appears that iron is absorbed more readily when in a ferrous state than as a ferric salt, that an acid reaction in the stomach favors the absorption of dietary iron, and that absorption is regulated by the body need.<sup>7-8</sup>

The present study was undertaken in order to ascertain the effects of an acid and an alkaline salt on the urinary excretion of iron. It has been demonstrated that an acid media in the stomach favors absorption of dietary iron, but further effects of alkalization, such as is commonly employed in the treatment of peptic ulcer, on iron metabolism have not been studied adequately.

### PROCEDURE

This study was carried out on twenty-one persons (11 men and 10 women). Ten of the subjects had peptic ulcers. The remainder were patients on the medical wards who had no disease which would interfere with intestinal absorption and who were not passing blood from the urinary or gastrointestinal tract. The subjects continued with their ordinary routine and with their hospital diets—the iron contents of which were calculated from the table of Waller.<sup>10</sup> No patients were receiving or had received iron medication so that no abnormal or sudden increase in the serum iron was induced. No medications were given aside from the alkaline or acid salts. Fluids were allowed as desired at all times.

From the Department of Medicine, State University of Iowa Medical School.  
Received for publication April 29, 1949.

During the control period, twenty four hour urine specimens were collected for three days in glass containers which were especially cleaned to prevent iron contamination. Creatinine determinations were done each day to check the completeness of collection. Iron determinations were done in triplicate on aliquots of the pooled three day specimens using the method of Reis and Chakmakjian.<sup>11</sup>

Following a control period of three days the patient was given 1 Gm. of sodium bicarbonate six times a day, and twenty four hour urine specimens were collected for a three day period and handled in the same manner as in the control period. After an interval of one day during which the specimens were discarded eleven of the subjects received 1 Gm. of ammonium chloride four times a day for a three day period. Specimens were handled as before.

Hemoglobin determinations were made at the beginning of each three day period by the acid hematin method using a photoelectric colorimeter. A hematocrit was done at the same time by the Van Allen method.<sup>1</sup> All values were well within the range of normal, and the periods of observation were of too short duration to note any significant changes in hemoglobin or hematocrit values.

## RESULTS

A summary of the significant findings is presented in Table I in which the data for the male and female patients are presented separately.

On subjecting these data to analysis the results are found to be statistically significant. Applying the *t* test to the relationship between the control period and the period in which soda bicarbonate was administered we find that  $t = 3.97$  with 40 degrees of freedom which indicates a highly significant difference. Similarly, in comparing the difference between the control period and the period of ammonium chloride administration we find  $t = 3.41$  with 40 degrees of freedom again a statistically significant difference.

*Administration of Sodium Bicarbonate*—It will be noted in the table that without exception, after the administration of this alkaline salt there was a drop in the daily urinary non excretion varying from 04 mg (Patient 8) to 28 mg (Patient 18) per day, or from 15 per cent (Patient 8) to 54 per cent (Patient 12). Analysis of these figures revealed the changes to be statistically significant. The soda bicarbonate produced no consistent or significant change in the amount or specific gravity of the urine. The average daily urinary non excretion for men during the control period was 35 mg and during the period of alkalinization was 22 mg or a decrease of 37 per cent. In the women the average excretion fell from 38 to 23 mg per day or a decrease of 39 per cent.

*Administration of Ammonium Chloride*—This medication was not given to those patients with peptic ulcer but was subsequently administered to the eleven other patients. The urinary non excretion was increased in every case, not only above the period during which soda bicarbonate was given but above the control period as well. In two cases the increase was slight, being 01 and 02 mg respectively, whereas in Patient 18 the increase was 60 milligram. Analysis again revealed these changes to be of statistical significance. In the men the average increase above the control level was 40 per cent, and in the women, 86 per cent. The period of ammonium chloride administration was associated with an increased urine volume in all female patients but in only three of the men.

#### DISCUSSION

These data show that the administration of an alkaline salt diminishes the amount of non excreted in the urine, whereas the administration of an acid salt causes a marked increase when given to patients on a normal dietary non intake. Previous work<sup>13</sup> has shown that achlorhydria decreases the retention of non from a normal dietary non intake, and Mettier and Minot<sup>14</sup> have shown that a better utilization is obtained from small amounts of non when given in an acid medium. Lintzel<sup>15</sup> states that non is absorbed only in an ionized form and that an acid reaction is necessary for this ionization. These data on the urinary non excretion are in keeping with the foregoing observations on the absorption of non from an acid media.

#### CONCLUSIONS

The urinary non excretion from a normal dietary non intake is increased when an acid salt is administered by mouth and decreased when an alkaline salt is given.

and Dodds, glacial acetic acid was added to the urine hemoglobin mixtures in which turbidity or precipitation had not occurred in forty minutes. Sufficient glacial acetic acid was used to depress the pH from the original levels to a range such as might be encountered during acidosis, approximately a pH of 5. Depending on the combined buffering capacity of urine and the hemoglobin, 1 to 3 drops (0.05 to 0.1 ml) were necessary for each tube. Lowering the pH to 4.8 to 5.2 with acetic acid caused turbidity and precipitation in approximately half of the urine samples. In order to observe the effect of chlorides on hemoglobin solubility in acid urine as well as to determine whether other ions exert any influence, the following tests were carried out: (1) urine samples were analyzed for their ash content by Neumann's method<sup>8</sup>; (2) chlorides were determined by Whitchorn's modification<sup>9</sup>; (3) inorganic phosphorus was determined by the method of Youngburg<sup>10</sup>; (4) inorganic sulfate by Folin's method<sup>11</sup>; (5) urinary ammonia was determined by Conway's microdiffusion technique.<sup>1</sup> These determinations were done on urine samples which caused the precipitation of hemoglobin without acidification and on ninety-three samples following the addition of acid. In the latter group approximately 50 per cent of the urine samples showed precipitation. Such studies permitted an analysis of the relationship between the concentration of chloride, sulfate, and phosphate anions and the presence or absence of precipitation.

To test the effect of various electrolytes on the solubility of normal and modified hemoglobin, experiments were done with solutions consisting of a mixture of a given salt and hemoglobin at pH levels of 4.5 to 5.2. The influence of acidification of hemoglobin previous to mixing with the salts was determined by spectrophotometric absorption at different wave lengths in a Coleman spectrophotometer.

## RESULTS

When urine renders hemoglobin or its derivatives insoluble, one may observe a number of physical changes. Red hemoglobin is converted to a denatured protein, brown in color. The soluble hemoglobin becomes turbid either before or after the color change occurs. The turbidity may persist or in turn, be followed by the formation of visible aggregates which eventually precipitate. Some urine samples will precipitate minimal quantities whereas others can effect a complete precipitation of hemoglobin derivatives. Since the quantity which precipitated was not measured, the results are expressed either as positive or negative. Human hemoglobin when added to distilled water and acidified slowly forms a few light colored aggregates without any evidence of turbidity. A comparable reaction was observed rarely in urine and commonly in salt solutions. Hemoglobin in distilled water at a pH of approximately 5.0 was used as a control to ascertain if the test sample caused precipitation.

Following the filtration of urine and mixing with a solution of hemoglobin, seven of 302 samples caused precipitation at room temperature within forty minutes. Turbidity without precipitation which we consider as evidence of minimal reaction occurred four times. Therefore, eleven of 302 urine samples caused precipitation of hemoglobin derivatives. The pH values in these eleven samples varied from 5.1 to 5.8. In the remaining 291 samples the pH was higher than 5.5, over 90 per cent falling between 5.5 to 6.8.

During these studies it became apparent that temperature exerts a decided influence on the rapidity with which precipitation occurs. To evaluate the influence of temperature, sixty-six urine samples were tested simultaneously at room temperature (25 to 31° C) and at 37.5° C. In fifty-nine of

sixty-six samples neither turbidity nor precipitation occurred. In this group the temperature did not exert any apparent influence. In the remaining seven urine samples precipitation occurred once, four revealed turbidity, whereas two were negative at room temperature after forty minutes. Samples of the same urine, when mixed with hemoglobin and placed in the incubator at 37.5° C, all caused precipitation within forty minutes.

The anion concentrations in seven urine samples which caused precipitation at 37.5° C are shown in Table I.

The anion and ash concentrations were high in six of seven samples which were analyzed. The pH values varied from 5.1 to 5.8, in six samples the pH was 5.4 or less. Why precipitation occurred in the last urine sample is not apparent, since neither the pH nor the anion concentration is comparable to that of the other six samples. The findings show that hemoglobin is rendered insoluble by urine and suggest that the pH, electrolyte concentration, and temperature exert an effect on hemoglobin solubility.

It seemed desirable at this point to establish whether any of us could excrete urine which was capable of precipitating hemoglobin *in vitro*. Water was restricted to help increase the urine specific gravity. Acid-producing diets, augmented by the oral ingestion of mandelic acid and sodium sulfate separately at spaced intervals, were also taken. It was difficult to depress the urine pH, and the thirst became oppressive. However, after four days on this regime two of five were successful in excreting a urine which did precipitate hemoglobin derivatives within forty minutes at 37.5° C.

Observations on the relationship of urine anion concentration and *in vitro* hemoglobin precipitation following acidification were made in ninety-three samples of urine. The anion concentrations are expressed in milliequivalents per liter of urine. Since the pH was lowered in each case by the addition of acetic acid to a range of 4.8 to 5.2, the ratio of  $\text{H}_2\text{PO}_4^-$  to  $\text{HPO}_4^{2-}$  would be, as is diagrammatically illustrated by Gamble,<sup>13</sup> approximately 50 to 1. For this reason the phosphates are calculated in milliequivalents of  $\text{H}_2\text{PO}_4^-$ . The relationship of precipitation with respect to the various anions at varying concentrations is shown in separate columns in Table II. The range of total

measured anion concentration in single urine samples is also shown. The frequency of precipitation is expressed in fractions, e.g. 3/8 indicates that precipitation occurred in three of eight urine samples at the specified anion concentration.

TABLE II RELATIONSHIP OF IN VITRO HEMOGLOBIN PRECIPITATION FOLLOWING ACIDIFICATION TO THE ANION CONCENTRATION

Cl		SO		H PO		TOTAL ANIONS†

141-60	1/1					176-200	8/8
161-180	1/1					201-225	2/2

Data of the various anions in the first three columns is tabulated on the basis of concentration and not separate urine samples.

†The sum of Cl, SO, and H PO in a given urine sample is shown in the last column.

The relationship of precipitation to individual anion concentration is shown in the first three columns. The chloride concentration was the greatest in most of the samples. Not evident from the table, however, is the fact that the separate anions fluctuated over a wide range independently of each other. This fact explains the presence of precipitation at some of the lowest Cl<sup>-</sup>, SO<sub>4</sub><sup>-</sup>, and H PO<sub>4</sub><sup>-</sup> concentrations. In such urine samples the concentration of the other two anions was usually elevated above average values. The presence of precipitation at the lowest anion concentration in all three columns indicated that this phenomenon is not due solely to the action of a single anion. As the milliequivalent concentration of the different anions increases respectively, the ratio of hemoglobin precipitation also rises.

Examination of the total anion concentration in single urine specimens shows a considerable variation. The range from 51 to 175 meq per liter includes the majority of the urine samples. Precipitation occurred in nine of fifty-five samples in which the total anion concentration was 125 meq per liter or less. In a majority of these which caused precipitation the chloride concentrations tended to be low, whereas the SO<sub>4</sub> values were above average. In thirty-eight samples with a total concentration of 126 meq per liter or more, hemoglobin precipitation occurred in thirty-six samples. It is apparent that when the total anion concentration exceeds 126 meq per liter, hemoglobin precipitation almost always occurs at pH values close to 5.0.

A comparison of results in Tables I and II indicates the following. The total concentration of the anions measured in urine samples which caused precipitation without the addition of salts or acids is in agreement with but one exception with the values observed in urine samples following acidification. Interestingly, the SO<sub>4</sub><sup>-</sup> concentrations were higher in the unmodified samples. In some of the urine samples the hemoglobin solubility was not affected as anticipated. That is, precipitation occurred at unusually low total

anion concentrations or in the intermediate range (76 to 125 meq per liter). The cause for hemoglobin precipitation in the unusually low concentrations is not evident. However, when precipitation was observed at concentrations of 76 to 125 meq per liter it was customary to have low  $\text{Cl}^-$  and high  $\text{SO}_4^{2-}$  values.

To determine the influence of different electrolytes on precipitation in a pH range of 4.5 to 5.2, a series of experiments was performed with pure salt solutions and hemoglobin. Solutions of normal and modified hemoglobin were used. The hemoglobin was changed by direct acidification with N/10 HCl until the pH was depressed to 4.92. This acidified hemoglobin was then incubated at 37.5° C for sixty minutes. Prior to mixing with pure salt solutions, the normal and acidified hemoglobin were diluted 1:200 in 0.1 per cent  $\text{Na}_2\text{CO}_3$  and analyzed spectrophotometrically. The absorption curve of the acidified hemoglobin was slightly modified, it crossed the curve of normal hemoglobin at 585 and 512  $\text{m}\mu$ , indicating that acidification and incubation had caused a change in the hemoglobin molecule. Solutions of pure salts at different molar concentrations in 5 ml quantities were mixed with 0.5 ml of hemoglobin, and the pH was adjusted to approximately 5.0, when necessary, with N/10 HCl. The results of some of the studies with mixtures of pure salts and solutions of normal and partially denatured hemoglobin are shown in Table III.

TABLE III THE INFLUENCE OF DIFFERENT SALT CONCENTRATIONS AND THE PURITY OF HEMOGLOBIN ON PRECIPITATION IN THE SPECIFIED pH RANGES

SALT	NORMAL HEMOGLOBIN				ACIDIFIED HEMOGLOBIN				
NaCl	Molar concentration	0.5	0.4	0.3	0.2	0.4	0.3	0.2	0.1
	pH	5.2	5.2	5.2	5.2	5.2	5.2	5.2	5.1
	Reaction	-	-	-	-	+	+	-	-
$(\text{NH}_4)_2\text{SO}_4$	Molar concentration	0.4	0.36	0.32	0.28	0.2	0.1	0.05	0.025
	pH	5.4	5.0	5.0	5.4	5.2	5.2	5.3	4.9
	Reaction	-	-	-	-	+	+	-	-
$\text{Na}_2\text{SO}_4$	Molar concentration	0.5	0.4	0.3	0.2	0.2	0.1	0.05	0.025
	pH	5.1	5.1	5.2	5.1	5.3	5.2	5.2	5.2
	Reaction	-	-	-	-	+	+	+	-
$\text{Na}_2\text{HPO}_4$	Molar concentration	0.1	0.05	0.038	0.025	0.2	0.1	0.05	0.025
	pH	5.0	4.9	5.1	5.1	5.1	5.2	5.1	4.9
	Reaction	+	+	-	-	+	+	-	-
$\text{NaH}_2\text{PO}_4$	Molar concentration	0.5	0.4	0.3	0.2	0.5	0.45	0.4	0.35
	pH	4.7	4.8	4.9	5.0	4.5	4.6	4.6	4.6
	Reaction	-	-	-	-	+	+	-	-

Reactions followed for twenty minutes. Hemoglobin acidified and the pH of salt mixtures adjusted by N/10 HCl acid.

When normal hemoglobin was mixed with solutions of NaCl,  $(\text{NH}_4)_2\text{SO}_4$ ,  $\text{Na}_2\text{SO}_4$ , and  $\text{NaH}_2\text{PO}_4$  in which the molar concentrations varied from 0.5 to 0.1 precipitation did not occur in twenty minutes. Addition of hemoglobin to  $\text{Na}_2\text{HPO}_4$  solutions in molar concentrations of 0.1 to 0.05 produced minimal precipitation following the adjustment of pH to 4.9 to 5.1. The difference observed when using  $\text{Na}_2\text{HPO}_4$  instead of  $\text{NaH}_2\text{PO}_4$  solutions is probably related to the initial high pH value of  $\text{Na}_2\text{HPO}_4$ , since the final ratio of  $\frac{\text{H}_2\text{PO}_4^-}{\text{HPO}_4^{2-}}$

would be equal after the pH was adjusted. The pI values for  $\text{NaH}_2\text{PO}_4$  are lower than for the rest of the salts because of the difficulty encountered in adjusting the pI to 5.0. The partly modified hemoglobin, on the other hand, was almost completely precipitated within twenty minutes by the higher concentrations of all the electrolytes used.

#### DISCUSSION

Proteins have been shown to be least soluble in the neighborhood of their isoelectric points.<sup>14</sup> In this study hemoglobin was not precipitated by urine at or near its isoelectric point of 6.4. It is felt therefore that the *in vitro* influence of urine on hemoglobin solubility is not due to this factor. Hemoglobin is known to be amphoteric; it acts as an acid on the alkaline side of its isoelectric point and as a base below a pH of 6.4 when it has a net positive charge.<sup>14</sup> In view of this one would expect the hemoglobin to bind the anions ( $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$  and  $\text{H}_2\text{PO}_4^-$ ) more strongly at a pH of 5.0 than at its isoelectric point. Furthermore it is well known that ions of higher valence are more effective precipitating agents. In this respect the  $\text{SO}_4^{2-}$  anion would be quite effective since at a pH of 5.0 it exists almost entirely in the bivalent form.

Green has shown that electrolyte concentration exerts a decided influence on hemoglobin solubility at different pH levels.<sup>15</sup> Green's experiments, however, were conducted at pI levels higher than 5.8. Likewise her studies were done with unmodified hemoglobin whereas the present studies are complicated by changes in hemoglobin and the presence in urine of other solutes which might either augment or inhibit the effect of electrolytes. It is apparent that hemoglobin precipitation in urine *in vitro* is a complex phenomenon in which multiple variables are operating. At the present time the *in vitro* hemoglobin precipitation can be attributed to pI and anion alterations. However, an explanation for the mechanism of precipitation will require further study and would appear to entail individual study of the variables known to exist in this system.

Baker and Dodds<sup>1</sup> originally suggested that two entirely independent factors are required for the precipitation of hemoglobin in urine. First a pH of 5 to 6 is required to convert hemoglobin to methemoglobin and possibly acid hematin. Second the urine must have a minimal concentration of about 1 per cent NaCl. Our studies are in agreement with the first suggestion that acid urine which converts hemoglobin to other derivatives is conducive to precipitation. However our findings do not support the hypothesis that a NaCl concentration in excess of 1 per cent is required. In our study the urine samples which caused *in vitro* precipitation of hemoglobin never had a calculated NaCl concentration of 1 per cent. We did, however, find a close relationship between the total anion concentration and precipitation in urine samples in which the pH is 5.4 or less.

It became evident that three factors are necessary before urine causes precipitation of hemoglobin: an acid urine of proper pH, anions in sufficient concentration and last, a modified hemoglobin. Initially we were not aware

that hemoglobin modification markedly accelerates precipitation until a study of the influence of pure salts on hemoglobin solubility was undertaken. Baker and Dodds do mention denaturation as a factor in conjunction with acid urine. However, one is not apt to consider hemoglobin changes of significant importance because a pH of 5.0 to 5.4 is desirable in urine before the ions begin to exert significant activity. In view of this, one is likely to assume that hemoglobin modification is merely an associated change rather than a factor which exerts a decided influence on the rapidity and quantity of precipitation.

Whether the ability of urine to precipitate derivatives of hemoglobin is of any importance in the production of hemoglobinuric nephrosis remains to be established. We are able to confirm that acidification of human urine within the physiologic range causes precipitation of modified hemoglobin. It was possible to show that unmodified human urine with the proper acidity and anion concentration also precipitates hemoglobin derivatives. It is hazardous to conclude from *in vitro* experiments whether precipitation will occur *in vivo* under similar conditions. However, one cannot help but wonder whether the mechanisms responsible for hemoglobin precipitation *in vitro* are not also in part responsible for intratubular hemoglobin cast formation.

#### CONCLUSIONS

It has been possible to confirm the observations that acidification of urine within the physiologic range will effect a precipitation of hemoglobin by some of the urine samples.

Urine which is not modified by the addition of either salts or acids and which is capable of precipitating modified hemoglobin can be obtained from some patients. Healthy individuals existing on an acid-producing diet which is augmented by the oral ingestion of mandelic acid and a limitation of water intake are able to excrete urine capable of effecting precipitation of hemoglobin.

Urine which precipitates hemoglobin in most instances would appear to possess several variables. In addition to pH and anion concentration studied in this work it would seem that the known and unknown factors, which are responsible for modification of hemoglobin, play an important role in this system.

Tyrode solution containing 20 per cent sucrose by volume extracted an average 52.1 mg per cent nonprotein nitrogen in three to four hours by isolated loop perfusion, or more than six times the quantity recovered in any other hypertonic perfusion experiment and ten times the amount recovered with an isotonic solution (Fig 1) The quantity of nonprotein nitrogen extracted in the perfusate was roughly directly proportional to the hypertonicity of the

Fig 1—Nonprotein nitrogen recovered in perfusate using Tyrodehypertonic solutions under standard conditions

perfusion solution (Fig 1) Enteric perfusion using Tyrode's isotonic solution produced the greatest reduction of plasma nonprotein nitrogen (Fig 2) No correlation between the degree of plasma nonprotein nitrogen reduction and the amount of nonprotein nitrogen extracted in the perfusate could be established (Figs 1 and 2) Individual variations of protein metabolism, state of hydration, and nonprotein nitrogen-cellular-interstitial space-vascular equilibrium may account for these discrepancies

Tyrode solution containing 20 per cent MgSO<sub>4</sub> reduced plasma nonprotein nitrogen rapidly Dehydration, salivation, vomiting, apparent disorientation, and exhaustion prompted perfusion discontinuance after one and one-half hour respectively Eight hours later, both dogs had fully recovered

Isotonic and hypertonic Tyrode sucrose solutions containing 0.001M HgCl as a protoplasmic poison extracted nonprotein nitrogen in comparable quantity to Tyrode sucrose solutions without the protoplasmic poison (Fig 3)

Fig 2—Plasma nonprotein nitrogen loss following isolated loop perfusion with hypertonic Tyrode solution under standard conditions

Fig 3—The effect of perfusion fluids containing a protoplasmic poison on the quantity of nonprotein nitrogen recovered (standard conditions)

No constant changes were observed in weight, hematocrit chloride, or total base values following isolated loop perfusion with hypertonic sucrose-Tyrode solutions. No general edema nor evidence of hyperchloremic acidosis was encountered during the reported experiments.

Perfusate collected from dogs irrigated with Tyrode hypertonic sucrose fluids gave a negative benzidine occult blood reaction. Microscopic examination showed no significant cellular structures after three to four hours of perfusion.

Increased urine concentration was observed in the majority of experiments, although corresponding weight changes and hematocrit values failed to reflect dehydration. Urine qualitative reduction tests yielded a ++ to +++ reaction in animals perfused with a Tyrode 20 per cent sucrose solution.

#### DISCUSSION

Twenty per cent hypertonic sucrose-Tyrode solution was the most effective perfusion fluid in removing nonprotein nitrogen from the experimental animal. Wells and Johnson<sup>28</sup> have suggested that hypertonic solutions increase the excretion through the bowel wall by producing a chemical or physical irritation rather than by a purely osmotic process. In order that the electrolytic balance of the experimental animal be preserved, and since the process of dialysis is reversible, an irrigating fluid (Tyrode solution) closely resembling the electrolyte pattern of the blood was chosen. Distilled water alone as a perfusion fluid destroys bowel mucosa.<sup>9</sup> Electrolyte balance, particularly with reference to the concentration of the monovalent ions, is not entirely dependent on the action of dialysis alone. Visscher<sup>30</sup> has shown that monovalent chloride ions may pass from the bowel lumen by selective action of the mucosa into the circulating blood stream against higher concentration gradients. Comparable clinical observations have been noted by Daugherty and co-workers.<sup>6</sup> Apparent alterations in the electrolyte patterns may be caused by changes in hydration of the experimental animal as well. There was no significant constant change in hemoconcentration as measured by hematocrit values, fluid balance, or electrolyte equilibrium during the perfusion period.

MgSO<sub>4</sub> in concentrations greater than 10 per cent is not satisfactorily tolerated for prolonged periods of perfusion. Greater molecular concentrations of relatively nontoxic molecules in an electrolytically isotonic solution appeared to us to offer a solution for a more effective perfusion fluid. Sucrose was chosen because of its (1) low molecular weight, (2) low toxicity to living tissue, (3) potential caloric value if hydrolyzed and absorbed, (4) availability, and (5) low cost.

With concentrations of sucrose of 50 per cent, vomiting and other toxic manifestations occur. Sucrose in hypertonic solution is damaging to cell structure. It is reasonable to expect that with prolonged irrigation the effect of intestinal perfusion, as measured by the recovery of nonprotein nitrogen might decrease. However, by damaging the action of the mucous membrane with a mercuric chloride 0.001 molar solution<sup>30</sup> in Tyrode solution for perfusion purposes, comparable amounts of nonprotein nitrogen were recovered as compared

with those experiments where isotonic Tyrode solution or 20 per cent sucrose Tyrode solution was used alone. This suggests that the state of physiologic integrity of a bowel wall will not greatly affect dialysis.

Dogs perfused with 20 per cent  $MgSO_4$  Tyrode solution and other high concentrations of hypertonic fluids were able to extract water from the perfusion fluid. In both experiments in which 20 per cent  $MgSO_4$  Tyrode solution was employed as a perfusion fluid, the recovered volume of irrigating solution was less than the volume introduced. Comparable observations have been made by White and Harkins.<sup>9</sup>

## PART II

### MATERIALS AND METHODS

The animals utilized in Part I were bilaterally nephrectomized under sodium pentothal anesthesia. Twenty-four hours after operation, continuous irrigation of the Thiery Vella loop was instituted with 20 per cent sucrose Tyrode solution modified after the methods employed in Part I. Water but no food was offered during the continuous perfusion period. Intramuscular divided doses of sodium pentothal were administered as a sedative. Parenteral fluids and salts were given intravenously as required based on plasma studies as outlined in Part I.

The following determinations were carried out before nephrectomy and every twenty-four hours thereafter until the animal expired: hematocrit, plasma chloride, total protein, nonprotein nitrogen, and total base. The recovered perfusate was volumetrically measured and examined for urea, nonprotein nitrogen, chlorides, total protein, total base, occult blood, and fragments of tissue. The period of survival was measured from the conclusion of the nephrectomy operation until the animals expired.

### RESULTS

Average survival time of nephrectomized dogs treated by continuous hypertonic (20 per cent sucrose Tyrode solution) isolated loop irrigation was 80.1 hours. In spite of 4.38 to 6.12 Gm urea recovered in the twenty-four hour periods, the plasma nonprotein nitrogen progressively increased (Fig. 4). The typical clinical picture of uremia characterized by anorexia, vomiting, excitatory phase, spasmodic muscular contractions, apparent irrationality, lethargy, and death was observed. There was no evidence of edema. All animals lost from 3 to 5 pounds of weight accounted for by (1) vomiting, (2) salivation, (3) insensible water loss, (4) fecal incontinence. Two hundred to five hundred milliliters intravenous fluids per animal per twenty-four hours were sufficient to maintain normal hematocrit values. Total plasma proteins and chloride values remained relatively constant except as temporarily affected by the animal's state of hydration.

Perfusion fluid recovered (24.4 liters per twenty-four hours average volume) yielded 0.2 Cm urea per liter or 4.87 Gm per twenty-four hours (Fig. 4). Occult blood was detected after forty-eight hours of continuous lavage, and fragments of tissue were seen in the perfusate after seventy-two hours.

Post mortem studies revealed no pleural but slight (15 to 20 ml) peritoneal effusion. The Thiery Vella loops (average length 82 cm) contained multiple mucosal ulcerations from 1 mm to 4 cm in diameter. In two speci-

mens, the isolated loop walls were thickened two to three times normal size by edema and hyperemia. Subserosal hyperemia was pronounced. The amount of bowel damage was directly proportional to the duration of perfusion.

Fig. 4—Relationship of plasma nonprotein nitrogen to recovered urea by continuous hypertonic lavage (20 per cent sucrose-Tyrode solution) in nephrectomized dogs (Average values, five experiments)

### DISCUSSION

Survival time (eighty hours) of nephrectomized dogs treated by continuous hypertonic (20 per cent sucrose-Tyrode solution) perfusion was insignificantly longer than that of the controls of Bliss and co-workers<sup>4</sup> (three days) and White and Harkins<sup>29</sup> (seventy-three hours) and was comparable to that of the controls of Abbott and Shea<sup>1</sup> (three to five days). Survival time of untreated nephrectomized dogs is variable. Ivy, Barry, and co-workers had control animals survive for more than one hundred hours average<sup>3, 10, 18</sup>.

On the basis of comparative survival times of the untreated nephrectomized dogs, any claim of therapeutic success by the method studied must be regarded as invalid.

Hypertonic isolated loop enteric lavage yielded significant quantities of urea in spite of extensive mucosal damage, a fact foreshadowed (Part I) by the

relatively large nonprotein nitrogen yield through the isolated bowel wall, the mucosa of which was damaged by a protoplasmic poison (Fig 3)

It was not within the scope of this work to observe, in great detail, the effect of hypertonic isolated loop lavage upon the chemical structure of the plasma or extracellular fluid. However, from our data, little deleterious effect was observed upon the normal values of proteins, chlorides, total base, and hematocrit. Prolonged continuous irrigation produced mild dehydration readily corrected by intravenous fluid replacement.

We are in accord with Gamble's belief<sup>13</sup> that "in uremia, the defense of the chemical structure of extracellular fluid is of much more importance from the point of view of survival than the reduction of azotemia." Recent work<sup>24</sup> has strengthened this belief.

Therefore, it would seem reasonable that a more promising approach to the therapy of uremia would be a combination of azotemic reduction and proper administration of a balanced solution of electrolytes.

#### SUMMARY AND CONCLUSIONS, PARTS I AND II

1 Hypertonic (20 per cent sucrose Tyrode) perfusion fluid was ten times more effective than isotonic fluid (Tyrode) in extracting nonprotein nitrogen from a dog's isolated enteric loop.

2 The amount of nonprotein nitrogen extracted by isolated enteric lavage was roughly proportional to the hypertonicity of the perfusion fluid.

3 Hypertonic (20 per cent sucrose Tyrode) solution for isolated enteric loop lavage produced no appreciable changes of plasma acid base or water equilibrium over three to four hour periods.

4 Continuous hypertonic (20 per cent sucrose Tyrode) isolated enteric lavage did not prolong the survival period of nephrectomized dogs.

5 Continuous hypertonic (20 per cent sucrose Tyrode) enteric lavage eventually produces mucosal ulcerations and bowel damage.

The authors are indebted to Dr D. A. MacFadyen for his many helpful suggestions and to Miss Helen Ellis for her technical assistance in this study.

# PROGRESSIVE CHANGES IN LIVER COMPOSITION, FUNCTION BODY FLUIDS AND LIVER CYTOLOGY DURING PROTEIN DEPLETION IN THE RAT AND THE EFFECT OF CHOLINE UPON THESE CHANGES

CHENG FA WANG M B CH B D MARK HEGSTED, PH D, ANGELO LAPI M D,  
NORMAN ZAMCHECK M D AND MELVIN B BLACK, M D  
BOSTON, MASS

IT IS known that the liver is the first organ to suffer a serious loss of protein during starvation or the development of protein deficiency. Addis, Poo, and Lew<sup>1, 2</sup> found for example that 20 per cent of the protein of the liver of well fed rats was lost during a two day fast and that 40 per cent was lost after a week of fasting. Kosterlitz<sup>3, 4</sup> reports that rats fed a protein free diet lost 15 per cent of the liver cytoplasm during the first day. It thus appears that a considerable amount of the liver protein is easily mobilized. After the first few days the liver losses become much less and according to Campbell and Kosterlitz follow an exponential curve as protein starvation continues.

Cytologic evidence has shown that the ribonucleic acids also are rapidly lost from the liver during protein deficiency. Elman and associates<sup>5, 7</sup> Kosterlitz<sup>3, 4</sup> and Wang and Hegsted<sup>8</sup> observed simultaneous clearing and vacuolization of the cytoplasm together with losses of the basophilic staining material which was apparently ribonucleic acid<sup>9, 10, 11</sup>. It is not clear whether or not these losses represent serious functional changes of the liver.

An accumulation of fat in the liver has been observed during the development of protein deficiency<sup>4, 6, 12</sup>. In view of the diets which have been used it may be expected that this may be partially related at least to a simultaneous deficiency of choline. Hough and co workers<sup>13</sup> observed that the administration of choline to protein depleted dogs largely prevented the changes in hepatic dye clearance and the rise in serum phosphatase which occurred on the protein deficient diet they were using. It may be expected that the development of protein deficiency in man may also be complicated by low choline intakes.

This paper reports the results of studies of protein deficiency in rats which received diets either poor or rich in choline. Changes in the composition of the liver blood and plasma volumes thiocyanate space bromsulfalein clearance and plasma nitrogen were determined and histologic examinations of the livers were made in an attempt to correlate morphology with the analytic data obtained.

## EXPERIMENTAL

The study was made with young adult female rats which weighed approximately 200 grams at the time they were given the protein-free diet. The diets were of the purified type previously described<sup>8</sup> and contained glucose, 89 per cent, corn oil, 5 per cent, salt mixture,<sup>14</sup> 4 per cent, cod-liver oil, 2 per cent, and supposedly adequate levels of all of the B complex vitamins except choline in the low choline diet. This diet contained 30 mg of choline chloride per 100 Gm, while the high choline diet contained 500 mg per 100 grams. The animals were housed in individual cages in a room of approximately constant temperature, 78° to 80° F. The diets were fed ad libitum but food intake was recorded at two- or three-day intervals by weighing the amount of food not eaten. Animals were killed at intervals of three, twelve, twenty-five, or more days as indicated below. A total of thirty animals was started upon each diet but it was not possible to make all measurements on each animal. The figures presented below show the number of animals from which data were obtained at each period of deficiency.

At the time of sacrifice, the blood and plasma volumes, thiocyanate space, and biomsulfalein clearance were determined as previously described.<sup>15</sup> The liver was immediately removed, samples were taken from both the right and left lobes for histologic study, and the remainder was prepared for chemical analysis. Water content was determined by drying at 95° C, glycogen and fatty acids plus the unsaponifiable fraction as previously described,<sup>8</sup> and total nitrogen by the macro-Kjeldahl method. Total plasma nitrogen was measured colorimetrically by the Nessler method after digestion.

## RESULTS

*Biochemical Analysis*—Fig 1 summarizes the changes observed in the liver weight. On the high choline-low protein diet there was an immediate fall during the first three days from approximately 8 grams to about 5.5 grams. This weight was maintained approximately constant for about two weeks and then gradually fell. When expressed as per cent of body weight the original decrement is still apparent, but after a period of depletion it again regained the original relation to body weight and was maintained at this level throughout the depletion. These changes are interpreted as an original loss of liver substance which is much greater than the relative loss of body substances, but during the following two weeks the relative loss of body weight exceeded that of the liver. During the latter stages of depletion the percentage losses from liver and the remainder of the body are approximately equal.

Animals which received the low choline diet failed to show the original liver weight loss because of the accumulation of fat as shown below. During later periods most, but not all, of the fat was lost so that the liver weight changes were approximately the same as in the high choline group. This was also shown by the similarity of the two groups when fat and glycogen were subtracted from the dry liver weight to give nonfat, nonglycogen liver weight, presumably protein weight. This fell gradually and approximately to the same extent in both groups.

Fig 1—Changes in liver weight with respect to time on protein free diets

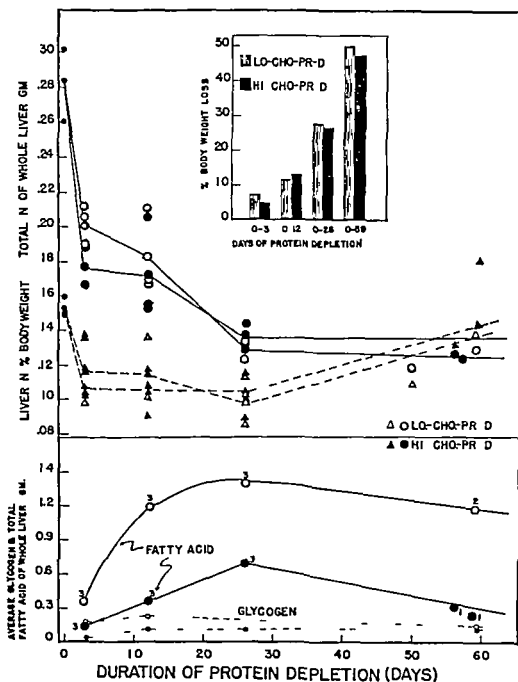

Fig 2—Changes in liver nitrogen, fat, and glycogen and body weight losses with respect to time in rats receiving high and low choline, protein free diets. Numbers in the lower part of the figure indicate the number of livers analyzed

The loss of nitrogen from the liver was similar regardless of the choline content of the diet (Fig 2). Body weight loss was also similar in the two groups (Fig 2, insert). In the latter stages of deficiency the rate of body weight loss exceeded that of liver nitrogen loss. Some fat accumulated in the liver during the early stages of deficiency even though choline was supplied. Consistently larger amounts of glycogen were found in the livers of animals which received the lower level of choline.

Fig 3—Scatter diagram showing the relation of blood bromsulfalein concentration five minutes after injection to total liver nitrogen as compared with total liver fat. The apparent correlation with liver nitrogen is mainly due to a simple decrease in liver size with loss of weight.

The absolute amount of bromsulfalein cleared from the blood fell markedly during the depletion period. This may be inferred from Fig 3 since the blood concentration of bromsulfalein five minutes after the injection of a 5 mg dose is much higher in those animals with less total nitrogen per liver, that is, the animals subjected to protein deficiency for the longest period of time. It is also clear from the right-hand side of the same figure that the blood level is not well correlated with the degree of fatty infiltration which developed in these animals. Thus as protein deficiency developed, the animals were able to remove smaller amounts of a standard dose of bromsulfalein from the blood in a given time period. However, the deficiency is not only associated with a decrease in liver size but with a fall in body weight and blood volume as well, and an adequate representation of the situation must take these changes into account. Results presented earlier<sup>12</sup> showed that the bromsulfalein clearance of normal rats in the first five minutes after injections yielded a straight-line relationship with dosage.

when both clearance and dosage were expressed in terms of milligrams per 100 grams of body weight. The values obtained with the protein depleted animals were therefore compared with the values expected from normal rats of the same weight. The deviations from normal (negative deviation equals increased bromsulphalein retention) are shown in Table I. In none of the animals was the deviation from the expected value great and none of the mean values presented in Table I were significantly different from the expected value when tested statistically by the 't' test. Thus it is concluded that essentially all the decrease in bromsulphalein clearance is accounted for by the loss of body and liver weight, and there is no proof of malfunction of the remaining liver tissue. It is true that the deviations from normal tend to become greater as the deficiency is prolonged, and additional data might prove these deviations significant statistically.

TABLE I. BROMSULPHALEIN CLEARANCE IN PROTEIN DEFICIENT ANIMALS COMPARED WITH VALUES FOR NORMAL RATS

DIET	TIME ON DEFICIENT DIET	NUMBER OF ANIMALS	MEAN DEVIATION OF BROMSULPHALEIN CLEARANCE FROM NORMAL (MG/100 GM BODY WEIGHT)
High choline protein free	3	9	-061 ± 024*
	12	10	-149 ± 096
	25	1	-187 ± 095
	40	2	-225 ± 0087
	56	2	-370 ± 322
Low choline protein free	3	7	-076 ± 157
	12	9	-181 ± 137
	24	7	-092 ± 296
	50	1	-40

Standard error of the mean

The changes in the body fluid volumes are indicated in Fig. 4. The thiocyanate space fell gradually and nearly parallel to the fall in body weight so that the ratio of thiocyanate space to total body weight remained constant for approximately forty days. After this period there appeared to be a slight tendency for the thiocyanate space per unit body weight to increase. This increase if significant would represent a tendency toward edema. The changes in plasma volume showed the same trend as those of the thiocyanate space so that the ratio  $\frac{\text{ECFV}}{\text{PV}}$  remained essentially constant even after prolonged depletion.

The total plasma nitrogen concentration showed an early marked drop at the same time that the plasma volume was shrinking. This resulted in a considerable decrease in the total circulating plasma nitrogen (TCPN). The loss in body weight was also large (Fig. 2 insert) and the total circulating plasma nitrogen per 100 grams of body weight showed only a slight and apparently insignificant drop. During the latter stages of the deficiency the plasma nitrogen concentration increased considerably so that the total circulating nitrogen per 100 grams of body weight rose. This occurred simultaneously with the rise in thiocyanate space. It is clear that there was no consistent relation between the plasma nitrogen and the thiocyanate space. Since the formation of edema

is expected to be related to a fall in plasma protein concentration, the changes observed are the opposite of those expected. The total plasma nitrogen figures reflect changes in both plasma proteins and nonprotein nitrogen. Since the

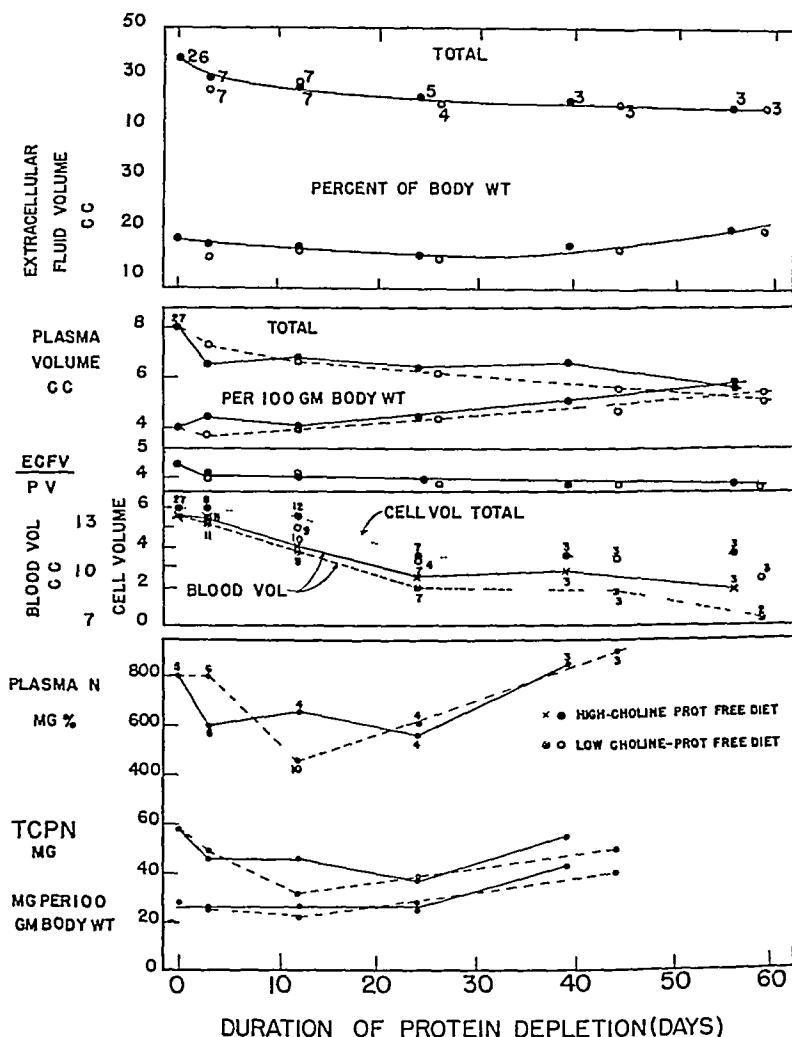

Fig 4—Variations in the distribution of body fluid volumes and plasma nitrogen during protein depletion. Numbers at the various points indicate the number of animals used.

nonprotein nitrogen of typical animals at various stages of depletion remained essentially constant, and less than 30 mg per cent, it is apparent that an increase in plasma nitrogen represents an increase in the total plasma proteins.

None of the data in Fig 4 indicates that choline deficiency and the resultant fatty livers are of importance in the changes in fluid volumes observed.

**Gross Pathology**—As early as the third day, some of the livers appeared paler than those of normal animals. As the deficiency period increased, the livers became successively paler and yellower until at twenty days of deficiency they were definitely and uniformly yellowish-brown rather than the normal

purplish red color. After twelve days on the deficient diet, some animals showed marked involution of the thymus. From this time on, subcutaneous edema appeared in a few of the animals. Although difficult to evaluate because of the great loss of tissue and fat this appeared more severe and more uniform after long periods of deficiency.

*Microscopic Pathology*—Blocks of tissue were fixed in 4 per cent aqueous formaldehyde, Zenker acetic solution and absolute alcohol. Eosin, methylene blue, hematoxylin and eosin, Best carmine, and sudan IV stains were made.

The histologic changes observed were similar to those described by Elman, Smith and Sachar,<sup>7</sup> Wachstein,<sup>10</sup> Kosterlitz,<sup>4</sup> and Kosterlitz and Campbell,<sup>8</sup> and with the exceptions noted below, they were essentially the same in both the high and low choline diets (Fig. 5). The earliest change consisted of enlargement of the liver cells at the expense of the sinusoids, especially in the peripheral zones of the lobules. The sinusoids were compressed and largely obliterated after a few days on the deficient diet. Simultaneously the cytoplasm became less dense ("cytoplasmic clearing") and was represented by a few coarse eosinophilic or basophilic strands. There was an apparent decrease in basophilic granules in the cytoplasm which have been demonstrated to be composed of ribonucleic acid by Caspersson and Schultz and others.<sup>9, 11</sup> The remaining basophilic granules appeared to have been displaced toward the cell membrane which stained deeply and conspicuously ("cytoplasmic rimming").

Whereas in normal animals the nuclei of liver cells were round, vesicular, and uniform in size with finely granular and evenly distributed chromatin, the nuclei of some of the liver cells of rats on the deficient diets were variable in size and shape and tended to be hyperchromatic. These changes were not necessarily more pronounced in those cells showing the cytoplasmic changes described. Also as early as the third day, fat in the form of large or small droplets appeared in the liver cells of the periportal areas. This was more marked in the animals receiving the low choline diet. Best carmine stains also indicated an increase in glycogen, mainly in the periportal cells, but the zonal distribution was not as marked as that of fat.

These changes, typical of all the animals on the low protein diets, were more marked in the low choline than in the high choline group. In Table II the various changes have been graded and are listed at different stages of the experiment. In general the most striking changes were consistently observed in animals depleted for twelve to twenty-six days. In a few of the low choline animals, however, cytoplasmic clearing and rimming of equal intensity was found as early as three days. Typically these livers appeared as a mosaic of polygonal clear cells with central nuclei. In the few animals that were sacrificed as late as fifty days it was noted that in the low choline protein free group the findings of markedly increased cell size, cytoplasmic clearing and rimming were the same as in the twelve and twenty-six day groups. A moderate amount of fat was found centrally in the lobules, differing from the periportal distribution noted earlier. There was also considerable variation in the size and staining quality of the nuclei. Many cells were multinucleated. In the animals receiving the high choline low protein diet, the changes were similar except that they

Fig. 5—Liver changes with protein depletion. *A* Normal rat (eosin-methylene blue  $\times 350$ ). *B* three days of depletion (eosin-methylene blue  $\times 350$ ). *C* twenty-six days of depletion (eosin-methylene blue  $\times 350$ ). *D* seventy-six days of depletion (sudan IV frozen section  $\times 350$ ). As early as three days there is marked rarefaction of the cytoplasm with the remaining basophilic material chiefly at the edges of the cells. The sinusoids have been largely obliterated. At twenty-six days the liver appears as a mosaic of rarefied polygonal cells but by seventy-six days (high choline protein-free animal) the appearance approaches that found in the well-nourished animal with slight to moderate fatty infiltration chiefly central in location.

became less marked as the depletion was prolonged. A few animals survived as long as seventy-six days and in these the cell size was essentially normal and there was no cytoplasmic clearing or rimming. The fat which persisted tended to be centrally or variably dispersed in the lobules. Nuclei were variable in size and shape.

TABLE II SUMMARY OF THE HISTOPATHOLOGIC CHANGES IN THE LIVER AFTER VARIOUS PERIODS ON THE PROTEIN DEFICIENT DIETS

TIME ON DEFICIENT DIET (DAYS)	CYTOPLASMIC CLEARING		CYTOPLASMIC RIMMING		FAT QUALITY		FAT DISTRIBUTION		NUCLEI		CELL SIZE	
	HIGH CHOLINE	LOW CHOLINE	HIGH CHOLINE	LOW CHOLINE	HIGH CHOLINE	LOW CHOLINE	HIGH CHOLINE	LOW CHOLINE	HIGH CHOLINE	LOW CHOLINE	HIGH CHOLINE	LOW CHOLINE
3	0	++ to +++	0	++ to +++	0 to +	+	Periportal	Periportal	Normal	Normal	0	+
14	+ to ++ (Variable)	++++	0 to +	+++	0 to ++	++	Periportal but some loaded cells throughout	Periportal	Normal or slightly hyperchromatic	Normal	±	+
20	+ to ++ (Variable)	+++ (Variable)	0 to +	++ to +++	+ to ++	++	Periportal	Periportal	Variable in size and stain	Hyperchromatic	±	+
30	+++ (Variable)	+++ (Variable)		++ (Variable)	++	++		Central		Variable in size and stain		+
60	0		0		+ to ++	+	Central and variable		Variable in size and stain		0

## DISCUSSION

In general the results of these studies agree with previous investigations<sup>4,6</sup>. The cytologic evidence and the chemical findings both show marked changes in the liver during early protein deficiency. Early in the period of deficiency the large losses of protein are accompanied by a considerable accumulation of fat. The fatty infiltration is apparently not completely preventable by choline in the amounts used, although larger amounts might prove more effective. Glycogen accumulates at the same time and to a greater degree in the livers of the choline deficient animals.

During later periods, when the deficiency is greater, the nitrogen losses from the liver are less and a large proportion of the loss is from the other body tissues. The ratio liver weight/total body weight actually increases at this time. It may be significant that the food intake of the animals is fairly well maintained for three or four weeks upon the diet, but then begins to diminish. During the latter stages of the deficiency there may be a caloric as well as a protein deficiency. The present data are insufficient to evaluate this aspect of the problem, however, since nothing is known of the metabolic rates or caloric requirements of severely deficient animals. It may be expected that the metabolic rate has declined if the animals behave as in starvation, and this together with a marked loss in body weight should lower the caloric needs. However this may be, the evidence is clear that after severe depletion there is a return toward normality in liver structure both chemically and histologically, and this is aided and increased by the presence of choline. There is apparently no basis for deciding whether this is advantageous for the animal, at least from this study. Choline obviously cannot replace protein in the diet, and the animals, regardless of the presence or absence of choline, lose weight, become emaciated, and eventually die. There also does not appear to be any great change in over-all nitrogen metabolism as the result of the degree of fatty infiltration of the liver which occurred on the diets used.

The absolute clearance of biomsulfalein per rat falls markedly during the depletion period, but the clearance per unit body weight is not significantly less than normal. It therefore appears that the total ability of the liver to remove biomsulfalein is greatly changed by the decrease in size, but the function per gram of liver tissue remains nearly normal. This finding is somewhat at variance with the results of previous studies with dogs. In the experience of Hough and Freeman and co-workers,<sup>12, 13</sup> dogs fed a low protein diet soon showed high serum phosphatase values and decreased rates of clearance of rose bengal. However, their basal diet probably contained less choline than our low choline diet. Most of the changes observed by these authors were prevented by the feeding of choline and therefore were due primarily to choline deficiency. McKibbin and associates<sup>17</sup> found lowered biomsulfalein clearance in choline deficient puppies. Similar results also were observed in choline-deficient rats by Maclean, Ridout, and Best,<sup>18</sup> but only in those animals with very large amounts of liver fat. One may conclude that changes in dye clearance per unit body or liver weight due to protein deficiency are relatively slight and are detectable only after relatively severe depletion. On the other hand, unless

choline is specifically added most low protein diets will also be low in choline and this may be the primary factor in lowering the rate of dye removal. The accumulation of fat, however, must be relatively great before it is effective in changing the bromsulfalein clearance in rats.

The modifications in the volumes of the body fluids will receive more attention in a following paper in which the effect of low temperatures has been studied in conjunction with protein deficiency. It may be noted however, that (a) the tendency toward edema as indicated by an increase in thiocyanate space relative to body weight occurred only after very severe protein depletion and was then only slight (b) the plasma volume decreased approximately equally with body weight and the ratio of thiocyanate space to plasma volume remained nearly constant during the depletion and (c) although there was a marked decrease in the plasma nitrogen on the deficient diet, this not only showed no relation to the tendency toward edema but actually was higher at the time when the thiocyanate space tended to increase. This lack of correlation between plasma proteins and edema has been described by Keys and associates in human volunteers subjected to starvation<sup>19</sup> and in several reports of starvation edema from various parts of the world.<sup>20</sup>

It is of some interest that the data, chemical as well as cytologic suggest a return of the liver toward 'normal' as the animal becomes severely depleted. The animal apparently attempts to conserve liver tissue after the first primary loss and as body weight falls the liver weight finally regains its original relation to body weight. Fat is lost from the liver and the composition with regard to the constituents determined in this study becomes nearly normal. Histologically this loss of liver fat is also suggested, as well as an increase in the density of the cytoplasm and an approach toward normal of the appearance of the nuclei, cell size, and distribution of the basophilic material in the cytoplasm. It is of course not possible to deduce from these data that the liver has improved functionally.

#### SUMMARY

The progressive changes in liver composition, bromsulfalein clearance, blood and plasma volumes, thiocyanate space, total plasma nitrogen and liver cytology have been followed in rats subjected to severe protein depletion. The effect of low and large supplies of choline upon those changes has been studied.

In agreement with the findings of previous investigators the liver shows a very rapid loss of nitrogen while fat and glycogen accumulate. The fat accumulation is only partially preventable with choline in the amounts used. Cytologically the livers show a rapid loss of basophilic material, the cytoplasm becomes less dense and the sinusoids are largely obliterated. These changes are progressive for approximately one month. After more prolonged depletion the liver size approaches its original relation to body weight, the amount of fat and glycogen decrease and the liver approaches the original cytologic state.

The fall in plasma volume and thiocyanate space during the first month of depletion was approximately proportional to the decrease in body weight. After prolonged depletion the volume occupied by these fluids per unit body weight increased slightly and proportionately. The total circulating plasma nitrogen

per 100 grams of body weight was also essentially constant for approximately one month and then increased slightly

Although the bromsulfalein clearance per rat decreased markedly during protein depletion, this change was accounted for by the loss in weight which occurred. No proof of malfunction of the remaining liver tissue was obtained by this test.

## BROMSULFALEIN CLEARANCE

G. D. LAVERS M.D. WARREN H. COLE M.D. R. W. KEPTON M.D.  
M. C. GEPHARDT M.D. AND J. M. DYNIEWICZ, Ph.D.

CHICAGO, ILL.

THE conventional bromsulfalein test has been widely recognized as one of the better determinations of liver function<sup>1,2</sup> although it does not detect minor degrees of impairment. Furthermore it has been noted that in some instances the results of this method do not coincide either with clinical evaluation or with other tests. It was hoped that by determining the rate of clearance of bromsulfalein from the blood stream rather than by measuring retention alone a more sensitive index of liver function could be obtained.

This report deals with an improved bromsulfalein test and an evaluation of liver damage in patients with chronic gall bladder disease as measured by this test.

### METHOD

The subjects used in the study consisted of a control group of forty-two patients with no known liver pathology submitted to elective herniorrhaphy, another group of thirty-eight patients submitted to elective cholecystectomy, and a third miscellaneous group of eighteen subjects with known severe liver damage including patients with hepatitis, cirrhosis and malignant metastases to the liver.

The standard 5 per cent bromsulfalein solution was used and all tests were run by multiple determinations with the patients under basal conditions. For this purpose an indwelling needle attached to a glass adapter and a rubber cap<sup>3</sup> was inserted into an arm vein and left in place. A sample of blood was drawn as a control before the injection of the dye and others were obtained at intervals during the test. Small amounts of diluted heparin solution (1000 I.U. per cubic centimeter diluted to 1 in 50 with normal saline) were injected through the rubber cap between samples to keep the needle open. The dye was administered intravenously into the other arm at a slow rate in order to prevent the irritating effect of the concentrated material from producing a phlebitis or if extravascular a severe cellulitis. Care was also necessary in the sampling to prevent hemolysis. All samples were immediately centrifuged without anticoagulant with a portable centrifuge.

The serum was treated by a procedure modified for use with the Coleman Junior spectrophotometer Model 6A. One half cubic centimeter of serum was mixed with 2 c.c. of 1 per cent saline and the mixture was divided into two equal parts. One portion was acidified by the addition of 0.05 c.c. of acidified 1 per cent HCl made by adding 0.5 c.c. of concentrated HCl to 100 c.c. of 1 per cent NaCl. The other portion was alkalinized by the addition of 0.05 c.c. of 5 per cent NaOH.

For each blood sample including the control the spectrophotometer was set at 100 (no dye) at wave length 580 with the acidified portion, then the alkalinized portion was read. In this way a correction was made for any hemolysis in each specimen and for any substances in the control serum other than bromsulfalein which might affect the reading.

From the Departments of Medicine and Surgery, University of Illinois College of Medicine.

This work was aided by a cooperative contract between the Office of Naval Research and the University of Illinois. Contract # N6ori 71 Task 13. Office of Naval Research, Department of the Navy.

Received for publication April 1949.

Originally the readings were made on a photometer, but later the more accurate spectrophotometer was used exclusively. The block comparator method of estimating retention was found too gross.

Spectrophotometric readings were converted to plasma concentration in milligrams per cent from a scale made previously with known dilutions of the dye

With regard to dosage, subjects were divided into three groups, multiple samples being obtained in all. In one, single tests were performed, in another, different doses of dye were used on the same individual, and in the third, repeated tests were run on the same patient before and after surgery, using the same quantity in each instance. The dose used in this last group was determined preoperatively by giving variable amounts on successive days, in order to obtain a dose which would give levels high enough to be read accurately.

All results were graphed on semilogarithmic paper, using the abscissa for time and the ordinate for dye concentration. In this way the rate of removal of the dye was readily visualized. The clearance coefficient,\* which represents the slope of such a graph, was used to express a numerical result of the test. The coefficients used in this study were for the ten minute period from twenty to thirty minutes following injection of dye. The reasons for using this period are given in the discussion.

## RESULTS

*Types of Clearance Obtained With Multiple Samples*—Twenty reliable tests were obtained by this method. With a normal circulation time, there is a rapid rise in concentration to a peak at one to three minutes after injection, because of mixing (Fig 1). Thereafter there is a rapid fall which, in patients with good liver function, may continue until disappearance of the dye. In the presence of poor liver function, there is a slowing in the rate of removal starting at approximately fifteen to twenty minutes and continuing until all the dye has disappeared (Fig 2).

*Normal Value for Clearance Coefficient*—It was found that there was great variation in the values of clearance coefficient in the different groups. No detectable change in plasma dye level in the ten-minute period from twenty to thirty minutes following dye injection gives a coefficient of zero. This result is obtained in cases of obstructive jaundice and the test is therefore not used in them. The group of patients with known liver damage all showed very slow excretion and coefficients less than 0.037. The gall bladder group showed better liver function, average coefficient for this group was 0.063. But a few in this group had severe liver damage, as shown by the lowest reading obtained (Table I), 0.003. The control group (heinnas) had repeated preoperative tests. A clearance coefficient of 0.037 was established on the controls as the lower limit of normal (90 per cent of the group had values higher than this). Because the average for this group was 0.082, values ranging from 0.08 to 0.03 should be considered as border line and below 0.03 as definite evidence of liver damage.

*Effect of Variation in Dosage*—This group of tests was made in order to determine the role of dosage in the rate of clearance in the same patient. Altogether twenty-five reliable comparisons were obtained in this group, which

\*The clearance coefficient for any time interval during dye removal was approximated by the following formula

$$k = \frac{\log_e [B_1] - \log_e [B_2]}{t_2 - t_1}$$

where k = the first approximation of the clearance coefficient,  $B_1$  = bromsulfalein concentration at ( $t_1$ ) time of collecting first sample and  $B_2$  = bromsulfalein concentration at ( $t_2$ ) time of collecting second sample.

Fig 1—Bromsulfalein clearance in patient with good liver function. Mixing shown in early part of graph (All graphs on semilogarithmic paper)

Fig 2—Bromsulfalein clearance in patient with poor liver function. Slow prolonged excretion of dye

included patients with normal and abnormal liver function. These tests were obtained under basal conditions and at such times in the clinical course that significant changes in liver function would not be expected. In most cases a 5 mg per kilogram dose was given first then depending on the concentrations attained, the next dose was increased or decreased.

TABLE I RESULTS OF PREOPERATIVE BROMSULFALEIN TEST EXPRESSED AS CLEARANCE COEFFICIENT IN PERIOD FROM 20 TO 30 MINUTES AFTER INJECTION

OPERATION	NUMBER OF CASES	RANGE	AVERAGE
Cholecystectomy	38	0 140 0 003	0 063
Herniorrhaphy	42	0 168 0 022	0 082
Difference			0 019*

\*Difference is statistically significant

Fig 3—Patient with good liver function Same clearance in spite of change in dye dose on consecutive days

Fig 4—Patient with cirrhosis Identical clearance in spite of change in dye dose on consecutive days

Figs 3 and 4 illustrate the rate of clearance in two patients following different dosage given on different days. The concentration of dye following a dose of 7 or 7.5 mg was greater than that following a 5 mg dose, but the rate of clearance was essentially the same. This is true in the patient with cirrhosis (Fig 4), as well as in the one with a normal liver (Fig 3). This parallelism in the rate of excretion was noted in all such tests conducted on other patients.

Fig 5.—Duplication of excretion graph. Same dye dose on consecutive days

*Changes in the Clearance Coefficient Produced by Operative Load*—In patients on a fixed regimen and in a stable physiologic state repetition of the test on consecutive days revealed identical curves for rate of clearance (Fig. 5). However, following hemorrhaphy or cholecystectomy (under gas ether anesthesia) changes were observed. In eight individuals the rate of clearance was followed preoperatively and every day after the surgical procedure until the preoperative clearance was reestablished. In most instances a test also was done on the afternoon of the day of surgery.

Following operation in every instance there was a lowering of the clearance coefficient. The greatest depression of clearance appeared on the afternoon of the day of surgery. The return to normal in most instances took four to five days. High fever, wound hematoma and other complications were immediately reflected by a slowing in the rate of clearance of the dye. The patients showing the best clearance before surgery demonstrated the least slowing as a result of the operation and recovered earliest.

*Value of Clearance Coefficient in Determining the Minimal Liver Damage in Patients With Chronic Cholecystitis*—The results of the clearance coefficient of bromsulfalein in patients admitted for elective cholecystectomy were compared with those obtained from a group of normal subjects (hemorrhaphy). This was done to determine if the test would demonstrate liver damage in patients with gall bladder disease. As shown in Table I, the gall bladder group had a

lower coefficient of clearance as compared with the control group. The difference is statistically significant ( $P = 0.015$ ). Since the gall bladder group consisted of older individuals than the control group, it was thought desirable to determine whether the difference between the two was not merely due to age.

TABLE II AGE DISTRIBUTION

OPERATION	CASES	AVERAGE AGE	UNDER 40	OVER 40
Cholecystectomy	38	42.63	13 (34.21%)	25 (65.79%)
Herniorrhaphy	42	36.46	26 (61.90%)	16 (38.10%)

It can be seen from Tables II and III that when grouped according to age alone no difference was apparent, but that a difference still existed between the gall bladder and the control groups. The control patients under 40 years of age revealed a higher coefficient than those in the same age group with gall bladder disease, the same is true for those over 40.

TABLE III RELATIONSHIP OF CLEARANCE COEFFICIENT OF BROMSULFALEIN TO AGE  
(RESULTS ARE THE AVERAGE SCORE FOR THE GROUP)

OPERATION	UNDER 40	OVER 40	ALL AGES
Cholecystectomy	0.059	0.066	0.063
Herniorrhaphy	0.080	0.085	0.082

## DISCUSSION

The customary method of performing the bromsulphalein test is dependent upon the assumptions that the patient's blood volume is 10 per cent of the body weight and that furthermore plasma volume is proportional to body weight. It has been considered that patients receiving the same dose of dye per kilogram body weight have the same plasma concentration of dye at the start of the test. This assumption appears to be a basic source of inaccuracy. It is obvious that, in persons of asthenic habitus or with changing fluid balance because of disease or other cause, plasma volume may be far from constant with relation to body weight. Patients with cirrhosis of the liver best typify this error. A large part of their body weight may be ascitic fluid and in them the dose of dye will be abnormally great per unit of plasma volume. Because of such observations, this work was designed to investigate the manner of removal of the dye from the blood and, if possible, to find a better way of measuring its removal.

As noted earlier, in patients with poor liver function, a flattening in the slope of dye excretion was noted fifteen to twenty minutes after injection. This phenomenon has been referred to by others and has led to speculation as to its meaning.<sup>11, 13</sup> The liver is the main site of removal of this dye from the blood,<sup>3, 13</sup> while other tissues account for small amounts, especially the extrahepatic reticulo-endothelial system including the spleen.<sup>5, 8</sup> Rosenthal, some years ago, demonstrated that the dye was adsorbed to protein and suggested that the size of this combination molecule accounted for its nonappearance in the urine of normal patients. After certain *in vitro* experiments,<sup>12</sup> he also proposed that the action of bile salts on surface tension allowed liberation of the dye from plasma protein in the liver. More recent work of Brauer and Pessotti<sup>2</sup> is in line with Rosenthal's theory and assigns to the true albumin fraction of human plasma the role

of binding bromsulfalein. The latter workers propose an exchange of protein bound dye between plasma and hepatic cells as the basic mechanism. This theory of removal from plasma seems acceptable. Retention of dye following India ink injection<sup>4, 8, 11</sup> may be just a mechanical blocking of the Kupffer cells with resulting decreased surface area for this physical reaction to occur.

With the usual dose of 2 or 5 mg per kilogram of body weight, the blood is cleared of the dye in from thirty to forty five minutes<sup>10</sup> but it keeps appearing in the bile for at least two hours and in some instances for as long as five or six hours<sup>3, 13</sup>. Excretion from the liver into bile is therefore obviously a separate mechanism. In patients with liver disease appearance in the bile is delayed and disappearance from the bile is slow. It seems reasonable then to assume that in these cases slow removal from the blood after fifteen or twenty minutes is a reflection of excretion from the liver into the bile. This is in contrast to the first fifteen or twenty minutes which measures mainly transfer from plasma to liver and so represents only one phase of the mechanism. This assumption would explain the fact that in nearly every patient, normal or abnormal, early fall in blood levels is relatively rapid, but the slow removal in liver disease is the most noticeable in the later stage of the test. If the liver can dispose of the dye rapidly it may continue to remove it from the blood at its maximum rate of acquisition and so in the normal subject no flattening of the graph occurs. However, if excretion into the bile is slow, then the liver becomes blocked and hence can lower the blood level later only at this reduced rate of clearance into the bile. This biphasic mechanism then, is one reason why the rate of excretion after twenty minutes can be considered more indicative of actual liver function than the response before this time.

The choice of thirty minutes as the late limit of the determinations is based on the principle of decreasing reliability of readings with high dilutions. At forty minutes there is often little or no dye left with the 5 mg dose. Therefore accurately timed samples at twenty and thirty minutes have been taken and the clearance coefficient obtained for this time interval has been considered as an index of the efficiency of the removal mechanism (mainly liver). If greater accuracy were required three samples could be taken at twenty, twenty five, and thirty minutes after injection, the coefficient from twenty to twenty five and from twenty five to thirty minutes calculated and the average determined. Thus without prolonging the test any error in one specimen could be minimized.

It may not be amiss to call attention to the work of Blumberg and Schloss<sup>1</sup> who have shown that circulatory inadequacy will slow dye excretion. Thus poor clearance in a cardiac patient with congestive failure may be evidence of poor circulation alone or combined with liver damage.

#### SUMMARY AND CONCLUSIONS

The results obtained with a modification of the bromsulfalein test, utilizing the clearance coefficient are presented. For practical purposes, the coefficient during the interval from twenty to thirty minutes after dye injection was found to be most useful, a lower limit of normal for this period being determined

This procedure measures the actual manner of removal of the dye and is a better index of liver function than present methods of studying dye retention. With it a comparison was made between a group of subjects with normal liver function and patients who were candidates for elective cholecystectomy and hence expected to show liver damage, and a significant difference was demonstrated between the two types of subjects.

The authors wish to thank Miss Ethel Carter, Mr Edward Eckert, and Mr Tohru Inouye for technical assistance in this work.

## THE CONCENTRATION OF COMPONENT A IN BLOOD, ITS ASSAY AND RELATION TO THE LABILE FACTOR

ARMAND J. QUICK, M.D. PH.D. AND MARIO STEFANINI, M.D.\*  
MILWAUKEE, WIS.

FOR clinical purposes it is advantageous to divide the clotting factors required for the formation of thrombin into two categories—the thromboplastin forms and constituents of the prothrombin complex.<sup>1</sup> The latter are essential for prothrombin activity as measured by the one stage prothrombin time. According to Quick and associates the agents in the complex are the labile factor components A and B and bound calcium.<sup>2, 3</sup> The labile factor is characterized by its instability especially in decalcified plasma and its nonadsorbability by tricalcium phosphate. Component A is the principle which is adsorbable by tricalcium phosphate, requires vitamin K for its synthesis and is deficient in one type of congenital hypoprothrombinemia. It is probably this component which is generally called prothrombin by other investigators. Component B is difficult to define. Its existence is postulated to explain a second type of congenital hypoprothrombinemia, in which the labile factor and component A appear to be normal.<sup>4</sup> This type of hypoprothrombinemia is particularly important because it is hereditary and the lowered fixed prothrombin time may run through several generations. Little is known concerning the functions of calcium in the formation of thrombin, but recent studies clearly show that it is not ionic but bound calcium that participates in the reaction.

The desirability of having methods for the quantitative estimation of the various constituents of the prothrombin complex is obvious. Recently we developed a simple procedure to estimate the concentration of the labile factor and found that rabbit blood contains fifty times and dog blood ten times as much as human blood.<sup>5</sup> In the present report experiments are described which not only yield a procedure for the estimation of component A but also furnish results which show its relationship to the labile factor.

### METHODS AND MATERIAL

The one stage method for the prothrombin time procedure was employed exactly as outlined by its originator.<sup>7</sup> The thromboplastin used was acetone dehydrated rabbit brain. It uniformly yielded a prothrombin time of 11 to 12 seconds for normal human plasma.

The tricalcium phosphate treated plasma was prepared according to directions previously described.<sup>6</sup> Plasma thus prepared is free of component A but retains practically all of its fibrinogen and all of the labile factor. Care was taken to take only the minimum quantity of tricalcium phosphate required, i.e. an amount just sufficient to render the plasma incoagulable to excess thromboplastin and an optimum concentration of calcium.

Each lot of stock solution was tested on the oxalated plasmas of the various species employed in the study. All studies were carried out on oxalated plasma (1 vol of 0.1M sodium oxalate to 9 vol of blood). It should be emphasized that tricalcium phosphate does not remove component A from citrated plasma.<sup>5</sup> For convenience, plasma treated with tricalcium phosphate is named in this paper either "calcium phosphate plasma" or " $\text{Ca}_3(\text{PO}_4)_2$  plasma."

*Isolation of a Concentrate of Component A*—The tricalcium phosphate after its removal from the plasma by centrifugation was washed with water and again packed by centrifuging. The water was poured off and the last traces adhering to the sides of the tube were removed with a filter paper. For every cubic centimeter of plasma treated, 0.1 cc of 0.2M sodium citrate was added and the mixture stirred for ten minutes. The tricalcium phosphate was removed by centrifugation. The eluate contained approximately 90 per cent or more of the component A present in the plasma.

*Vitamin K Deficiency*—Newly hatched chicks were put on a vitamin K free diet and the procedure was followed as recently outlined.<sup>9</sup>

## RESULTS

*The Estimation of the Concentration of Component A in Plasma by Mixing With Plasma Devoid of This Factor*—Since complete avitaminosis K can be achieved readily in chicks, a plasma showing little or no prothrombin activity was easily obtained. When such a plasma was progressively diluted with normal hen plasma, the prothrombin time decreased in accordance with the typical hyperbolic curve until the 50 per cent dilution was reached. After this the prothrombin time remained the same as that of the normal hen plasma (Table I).

TABLE I THE EFFECT ON THE PROTHROMBIN TIME WHEN AVITAMINOTIC K CHICK PLASMA AND HEN PLASMA TREATED WITH TRICALCIUM PHOSPHATE ARE PROGRESSIVELY DILUTED WITH NORMAL HEN PLASMA

Plasma of vitamin K deficient chick (cc)	0.1	0.09	0.08	0.07	0.06	0.05	0.04	0.03	0.02	0.01	0.0
Normal hen plasma (cc)	0.0	0.01	0.02	0.03	0.04	0.05	0.06	0.07	0.08	0.09	0.1
Prothrombin time (sec)	$\infty$	16	14	13½	12	11½	11	11	11	11	11
Hen plasma treated with $\text{Ca}_3(\text{PO}_4)_2$ (cc)	0.1	0.09	0.08	0.07	0.06	0.05	0.04	0.03	0.02	0.01	0.0
Normal hen plasma (cc)	0.0	0.01	0.02	0.03	0.04	0.05	0.06	0.07	0.08	0.09	0.1
Prothrombin time (sec)	$\infty$	17	15	14	12	11½	11	11	11	11	11

Exactly similar results were obtained when normal hen plasma was diluted with hen plasma from which component A was adsorbed with tricalcium phosphate. These results clearly show that the concentration of component A in normal hen plasma can be reduced almost 50 per cent before the prothrombin time begins to increase. In other words component A may vary between 50 and 100 per cent without affecting the prothrombin time. This was strikingly illustrated by injecting vitamin  $\text{K}_1$  into a chick with an initial prothrombin time of 10 minutes. Four hours later it was reduced to 11 seconds, i.e., to the same level as that of a hen on a complete diet. However, on comparing the prothrombin times obtained when this and normal hen plasma were mixed with plasma free of component A, it is plain that the concentration of component A in the chick blood was definitely lower (Table II). If one uses the data of Table I as a guide, it can be concluded that 0.03 cc of hen plasma contains as much component A

as 0.05 cc of the chick plasma, yet both had a normal prothrombin time. It is clear that component A does not become the determinant of the prothrombin time until its concentration is reduced below 50 per cent of the normal level.

TABLE II THE CONCENTRATION OF COMPONENT A IN THE BLOOD OF A VITAMIN K DEFICIENT CHICK AFTER THE ADMINISTRATION OF VITAMIN K<sub>1</sub>

Prothrombin time of chick plasma before giving vitamin K		10 min	
Prothrombin time of chick plasma 4 hr after giving 10 γ of vitamin K <sub>1</sub>		11 sec	
Vitamin K deficient chick plasma	0.05 cc	Vitamin K deficient chick plasma	0.05 cc
Normal hen plasma	0.05 cc	Chick plasma after vitamin K	0.05 cc
Prothrombin time (sec.)	11½	Prothrombin time (sec.)	13½
Hen plasma treated with Ca <sub>3</sub> (PO) <sub>4</sub>	0.05 cc	Hen plasma treated with Ca <sub>3</sub> (PO) <sub>4</sub>	0.05 cc
Normal hen plasma	0.05 cc	Chick plasma after vitamin K <sub>1</sub>	0.05 cc
Prothrombin time (sec.)	11½	Prothrombin time (sec.)	13½
Normal hen plasma	0.05 cc	Chick plasma after vitamin K	0.05 cc
Saline	0.05 cc	Saline	0.05 cc
Prothrombin time (sec.)	14½	Prothrombin time (sec.)	15

Because of the difficulty of attaining severe vitamin K deficiency hypoprothrombinemia in mammals and the relative infrequency of avitaminosis K in man, it was not possible to run a dilution titration such as was made with chick plasma. One of us (A. J. Q.) however found in his records of 1938 two important experiments. The first was the determination of the effect of mixing the plasma of a newborn infant having a prothrombin time of 45 seconds with an equal volume of normal human plasma. A prothrombin time of 12 seconds was obtained. Similarly, when the plasma of a jaundiced patient (prothrombin time 48 seconds) was mixed with normal human plasma the resulting prothrombin time was 12½ seconds. In both plasmas component A was greatly diminished, yet on adding half the volume of normal plasma the prothrombin time was restored to normal even though the mixture contained only about one half as much component A as normal plasma.

By using fresh human plasma treated with tricalcium phosphate as diluent the concentration of component A in normal plasma can be determined (Table III). Interestingly, almost identical results were obtained when rabbit plasma adsorbed with calcium phosphate was employed as diluent, provided the human plasma was collected with the utmost care to preserve platelets. It will be observed that as the calcium phosphate plasma was mixed with increasing amounts of normal plasma the prothrombin time decreased until a dilution of 50 per cent was attained. Beyond this the prothrombin time remained the same as that of normal plasma. As in the case of hen plasma, the prothrombin time remained normal until the concentration of component A was reduced below 50 per cent of the amount present in normal blood. Again it is clear that the concentration of component A is not the determinant of the prothrombin time. The labile factor likewise is not the deciding factor. Rabbit plasma contains fifty times as much labile factor as human plasma yet the results with rabbit and human calcium phosphate treated plasmas as diluents are almost identical.

TABLE III THE EFFECT ON THE PROTHROMBIN TIME WHEN NORMAL HUMAN PLASMA IS PROGRESSIVELY DILUTED WITH HUMAN AND WITH RABBIT PLASMA FROM WHICH COMPONENT A WAS REMOVED BY ADSORPTION WITH TRICALCIUM PHOSPHATE

\*The blood was collected in a silicone-coated syringe and transferred to a silicone coated test tube containing sodium oxalate

*Congenital Hypoprotrombinemia Deficiency of Component A*—It was fortunate that in the pursuit of this problem two patients with congenital hypoprotrombinemia of the type that lacks component A were available. Studies of the blood of these two brothers were reported previously.<sup>4</sup> Characteristically, when 1 volume of their plasma was mixed with an equal volume of normal human plasma, a normal prothrombin time was attained. In fact when the hypoprotrombinemic plasma was progressively diluted with normal plasma, a curve was obtained (Table IV) which was almost identical with that observed when avitaminotic K chick plasma was diluted with normal hen plasma. This is easily explained by postulating that both the chick's and the patient's plasma lacked component A, and since normal plasma contains nearly twice as much as is needed to produce the normal fixed prothrombin time, this minimum value is obtained when 50 per cent of the volume of normal plasma is added to the defective plasma. Interestingly, when the deficient plasma is diluted with normal human plasma treated with tricalcium phosphate, the prothrombin time increases progressively with the dilution and is practically identical with the results obtained when saline is the diluent. When rabbit plasma treated with tricalcium phosphate is used, the prothrombin times again increase progressively, but the values are shorter than those obtained with human calcium phosphate plasma. An explanation for this finding requires further study. It is clear that the plasmas of the two boys which have a consistent prothrombin time of 19 to 21 seconds lack component A. According to Quick's original prothrombin curve, those values indicate a prothrombin activity of 25 to 30 per cent of normal. In the light of the present findings, the concentration of component A in terms of per cent of the concentration of A in normal plasma may actually be lower than 25 per cent.

The present findings as well as other results from recent studies carried out in our laboratory show that the prothrombin time as determined by the one stage procedure does not measure any particular constituent of the prothrombin complex but rather the composite effect. The true determinant of the relatively fixed prothrombin time of 12 seconds in normal human plasma still remains unexplained. Because of the low concentration of the labile factor, after twenty

TABLE IV THE EFFECT OF THE PROTHROMBIN TIME WHEN PLASMA FROM A PATIENT WITH CONGENITAL HYPOTHROMBINEMIA (DEFICIENCY OF COMPONENT A) IS DILUTED WITH HUMAN AND WITH RABBIT PLASMA ADSORBED WITH  $\text{Ca}_3(\text{PO}_4)_2$  AND WITH SALINE

The patient was a 4 year old boy. He and his brother age 7½ years had prothrombin times which ranged between 19 and 22 seconds. Both had a mild bleeding tendency.

four hour storage human plasma may show a decrease of 50 per cent of prothrombin activity caused by destruction of this agent whereas rabbit plasma may show no loss as determined by the prothrombin time for a week or longer because the labile factor is in great excess. Component A may be decreased 50 per cent, according to the result of this study before the prothrombin time is prolonged. These findings do not condemn the one stage method, but rather emphasize that it measures the over all prothrombin activity. For the determination of the specific factors methods must be devised which are basically modifications of the one stage procedure. Thus a simple method of the assay of the labile factor was developed in our laboratory in which stored human plasma is the testing medium.\* From the results of the present study a simple determination of component A can be outlined. A sample of fresh oxalated plasma to be tested is mixed with increasing volumes of fresh normal human plasma treated with tricalcium phosphate and the prothrombin times of the mixtures are determined. If the concentration of component A is normal the results will be identical with those given in Table III. By means of eluting with sodium citrate the tricalcium phosphate to which component A is adsorbed a new means for assaying this component becomes available as will now be described.

*The Concentration of Component A in Human and in Dog Plasma as Determined by Re-adding to Component 1 Free Plasma the Factor Concentrated by Adsorption and Elution*—In this study evidence was offered to show that tricalcium phosphate removes only component A from oxalated plasma, therefore plasma thus treated becomes an ideal assay medium for determining component A. All that is required is to add it to the calcium phosphate plasma and determine the prothrombin time. Since the only significant component adsorbed is A and since sodium citrate elutes it almost completely the eluate is presumably a relatively pure and concentrated solution of component A. Since 0.1 cc of sodium citrate is employed to elute the product adsorbed from 1 cc of plasma, this amount when re-added to 1 cc of calcium phosphate treated plasma should restore the prothrombin time to normal. This was found to be true if human

eluate was added to human plasma, and dog eluate to its respective plasma, but when human eluate was added to dog plasma ( $\text{Ca}_3(\text{PO}_4)_2$  treated) or rabbit plasma somewhat shorter times were obtained. On the other hand, when dog eluate was added to human plasma, the resulting prothrombin time was approximately the same as that of normal human plasma. In Table V the prothrombin times obtained by adding component A eluate in progressively decreasing amounts to deprothrombinized plasma are presented. It will be observed that by adding decreasing amounts of human eluate to human deprothrombinized

plasma, prothrombin time values are obtained which correspond closely to the values of Quick's prothrombin curve. It also should be noted that only one third to one-fifth as much dog eluate as human eluate must be added to human deprothrombinized plasma to obtain a normal prothrombin time of 12 seconds. This clearly shows that dog plasma contains several times as much component A as is normally present in human plasma. This agrees with the original findings obtained with the one-stage method that dog plasma contains five times as much prothrombin as human plasma<sup>10</sup> and casts serious doubt on the hypothesis that the difference between the prothrombin times of dog and human plasma is due to variations in conversion factors.

The reason dog eluate added to human depiothrombinized plasma produces a prothrombin time of only 10 seconds instead of 6 seconds as in dog plasma is the inadequate concentration of the labile factor in human blood. Either component A or the labile factor can be the limiting factor in the production of thrombin and in determining the prothrombin time. This is strikingly illustrated by Experiment I. A small quantity of rabbit plasma supplied sufficient labile factor to reduce the prothrombin time to 10 seconds. This emphasizes the importance of controlling the concentration of the labile factor in assaying component A. Fortunately, the concentration of the labile factor has been found to have a fixed and relatively constant level for any particular species. When human plasma is employed as the assaying medium it should be used within a few hours after the blood is collected and be preserved in an ice bath. Normal human plasma does not contain sufficient labile factor to permit its use for assaying concentrated solutions of eluate such as is obtained from dog plasma.

## EXPERIMENT I

Stored human Ca (PO) plasma	0.09 cc	Fresh human Ca (PO) plasma	0.09 cc
Fluate from human plasma	0.01 cc	Fluate from human plasma	0.01 cc
Prothrombin time	25 sec	Prothrombin time	12 sec
Stored human Ca (PO) plasma	0.08 cc		
Rabbit Ca (PO) plasma	0.01 cc		
Eluate from human plasma	0.01 cc		
Prothrombin time	10 sec		
Prothrombin time of stored plasma	25 sec.		

*The Concentration of Component A in the Plasma of Congenital Hypoprotrombinemia*—The lack of component A in the type of congenital hypoprotrombinemia studied is clearly shown by the results given in Experiment II. The prolonged prothrombin time of Subject B B is due purely to a deficiency of component A. The eluate obtained from his plasma when tested for component A potencies either on normal calcium phosphate plasma or on his own plasma yielded the same low result whereas the eluate from normal human plasma restored his prothrombin level to normal exactly as it did in normal calcium phosphate plasma.

## EXPERIMENT II

Subject B B	Prothrombin time	20 sec	(Congenital hypoprotrombinemia)
Normal subject	Prothrombin time	11½ sec	
B B Ca <sub>2</sub> (IO) plasma	0.09 cc	B B Ca (PO), plasma	0.09 cc
Eluate from B B plasma	0.01 cc	Eluate from normal human plasma	0.01 cc

Normal human (Ca (PO), plasma	0.09 cc	Normal human Ca <sub>2</sub> (PO) plasma	0.09 cc
Eluate from B B plasma	0.01 cc	Eluate from normal human plasma	0.01 cc
Prothrombin time	25 sec	Prothrombin time	11½ sec

*The Concentration of Component A in Nutritional Hypoprotrombinemia*—After chicks were on a vitamin K free diet for ten days a severe hypoprotrombinemia was produced in fact a prothrombin time greater than 8 minutes occurred in about one fourth of a group of twenty chicks. An eluate of the plasma of these chicks

showed no prothrombin potency when tested on hen calcium phosphate plasma, indicating a complete lack of component A. An eluate obtained from normal hen plasma when tested on the plasma of these avitaminotic K chicks immediately restored the prothrombin to the same level as this amount of eluate did in normal hen plasma treated with tricalcium phosphate, Experiment III. It is logical to conclude that deficiency of vitamin K produces a pure component A type of hypoprothrombinemia.

## EXPERIMENT III

Prothrombin time of normal hen plasma		11 sec

Prothrombin time		13 sec	Prothrombin time	13½ sec

\*The prothrombin times of the plasmas of Chicks 2 and 3 after the addition of the eluate of normal hen plasma were 12½ and 13 seconds respectively. Previous treatment of these plasmas with tricalcium phosphate did not change their response to eluate.

*Concentration of Component A in Plasma After Administration of Dicumarol*—From the work in our laboratory, evidence has been obtained that the hypoprothrombinemia caused by Dicumarol is not identical with that brought about by vitamin K deficiency. Recently Dam and Søndegård<sup>11</sup> have also come to the conclusion that the two types of hypoprothrombinemia are not identical, although they emphasize that the primary deficiency in both is the "classical prothrombin."

In the present investigation, no attempt was made to determine the basic difference between the two types of hypoprothrombinemia. The sole objectives were to ascertain the quantitative effect Dicumarol had on the concentration of component A and to determine the response of Dicumarol plasma to the addition of an eluate of component A obtained from normal plasma. It was found, as shown in Table VI, that the response of Dicumarol plasma to the eluate from dog plasma was the same as that of normal plasma. This shows that the hypoprothrombinemia resulting from Dicumarol can be promptly and completely corrected by the addition of a concentrated solution of component A, i.e., the eluate from the tricalcium phosphate adsorbed plasma.

Eluate from Dicumarol plasma (cc) *	0.01	Eluate from Dicumarol plasma (cc) *	0.01		
Prothrombin time (sec)	38	Prothrombin time (sec)	67		

\*Eluate obtained from Dicumarol plasma which had a prothrombin time of 48 seconds.

From the results recorded in Experiment IV it is evident that this correction can be effected not only *in vitro* but *in vivo* as well. One can readily comprehend the therapeutic implications of this experiment. By two simple procedures, namely, adsorption with tricalcium phosphate and elution with sodium citrate one can concentrate the quantity of component A contained in 500 cc of blood to 25 cc and have it immediately suitable for intravenous injection. The clinical evaluation of the eluate is being studied at present.\*

## EXPERIMENT IV

Dog F, weight 8 kg given 5 mg of Dicumarol per kg of body weight daily for 4 days	
Eluate (concentrated component A) prepared from 22 cc. of fresh normal dog plasma	
Prothrombin time before injection of eluate	30 sec
Prothrombin time after injection of eluate	16 sec.

The basic defect in Dicumarol poisoning is lack of component A, the same as in avitaminosis K. This makes the hypothesis made by one of us (A J Q),<sup>2</sup> that Dicumarol causes a decrease of component B, untenable. Nevertheless there is evidence that the hypoprothrombinemia due to lack of vitamin K is not identical with that due to Dicumarol. It will be noted that the eluate obtained from Dicumarol plasma is more effective in normal than in Dicumarol plasma. Studies are being carried out to determine whether this observation is significant.

## SUMMARY

When normal ovalated plasma is added in progressively increasing amounts to plasma from which component A of prothrombin is absent or very low due either to vitamin K deficiency removal by adsorption with tricalcium phosphate or congenital lack the prothrombin time is characteristically decreased until approximately 1 volume is added to 1 volume of the defective plasma. After this the prothrombin times become the same as that of the normal plasma. This indicates that normal plasma supplies about twice as much component A as is required to attain a normal prothrombin time and that therefore it is apparently not the specific determinant of the prothrombin time even in the presence of an excess of the labile factor.

By means of adsorbing ovalated plasma with tricalcium phosphate and treating the latter with sodium citrate, an eluate is obtained which contains almost all of the component A present in the plasma. When this eluate is added in an amount equivalent to the volume of normal plasma from which it was obtained to plasma lacking component A, the normal prothrombin time is restored. By adding progressively decreasing amounts of the eluate to component A free plasma a series of values of prothrombin time are obtained which correspond well with the original prothrombin curve. Component A is active only if an adequate amount of the labile factor is present. The isolation of component A as an eluate and the testing of it on fresh tricalcium phosphate treated plasma offer a new method for its quantitative estimation.

The therapeutic possibilities of employing the eluate in various types of component A deficiencies are discussed. Its efficacy in reducing the prothrombin time in Dicumarol poisoning is illustrated in dogs.

# INTENSIVE IMMUNIZATION OF AN ALREADY SENSITIZED Rh NEGATIVE WOMAN, BIRTH OF A MILDLY DISEASED BABY

ELLIS N EAST MD \* WINNIPEG MANITOBA, CANADA AND  
C MELLIS MAIR MD † VICTORIA BRITISH COLUMBIA, CANADA

**O**NCE a woman has given birth to an Rh positive child with a fatal form of erythroblastosis, it is very uncommon for her to give birth to one less diseased<sup>1 2 3 4</sup>. This is still more rare when the woman has been sensitized by both pregnancy and transfusion. When the donor of the transfusion is the husband the outlook is almost hopeless. This situation developed in the family here recorded. The record was as follows:

## Family Blood Groups —

Dr E N E (husband) Group 0 MN P positive S negative CDe cDe (R<sub>1</sub>R<sub>0</sub>)

Mrs E N E (wife) Group 0, MN P positive S negative, cde cde (r<sub>1</sub>)

N J E (son) Group 0 S negative CDe cde (R<sub>1</sub> r)

Mr C E (father of Dr E N E) Group 0 S negative, CDe cde (R<sub>1</sub> r)

Mrs C E (mother of Dr E N E) Group A<sub>1</sub> cDE cDe (R<sub>1</sub> R<sub>0</sub>)

Mrs N C (sister of Dr L N E) CDe cDe (R<sub>1</sub>R<sub>0</sub>) ‡

## Pregnancy Record of Mrs E N E white age 35 years —

October, 1940 Abortion at twelve weeks followed by hemorrhage and pneumonia. Transfusion of 500 cc of husband's blood without reaction.

May 1942 Delivery of living child (N J E) moderately jaundiced for one week.

August 1945 Spontaneous abortion at eight weeks.

August, 1946 Delivery of macerated fetus at thirty nine weeks. Active fetal movements ceased two weeks prior to delivery. A necropsy was performed on the fetus §. The following are the gross findings:

Fetus weight 3500 gm length 48 cm. Very marked edema over the whole body, especially occiput, buttocks and extremities. Numerous ruptured blebs were present leaving a raw surface. Lips and tongue were purplish black in color. There was no fluid in the pleural or pericardial cavities. The lungs were brown firm and on section like cut meat. The heart and gut tract were normal. The liver was enlarged and of purplish brown color. The spleen was also enlarged.

From the Winnipeg General Hospital Winnipeg Manitoba Canada

Data on Rh isoimmunized woman (Mrs E. N. E.) showing injections intravenously and intramuscularly of husband's Rh positive blood. The Rh antibody titers are shown. (Tests performed by the Vancouver Red Cross Laboratory Vancouver British Columbia and occasionally confirmed by Dr Philip Levine Ortho Research Foundation Raritan N. J.) Throughout the titrations an absent or weak agglutination (negative prozone) to the albumin (blocking) anti D factor was noted in the first two to five tubes. Subjective reactions of the patient were graded as follows:

+ Slight, transient shooting pains usually of fingers

++ Few chills joint pains (see +) headache for one hour

+++ More severe chills pains and headache lasting for two hours

++++ Chills joint pains backache severe headache temperature to 101 F. Reaction lasting about three hours but responding in part to antihistaminic drugs

Tests for hemoglobin in the urine (benzidine test) were negative except as noted. Tests for urinary urobilinogen were consistently negative.

It would seem unlikely that this titer of 1 16 000 000 obtained on Feb 6 1947 is correct. The test was not confirmed.

The kidneys, adrenals and pancreas were normal. The occipital bones were both fractured in several places. The brain showed no evidence of injury or hemorrhage but marked softening and edema were present. The placenta was hypertrophic, pale and edematous.

Microscopic sections were prepared and reviewed\*. The report follows:

Single sections of tissue fixed in formalin and stained with hematoxylin and eosin were available from the following tissues: lung, adrenal, spleen, placenta, diaphragm, liver, thymus and kidney. Sections of the liver and spleen were stained for iron. Lung: The alveoli were distended with amniotic fluid but there was no inflammatory reaction. Normoblasts and large erythroblasts were present in large numbers in the capillaries of the alveoli and also in some of the larger vessels. There were several islands of blood formation in the subpleural connective tissue. These were chiefly erythropoietic but there was also

some leucopoiesis. *Adrenal* Radial streaks of cells of the fetal cortex contained each a single large vacuole which looks like a fat droplet. In some places in the adult cortex the capillaries are well preserved and contain many nucleated red cells, both normoblasts and erythroblasts. *Spleen* There was very extensive autolysis but cell nuclei could be seen throughout the section. No lymphoid follicles could be seen. There was an abnormal amount of iron within cells in circles and streaks as one sees the iron in erythroblastosis. *Placenta* Most of the villi were small with a condensed stroma but about 20 per cent were larger with a loose, empty and possibly edematous stroma. The maternal sinusoids were empty. The capillaries of the villi were fairly well preserved and contained nucleated cells, both normoblasts and erythroblasts. The remaining organs added no information, autolysis being far advanced. From the above we can say (1) The fetus had attempted to breathe in utero, aspirating amniotic fluid. (2) There had been an abnormal degree of blood destruction with deposition of iron in excess in the spleen. (3) There was abnormal blood formation with immaturity of the red cell series in the circulating blood. From these it can be concluded that the baby almost certainly had erythroblastosis and it can be assumed that the degree of anemia was so great as to cause anoxia with resulting attempted respiration. Finally, the lesion in the adrenal is commonly seen in fetuses and newborn infants dying of erythroblastosis, particularly those with hydrops, but also sometimes occurring in other clinical forms of the disease. I do not think it possible to say for certain that the fetus suffered from hydrops.

On the basis of gross and microscopic findings a diagnosis of erythroblastosis seems justified and it is assumed that death was due to this disease. A confirming factor was the persistence of Rh antibody to a titer of 1:256 (albumin anti-D) in the mother's blood two months post partum.

The outlook for the birth of a normal child to this couple appeared hopeless. It was therefore decided to attempt to "desensitize" or "stabilize" the woman by serial, increasing injections intravenously of her husband's blood. The possibility of severe reactions was recognized as well as the probability of making this isosensitized woman even more sensitive. The program of the procedure is presented in Table I and Fig. 1.

By the twenty-fourth injection (June 25, 1947) a maximum intravenous injection of 56 c.c. of the husband's blood was reached and it was obvious that no further increase could be undertaken without danger to the patient. Reactions proved almost as severe with the lesser amounts of 35 and 20 cubic centimeters. The patient had reached a stage of extremely marked sensitivity. In fact, she was given 5 c.c. of blood intravenously and suffered a reaction almost as severe as with 56 c.c. previously and much greater than with 43 c.c. on the way up. At this time it became apparent that the patient was pregnant, her last menstrual period having been on July 14, 1947. It was accordingly decided to give the husband's Rh-positive blood intramuscularly instead of intravenously. There were no subjective reactions to the intramuscular blood. The patient received a total of twenty-eight intravenous and forty-three intramuscular injections. From Nov. 9, 1947 (sixteenth week of pregnancy) until delivery the patient was given 3 to 5 Gm. per day orally of methionine (Meonine\*).

\*Meonine brand of methionine. Kindly supplied by Wyeth & Bro. Ltd., Walkerville, Ontario, Canada.

Fig 1—Mrs L. N. E. for details see Table 1

Fig —Baby L. V. E. for details see Table II

The expected date of delivery was April 21, 1948. The course of the pregnancy was uneventful with an average gain in weight of the mother and with fetal size, activity, and heart sounds being normal. Since the antibody titer had shown a continued rise from the twenty-third week of the pregnancy, a surgical induction with rupture of the membranes was performed on March 29,

Data on infant (Baby L E E) showing weight blood counts Rh antibody titer etc. Jaundice graded from + to +++ the latter indicating a deeply jaundiced condition. Spleen only slightly enlarged. At birth occasional erythroblasts were seen in the blood smear none subsequently. The red blood cell fragility was normal.

Platelets 516 600. X-rays of the skull long bones and chest were negative. All transfusions given were of compatible Rh-negative blood.

1948 (thirty-seventh week), with delivery of a lusty baby girl weighing 5 lb 12 oz (2,600 grams). The amniotic fluid was clear. The placenta was normal grossly and microscopically. On immediate thorough physical examination the infant appeared quite normal without evidence of jaundice or edema. The liver and spleen were not palpable. The following day the baby was slightly jaundiced and the tip of the spleen was palpable. The progress of the baby is recorded in Table II and Fig 2.

The Rh tests on the baby were as follows

(1) Cord blood at birth Group O cde cde (C-, D-, E-, c+) Anti human globulin test (Coombs' test) on the baby's cells was negative

	MOTHER'S SERUM WITH BABY'S CELLS	MOTHER'S SERUM WITH PANEL	BABY'S SERUM WITH PANEL
Saline	None	None	None
Albumin	None	Anti D-1 4.096	Anti D-1 4.096''

This test was repeated the following day on the same sample of blood with identical results \*

(2) Two days of age "Group O Behaves like an Rh negative blood but this is so only because of very intense coating with maternal antibodies" †

(3) Three weeks of age 'Group O Rh negative The cells are not now coated with maternal antibodies Antibodies (anti D) still demonstrable at a titer of 1:64" ‡

(4) Three and one half months of age "Group O Rh positive Type cDe cde (R<sub>0</sub> r), (C-, D+, E- c+ C-)" †‡

At date of writing (March 1949), the baby has progressed and developed quite normally

#### DISCUSSION

This case is not presented with any idea of recommending the procedure carried out as a method of treatment, even though the outcome of the pregnancy was a happy one. It does, however, present several interesting features and raises some question as to the validity of the current concepts of the pathogenesis of erythroblastosis.

One interesting feature of the case is the negative antihuman globulin test for 'cell coating' (Coombs' test) on the baby's cells at birth. Race<sup>8</sup> offers the following possible explanations of this: (a) The baby's cells were not adequately washed free from serum. (b) The antihuman globulin was not sufficiently active. (c) Though sensitized, the baby's cells failed to give a positive Coombs test. (d) At the time of birth the baby's cells were not sensitized and only became sensitized later.

Another feature was the consistent absence of or weak agglutination in albumin of the anti D factor (negative prozone) in the first two to five tubes of the titrations. Levine, Mohn and Witebsky<sup>9</sup> believe that this prozone phenomenon which usually occurs only in highly immunized individuals may be due to a third type of Rh antibody of true blocking character, in addition to saline (complete) and albumin (incomplete) antibodies. They believe that this type of blocking Rh antibody prevents agglutination by either of the others. Howard and co-workers<sup>10</sup> suggest that blocking antibody may act as a protection for the erythrocytes of the fetus. The hypothesis could be offered that this explains the successful outcome in this case.

A remarkably high titer of albumin antibody was obtained in this case. This was to be expected with the intensive additional immunizations. There

Tests performed by the Vancouver Red Cross Laboratory

†Philip Levine M.D.

‡Confirmed by Dr R. R. Race, The Lister Institute, London, England and by Dr L. K. Diamond, The Blood Grouping Laboratory, Boston, Mass.

was no correlation of the antibody titers with the reactions of the mother (Table I and Fig. 1). The recovery of an infant with such a high content and long persistence in its blood of maternal antibodies is certainly a rarity. Wiener and co-workers<sup>2, 10</sup> report a case of survival of an infant with massive exchange transfusions. In none of their previous cases had an infant survived if the mother had a titer as high as blocking test to 4 units and the albumin plasma conglutination test to 50 units. Statistics of Davidsohn and Stein<sup>4</sup> show that where blocking antibodies were present to 1:10 or less, 41.9 per cent of infants did not survive, and where the titer was above 1:10, 71.4 per cent did not survive. They also state, in regard to a mother with serum agglutinations to 1:20 and blocking antibodies to 1:5 at the eighth week of pregnancy, that the possibility that the antibodies were of the "carry-over" variety was the only hope in the case.

Carter<sup>11</sup> has very recently had considerable success in lowering antibody titers and preventing erythroblastosis by giving the mother prenatal injections intramuscularly of Rh haptens prepared by alcohol and ether extraction from pooled Rh-positive cells. The hapten<sup>12, 13</sup> also has been used with success in the treatment of erythroblastosis in the infant. It would seem to be a possibility in the case here presented that the breakdown and dissolution of the Rh-positive red blood cells at the sites of the intramuscular injections might have released some hapten for absorption.

#### SUMMARY

A report is presented of an isoimmunized Rh-negative woman. Following transfusion of her husband's Rh-positive blood and delivery of a stillborn, hydroptic infant, additional intensive immunization was brought about by intravenous injections of the husband's blood over a period of six months. An extremely high antibody titer was produced early in the course of the injections which fell rapidly and appeared to be stabilized. Pregnancy supervening and subjective reactions preventing any further intravenous injections, the patient was given a series of intramuscular injections of her husband's blood throughout the pregnancy. She was delivered of a mildly erythroblastotic infant which survived without any great difficulty. Tables and illustrations presenting the course of the mother and infant are included. Various interesting features of the case are discussed.

We would like to thank especially the Vancouver Red Cross Laboratory which performed most of our tests, Dr. R. R. Race of The Lister Institute, London, England, who confirmed the family genotypes, Dr. R. Galpin, Pediatrician, Victoria, British Columbia, who cared for the baby girl, Dr. Bruce Chown, Professor of Pediatrics, University of Manitoba Medical School, who assisted in the preparation of this report, and Dr. Philip Levine, The Rh Blood Testing Laboratory, Ortho Research Foundation, Raritan, N. J., who performed a number of the tests for us as noted in the text.

FOR several years papaverine has been used, both intravenously and orally, in the treatment of the anginal syndrome with conflicting reports as to its value. It is an isoquinoline alkaloid derived from opium which does not produce addiction<sup>1</sup>. Experimentally it has been shown in studies from this laboratory and elsewhere to be a powerful vasodilator<sup>2, 3, 4</sup>. It diminishes or abolishes premature systoles of ventricular origin<sup>5, 6</sup>. Pal<sup>7</sup> and Macht<sup>8</sup> recorded some beneficial effects with intravenous papaverine. Using oral doses of 26 mg ( $\frac{3}{8}$  gr) daily, Evans and Hoyle<sup>13</sup> reported questionable benefit. In 1942 this department administered oral papaverine in doses higher than those previously used with 400 mg (6 gr) daily there was apparent improvement in 75 per cent of the cases studied<sup>5</sup>. Since this report other authors have obtained divergent results. Swanson<sup>9</sup> reported improvement in eleven of twelve patients. Gray and co-workers<sup>10</sup> found no improvement in ten patients using daily doses of 400 mg (6 gr) and 800 mg (12 gr). White<sup>11</sup> and Gold<sup>12</sup> have both stated that the drug is of little or no value. Our clinical experience with the drug in the years since the initial optimistic report has been disappointing. This experience, plus the variable results of other investigators, demanded a critical reevaluation of the usefulness of papaverine in the treatment of the anginal syndrome.

### METHOD

The present study was carried out on patients attending the out patient Cardiac Clinic of the Michael Reese Hospital. Each of these patients had been attending the clinic for at least one year, and all had been thoroughly investigated. The criteria for selection of patients were (1) each individual must unquestionably suffer from angina pectoris, (2) the attacks must occur at least twice weekly and preferably more often, and (3) the patient must be sufficiently intelligent and cooperative for an evaluation to be made. In selecting cases for this study more than one hundred patients with the clinical diagnosis of angina pectoris were interviewed. Of these only twenty seven seemed to fit our criteria as stated. Of these twenty seven patients, fourteen were dropped as the study progressed. Of these, four improved so much during the control and placebo periods that they no longer sustained the required number of weekly attacks. The remaining ten were dropped for various reasons: consistent failure to keep appointments, inability to attend the clinic frequently because of long distance to travel, and doubt as to the accuracy of the diagnosis. The final group consisted of thirteen patients, six women and seven men, ranging in age from 35 to 73 years with an average of 64. The duration of the anginal syndrome was one to thirteen years with an average of four and one half years. Ten patients had arteriosclerotic heart disease, two had arteriosclerotic and hypertensive heart disease, and one had hypertensive heart disease. Three had definite histories of myocardial infarction.

Received for publication April 7 1949

A complete history and physical examination were done in each case. Laboratory data included a complete blood count, urinalysis, blood urea nitrogen, chest x-ray, fluoroscopy of the heart and lungs, and electrocardiograms taken before, during, and following papaverine therapy. The patients were seen biweekly, occasionally at three week intervals, usually by the same physician in an effort to establish and keep the patient-physician relationship as a constant environmental factor. Each patient was instructed to keep a diary on forms which were supplied showing the number and duration of attacks and the number of nitroglycerine tablets used each day. On each clinic visit the patient was questioned regarding subjective improvement, degree of activity indulged in during attacks, average number of blocks he could walk before anginal pain occurred, and changes in living habits and the environmental and emotional situation which might be contributory. All received nitroglycerine as required. In some instances other medication such as phenobarbital was used. The amounts of other medication were maintained constant. Three patients were on a maintenance dose of digitalis throughout the study.

At the beginning of the study, each patient was followed for at least six weeks before either placebo or papaverine medication was administered. This period served as one of adjustment for the patient and physician. When it appeared that the patient's angina had reached a basic level, he was given placebo (lactose) capsules which appeared in all respects identical with the papaverine capsules.\* These were taken four times daily before meals and at bedtime and the patient was told that the capsules were to reduce or prevent chest pain. After not less than four weeks on placebo therapy, during which time any improvement was evaluated, capsules containing 100 mg ( $1\frac{1}{2}$  gr) of papaverine hydrochloride were substituted for the placebo without the patient's knowledge. This dosage level was maintained for four weeks or more. In order to minimize the effects of spontaneous variations in the course of the disease and the psychic influence of drug administration, the patient was kept at various dosage levels of placebo or papaverine until his response appeared to have stabilized. When a definite decision could be made regarding response to the 400 mg (6 gr) daily dosage, the drug was increased to 600 mg (9 gr) a day, later to 800 mg (12 gr) daily. If there was any doubt about the response to papaverine, placebo capsules were substituted at the same dosage level. Finally, following cessation of placebo and papaverine therapy, each patient was followed for a further control period of at least four weeks. The total period of observation covered eight to twelve months.

#### CRITERIA FOR EVALUATION

The evaluation of therapy for chronic coronary insufficiency when manifested by the anginal syndrome is always a difficult task. There are at least three major reasons for this: (1) spontaneous variations in the course of the disease; (2) the noncontrollable psychic influences; (3) the absence of a reliable quantitative test to judge the effect of treatment. We believe that these factors have been mainly responsible for the variable results obtained by the different investigators who have attempted to evaluate the efficacy of papaverine in angina pectoris. The present study was undertaken with a view toward obtaining experimental conditions which would minimize the importance of the foregoing factors as much as possible. Directed toward this end were the careful selection of cooperative patients, the observation of the patient through a relatively long initial control period, and maintenance of the patient on placebo and successive dosage levels of papaverine until the response was clear.

In planning the study, consideration was given to the use of the exercise tolerance or anoxemia tests as possible objective (hence more reliable) methods to judge the effect of treatment. These tests were not used for the following reasons:

\*We are grateful to Eli Lilly & Company for supplying the papaverine and placebo capsules used in this study.

1 It would be impossible to assess the validity of changes in the patient's response to exercise or anoxemia without establishing a long control period during which these tests would have to be repeated as frequently as one or more times per week and as frequently during the placebo and drug periods. Such a program was impracticable. Furthermore, there is no evidence in the literature to indicate that either of these tests has or can be used as a fine reliable quantitative measure of the degree of coronary insufficiency.

2 Both the exercise tolerance and anoxemia tests are artificial procedures. Neither one can be considered an accurate reproduction of the total clinical state which results in angina pectoris. It was felt, therefore, that results from these tests could not be applied directly to the anginal syndrome as seen clinically. The efficacy of drug therapy in the treatment of angina pectoris can be determined only by observations on the naturally occurring syndrome.

Judging the effect of treatment in angina remains a difficult problem in clinical evaluation. When observed over periods of many months, patients with angina display wide variations in ability to walk distances and perform routine tasks, and striking differences in the number of attacks of pain suffered. Basing indications of improvement on either severity or duration of attacks or the number of nitroglycerine pills used in a given period might be misleading, although considered together these data suggest a trend. We considered the most useful criterion of the patient's course to be the number of attacks of pain suffered in a given period. It is true that with improvement the patient may increase his activity and thereby keep the attacks of pain at a constant frequency, however, the opposite is also true. Therefore, if the drug being investigated produces a striking or dramatic decrease in the patient's attacks of chest pain, there will be no doubt in the mind of the investigator as to the efficacy of his measures. Marginal results are difficult to evaluate. A dramatic result was considered to be an abrupt decrease by at least 50 per cent in the attacks of chest pain when they numbered in excess of forty per week, 75 per cent when they were between ten and forty, and 100 per cent when they were ten or less.

#### RESULTS

The results are summarized in Table I. All thirteen patients received a trial on 400 mg (6 gr) daily of papaverine. In only two patients was there a significant reduction in the number of attacks of pain. One of these (J S) showed a further reduction when the dosage was increased to 600 mg (9 gr) daily. However, at the higher level he complained of severe weakness and anorexia, and the papaverine had to be discontinued. Unfortunately the patient died suddenly before the final control period could be evaluated. The other patient (S M) who showed improvement on 400 mg (6 gr) daily was unusually sedated by the drug. Instead of his customary complaints of insomnia the patient now slept twelve to fourteen hours each night so that he no longer had frequent anginal attacks at night. This patient was so severely constipated by the papaverine that the drug had to be stopped.

Nine patients received 600 mg (9 gr) daily. Only the one already discussed (J S) showed significant decrease in the frequency of pain. Seven pa-

The numbers in parentheses indicate the duration of each observation period expressed in weeks

†This patient died suddenly shortly after papaverine was discontinued

‡This patient lost 34 pounds in weight during the period of observation. The decrease in anginal attacks and improvement in ability to work paralleled weight loss

§While taking 15 gr of papaverine daily this patient's anginal attacks became very frequent. Papaverine was decreased to 6 gr daily for a four week period without change in symptom. This was followed by a trial of placebo without significant change. During the final control period there was gradual lessening of attacks. There was no electrocardiographic evidence of myocardial infarction. This patient lost 57 pounds in weight during the period of observation and 61 pounds in a period of one year without affecting anginal syndrome

tients received 800 mg (12 gr) daily. In no case was there a clear cut improvement in the ability to perform routine activities at any dosage level of papaverine.

Toxic symptoms were observed at the 400 mg (6 gr) level in two patients. In both the complaints were of drowsiness and constipation. With the dosage of 600 mg (9 gr) daily one patient complained of weakness and anorexia and one of headache and epigastric distress. At the 800 mg (12 gr) daily level one patient complained of drowsiness and two of constipation.

#### DISCUSSION

This series is large enough and sufficiently well controlled to warrant the deduction that large doses of papaverine do not have a uniformly beneficial effect on angina pectoris distinct from a psychic action. It is possible that the random sample selected is weighted and the negative results obtained are not typical of a larger series, but even if this were so, the present study demonstrates that papaverine administered orally is of limited value in angina pectoris. This does not preclude its trial clinically since an occasional patient may be found in whom the drug has a striking, beneficial effect without untoward side reactions.

The present study differs from our earlier study in one very important respect, that is the criterion of improvement. If this criterion of a striking or dramatic reduction in the number of attacks of chest pain were applied to the earlier study it would be found that many cases classified as definitely improved would now be considered as marginal results. Thus, using our present more critical attitude the results of the two studies would not be far apart.

Since papaverine definitely acts as a powerful coronary dilator in animals, its failure to produce clinical results in man may be on the basis of one or several mechanisms. (1) Its action on the coronary vessels of man, particularly sclerotic coronaries, may be different from its action in animals. (2) Coronary dilatation in the cardiac region responsible for the anginal pain may not be great enough, or may be neutralized by dilatation of other systemic vessels with which the coronary vessels form parallel circuits. (3) Factors other than inadequate coronary flow may dominate the mechanism giving rise to anginal pain. (4) Dramatic results in patients with anginal pain, aside from psychic effects, may require a quick acting as well as a powerful coronary dilator such as nitroglycerine. Slower acting dilator drugs may permit readjustments not obtainable when a quick-acting drug is used.

#### CONCLUSIONS

1. The oral administration of papaverine in doses of 400 mg (6 gr) to 800 mg (12 gr) daily did not significantly reduce the frequency of attacks of angina pectoris or increase the patients' ability to perform routine activities. In eleven of thirteen cases followed over a period of eight to twelve months.

2. In two patients papaverine appeared to have a beneficial effect on the anginal syndrome. In one patient the results appeared to be due to the sedative effect of the drug, in the other the cause of improvement was not certain.

3 Toxic effects were noted in two patients taking 400 mg (6 gr) daily, two taking 600 mg (9 gr) daily, and three taking 800 mg (12 gr) daily. Constipation and drowsiness were the most common symptoms.

4 A careful reevaluation of the use of oral papaverine in the treatment of the anginal syndrome leads us to conclude that it is of limited value.

We are grateful to the clinic physicians for permission to use their patients in this study.

# SEMIWEEKLY TREATMENT OF SYPHILIS WITH PROCAINE PENICILLIN IN OIL

## REACTIONS AND PRELIMINARY RESULTS IN 228 PATIENTS

VIRGIL SCOTT, M D  
ST LOUIS, MO

THE superiority of penicillin over previous antisyphilitic agents has been clearly demonstrated by the results of the nationwide study of penicillin in syphilis<sup>1</sup> Early penicillin preparations, administered in aqueous solution, required hospitalization of the patient for frequent injections With the development of penicillin in peanut oil and wax by Romansky and Rittman,<sup>2</sup> the ambulatory treatment of syphilis was made possible, and results thus far available indicate that schedules employing daily injections of this material are at least as effective as aqueous regimens of similar duration More recently, longer acting repository penicillin preparations have been produced It is the purpose of this report to describe the use of one of these, crystalline G procaine penicillin in sesame oil, administered at more prolonged intervals (semiweekly) in the ambulant treatment of syphilis

The objectives of the present study were twofold (1) to determine the therapeutic efficacy of procaine penicillin in oil administered semiweekly in the treatment of syphilis, and (2) to determine the practicability of a semiweekly schedule in the treatment of ambulant patients from the standpoint of case holding The preliminary results herein presented are based on the treatment of 228 patients with all stages of syphilis At the same time, information has been obtained on the lack of toxicity of procaine penicillin in oil, particularly in respect to the procaine fraction and its continued administration over prolonged periods

### MATERIALS AND METHODS

Procaine penicillin, a slightly soluble salt, is prepared by the chemical combination of procaine hydrochloride and sodium penicillin G<sup>3</sup> The preparation employed (Duracillin, in oil\*) is suspended in sesame oil, with dispersing agents added, and contains 300,000 units of penicillin and approximately 125 mg of procaine per milliliter Ninety per cent of the penicillin is penicillin G with a potency of 940 units per milligram, and at least 50 per cent of the particles are of large size, 50  $\mu$  or more in diameter<sup>3</sup> Because of low solubility, large particle size, and suspension in oil, the penicillin is slowly absorbed and produces prolonged serum concentrations Following a single intramuscular injection of 600,000 units, the dosage employed in this study, detectable serum penicillin concentrations have been observed at forty eight hours in as many as 89 per cent of patients,<sup>4</sup> and excretion of penicillin in the urine continues for longer periods of time Because of its slow absorption, procaine penicillin in oil would appear on a priori grounds to be well suited for the treatment of syphilis

In a like manner the procaine is released slowly from its combination with penicillin and is absorbed over a period of hours Although widely used for its local anesthetic properties, and recently administered intravenously in the treatment of arthritis and other disorders,<sup>5</sup> occasional instances of intolerance or sensitivity to procaine have been reported<sup>6</sup>

From the Syphilis Clinic of Washington University Clinics and the Departments of Preventive Medicine and Internal Medicine Washington University  
Received for publication April 25 1949

\*We are indebted to Eli Lilly & Company Indianapolis Ind for this material

In the present study, because of concern in respect to the rather large amount of procaine contained in the preparation (approximately 250 mg per 2 ml dose) an attempt was made initially to screen patients in order to detect those who c tolerance to procaine might be low. Consequently each patient was questioned regarding previous procaine injections, e.g., for extraction of teeth, skin tests were performed by the injection of 0.1 ml of 2 per cent aqueous procaine solution (2 mg) intradermally and, in reference to systemic intolerance 0.5 ml (10 mg) was injected intramuscularly. After thirty minutes of observation, an initial dose of 300,000 units of procaine penicillin in oil was injected. All subsequent injections being of 600,000 units each. On each of the first three return visits, patients were questioned by a physician regarding both local discomfort and general reactions and the injection site was inspected and palpated.

**Regimens Employed**—The results of the national study of penicillin in syphilis have shown essentially similar failure (or retreatment) rates for aqueous penicillin with schedules varying in duration from four to fifteen days in dosage from 12 to 48 million units,\* and in interval between injections from two to six hours.<sup>9, 10</sup> Results with penicillin in peanut oil and wax administered either daily or twice daily for eight and for fifteen days in total dosages of 48 to 96 million units have not been significantly different.<sup>11, 12</sup> Because prolongation rather than intensification may prove to be the important factor in the treatment of syphilis and because of previous experience on a small scale using penicillin in peanut oil and wax schedules involving semiweekly injections of 600,000 units of procaine penicillin in oil were chosen. Experimental support for increasing the total duration of treatment has been presented by Eagle, Magnuson and Fleischman<sup>13</sup> who obtained successful results in treating rabbit syphilis with a schedule consisting of intramuscular injections of only 7 units of aqueous penicillin per kilogram of body weight over a prolonged period. It is significant that with this regimen Eagle and co-workers were at no time able to demonstrate detectable serum penicillin concentrations. Low concentrations acting over a long period of time were more effective than high concentrations acting over a short period of time. Subsequently, the same authors<sup>14</sup> found penicillin in peanut oil and wax to be two to fourteen times more effective than aqueous solutions in the treatment of experimental syphilis. For these reasons, therefore the duration of treatment of patients included in the study was arbitrarily prolonged to seven and one-half weeks (total dosage 90 million units) or alternately, in some patients with more serious late forms of the disease to ten weeks (120 million units).

**Clinical Material**—All new patients with syphilis regardless of stage of disease were treated with one or the other of the foregoing schedules. The diagnosis and treatment regimen in 28 patients are indicated in Table I. The division between early and late latent syphilis is based on the two year time period.

TABLE I. DIAGNOSIS AND TREATMENT REGIMEN EMPLOYED IN 28 PATIENTS

SCHEDULE	TOTAL DOSAGE	90 MILLION UNITS	120 MILLION UNITS	TOTAL
	DURATION	7½ Wk	10 Wk

## RESULTS

*Toxicity —*

*Procaine* Of forty-four patients subjected to the screening procedure for procaine toxicity, none reported previous untoward reactions to the drug. The intradermal test was interpreted as negative in forty-two and doubtful (slight erythema) in two. Although the intramuscular test dose resulted in no evidence of procaine intolerance, one patient reported suggestive symptoms following the injection of procaine penicillin in oil. This patient, a 38-year old white woman with late neurosyphilis recently receiving treatment with the arsenicals and bismuth, was unaware of any previous procaine injection. She was one of the two patients whose skin test showed erythema and, consequently, although 10 mg of procaine alone intramuscularly resulted in no subjective evidence of intolerance, she received only 150,000 units of procaine penicillin in oil as the initial dose. There were no immediate untoward symptoms but about ten hours later she awoke with feelings of extreme apprehension, nervousness, dyspnea, tightness in the chest, palpitation, tachycardia, and generalized numbness. These symptoms, varying in intensity but gradually diminishing, persisted for three days. Further injections of procaine penicillin in oil were refused, and treatment was subsequently carried out without difficulty with penicillin in peanut oil and wax. The symptoms described are compatible with procaine intolerance, but proof of its causal relationship is lacking.

Although the pretreatment procaine survey was discontinued after the original series of forty-four patients had been completed, all patients receiving procaine penicillin in oil were questioned on each return visit by the treatment nurse and at frequent intervals by a physician, and no further instances of suspected procaine intolerance occurred.

*Penicillin* Of the 212 patients who have completed treatment, two with pre-existing dermatophytosis pedis developed, after the first injection of procaine penicillin in oil, transitory vesiculopapular eruptions limited to the feet which disappeared promptly without interruption of treatment. Five patients developed generalized pruritic eruptions (papular in two, urticarial in three) during the course of treatment. In one patient, who one year previously had developed a giant hive at the site of injection of aqueous penicillin for pneumonia, generalized urticaria appeared after the first injection of procaine penicillin in oil. In two patients the generalized eruptions appeared after the fourth injection, and in one each after the sixth and seventh injections. In two of these five patients treatment was interrupted temporarily, in three, itching was controlled with an antihistaminic drug and treatment was continued uneventfully.

These eruptions were similar to those observed previously in patients treated either with aqueous penicillin or with penicillin in peanut oil and wax. The incidence of this type of reaction following procaine penicillin in oil (approximately 2.5 per cent of patients) is less in our experience than with penicillin in peanut oil and wax (5 per cent).

The procaine penicillin in oil preparation has proved superior to penicillin in peanut oil and wax in other respects. These include ease of handling and of administration, and absence of local discomfort and of nodule formation such as was observed following the inadvertent superficial injection of penicillin in oil and wax. Rarely, and because of faulty technique of injection, transient numbness of the leg on the injected side has occurred.

In summary, in approximately 3500 injections administered to a total of 228 patients, of whom 212\* have received from fifteen to twenty injections over seven and one half to ten week time periods, there has been only a single instance of suspected (but not proved) procaine intolerance and an incidence of 25 per cent or less of generalized eruptions of the type attributed to penicillin. From the standpoint of ease of administration and absence of local discomfort, this procaine penicillin in oil preparation has proved highly satisfactory.

#### THERAPEUTIC EFFICACY

In a chronic infection such as syphilis little information on the therapeutic effectiveness of an agent can be gained from a small series of patients with diverse stages of disease observed for only brief periods of time. It is to be emphasized that the data to be presented are meager, and final interpretation must wait upon future experience. Preliminary impressions of therapeutic effectiveness can be obtained (1) in early syphilis by the disappearance time of *Treponema pallidum*, by the rapidity of healing of lesions, by the serologic response and by the occurrence of relapse (2) by the healing of lesions in benign late syphilis and (3) by the trend of the cerebrospinal fluid abnormalities in neurosyphilis.

*Early Syphilis*—*T. pallidum* disappears rapidly (within twenty four hours) from the moist lesions of early syphilis following injection of an effective antitreponemal agent. In the twenty four patients with early syphilis treated with the semiweekly schedule (600,000 units per dose), dark field examination was frequently impracticable at the time of the first post treatment visit because of the advanced stage of healing. For this reason ten patients with dark field positive lesions of early syphilis† were observed eighteen to twenty four hours after an initial injection of 300,000 units of procaine penicillin in oil. In each instance *T. pallidum* were no longer present in serum expressed from previously dark field positive lesions‡. This corresponds with previous findings following penicillin either aqueous or in oil and wax.

As indicated the lesions of early syphilis promptly resolved; this is in conformance with observations following the administration of other penicillin preparations.

In respect to serologic response the data are too meager for statistical presentation. However, as of this writing, eight of twenty four patients have

\*Sixteen patients lapsed before completing treatment.

†Not otherwise included in this report.

‡The author wishes to thank Dr. Leland Hanchett, Medical Director, Midwestern Medical Center, for these observations.

achieved seronegativity, the remainder have doubtful or low-titered quantitative tests. None have relapsed either clinically or serologically, there have been no reinfections.

It should be emphasized that none of the above-mentioned criteria, other than relapse, are reliable indicators of therapeutic efficacy. The adequacy of any therapeutic agent (in early syphilis) can be determined only by the careful and prolonged observation of large numbers of patients for evidence of clinical and serologic relapse. However, there is reason to believe that procaine penicillin in oil will prove to be at least as effective as penicillin in oil and wax.

The lesions of benign late syphilis heal after even relatively minute amounts of aqueous penicillin.<sup>17</sup> The prompt response of the six patients with gummas (two cutaneous, one mucosal, two visceral) treated with procaine penicillin in oil would be anticipated.

*Neurosyphilis*—It has been emphasized by Dattner<sup>18</sup> that the most reliable indicator of therapeutic effectiveness in neurosyphilis is the response of the cerebrospinal fluid abnormalities, particularly in terms of cell count and total protein. Improvement in colloidal and quantitative complement fixation tests follows slowly and may require several years to become manifest. Of the seventy-four patients with neurosyphilis included in the present study, twenty-five have thus far had examinations of the cerebrospinal fluid approximately three to four months following completion of treatment. Evidence of "activity" of the syphilitic process before treatment is documented by the following data. Using the method devised by Reynolds,<sup>19</sup> but employing median values rather than means as a more representative centering constant for small series, the results of the pretreatment cerebrospinal fluid examination in these twenty-five patients were as follows: cell count =  $92/3$ ,\* total protein = 64 mg per cent, colloidal gold = 15,† complement fixation test = 16‡. The initial post-treatment results in these same patients obtained three to four months following completion of treatment are in striking contrast: cells =  $10/3$ , total protein = 46 mg per cent, colloidal gold = 3, complement fixation test = 4.

The three following brief case reports are typical of the cerebrospinal fluid response in patients observed for more prolonged periods of time. Although none thus far have required re-treatment, much longer observation will of course be necessary to determine the ultimate outcome.

CASE 1—A. B. (A 4271) a 41 year old white man with untreated late meningovascular neurosyphilis, received 12 million units of procaine penicillin in oil (600,000 units twice weekly) between January 30 and April 6, 1948. The cerebrospinal fluid results are indicated in Table II. The blood serologic titer over the same period decreased from 600 to 120 Kahn units.

\*Fuchs-Rosenthal counting chamber: 92 cells per  $3.2 \text{ mm}^2$  of spinal fluid.

†Arithmetic sum of the first three tubes: e.g.  $555+321000 = 15$ .

‡In this laboratory the spinal fluid complement fixation test is quantitated by using decreasing amounts of spinal fluid as follows: 1.0, 0.5, 0.25, 0.12, 0.06, 0.03, 0.01, and the result of each reported. In accordance with Reynolds' reciprocal values were assigned to the various readings: 0.01=100, 0.03=33, 0.06=16, 0.12=8, 0.25=4, 0.5=2, 1.0=1.

\*In this and in subsequent table the number refers to days before the end of treatment, to immediately preceding the beginning of treatment

CASE 2—J M (A 7483) a 49 year old colored man with a entirely untreated (two bi-month injections even years previously) late asymptomatic neurosyphilis of twenty years duration received fifteen injections of procaine penicillin in oil, total dosage 9 million units between Dec 19 1947 and Feb 6 1948. The cerebrospinal fluid response is recorded in Table III. The blood serologic titer remained unchanged during this interval.

\*See footnote to Table II

CASE 3—P M (A 844) was a 7 year old colored man with late asymptomatic neurosyphilis of twenty one years duration. Previous treatment administered elsewhere included fever therapy 1 injection of Mapharsen twelve of bismuth and nineteen of Aldarsone between March and December of 1946. As recorded the cerebrospinal fluid on admission here one year later showed evidence of marked activity. Between Dec 19 1947 and March 2 1948 he received 12 mill on units of procaine penicillin in oil (600 000 units twice weekly). The cerebrospinal fluid results are recorded in Table IV. The blood serologic titer, low at the onset remained unchanged during this observation period.

TABLE IV CEREBROSPINAL FLUID RESPONSE IN CASE 3

See footnote to Table II

The results obtained thus far in patients with neurosyphilis are comparable to those previously obtained by us using aqueous penicillin in similar amounts administered in divided doses every three to four hours to hospitalized patients over two to three week time periods. The advantage of the present method is its applicability to ambulant patients.

It should be emphasized that the particular schedules employed in this study are empirical and that no special virtue can be claimed for semi-weekly injections over the two time periods arbitrarily chosen. It seems probable that a variety of regimens e.g. daily three weekly etc. over varying periods of time will prove equally effective.

## HERXHEIMER REACTIONS

An evaluation of the Jarisch-Herxheimer phenomenon requires hospitalization of the patient, particularly in respect to the occurrence of fever. Since one of the objectives of the present study was to determine the practicability of procaine penicillin in oil in the treatment of ambulatory patients, only six patients were in the hospital at the time of their initial treatment. Three of these developed febrile reactions (tabetic neurosyphilis, 38.1° C, parietic neurosyphilis, 39° C, gumma of the liver, 40° C), three did not (primary syphilis, early latent syphilis, syphilitic aortic regurgitation). The time interval between the injection of procaine penicillin in oil and the height of the fever (six to sixteen hours) was the same as with aqueous penicillin. It can be said, therefore, that Herxheimer reactions of the febrile type occur with this penicillin preparation but data as to the incidence are not available in our material.

In view of current concern over the possible occurrence of the Jarisch-Herxheimer phenomenon in cardiovascular syphilis,<sup>15, 16</sup> it is of interest that no clinical evidence of such a reaction was detected in any of twelve patients with either syphilitic aortic regurgitation or aneurysm, or both. Nine of these had received prior treatment (recent or remote) with the metal antisyphilitic agents, three were untreated previously. No special precautions were employed in this group of patients. In the seventy-four patients with neurosyphilis, of whom the majority had active disease as reflected by the cerebrospinal fluid abnormalities, headache after the initial injection was rare and neither severe nor prolonged.

From the standpoint of Herxheimer reactions it would appear that the majority of patients with late syphilis can be treated safely on an ambulant basis. This statement is predicated on the assumption that a careful and complete medical history and physical examination do not reveal evidence of such lesions as gumma of the larynx or of the brain where Herxheimer reactions of a serious nature might occur. In patients with parietic neurosyphilis, because of the very nature of the disease as well as because of the high incidence of Herxheimer reactions, hospital rather than ambulant treatment is to be preferred. Although no convincing evidence of the occurrence of this type of reaction has been presented in cardiovascular syphilis, the advisability of routinely instituting treatment with penicillin remains to be determined.

## CASE HOLDING

Of primary importance from the public health standpoint is the number of patients who fail to complete treatment administered on an ambulatory basis. Therefore, in the evaluation of schedules for the outpatient treatment of syphilis, the success or failure of case holding is a paramount concern. Dexter,<sup>20</sup> in reporting the results of semi-intensive arsenotherapy (three injections of Mapharsen and one of bismuth per week for ten to fifteen weeks) at the Johns Hopkins Syphilis Clinic, recorded a lapse rate of 40 per cent. Others (cited by Dexter) using similar schedules have had equally poor success in

case holding. With penicillin in peanut oil and wax, on the other hand, lapses appear to have been distinctly less. For example, Hayman,<sup>21</sup> with schedules consisting of daily injections for six to ten days reported that 87 per cent of 110 patients completed treatment without interruption. Similarly in Chope and Malcolm's<sup>22</sup> series 96.6 per cent of 437 patients completed a ten day penicillin schedule, and Frost<sup>3</sup> reported that 98 per cent of 952 patients completed ambulatory treatment with penicillin, Mapharsen, and bismuth on two schedules, one of ten and one of twenty four days' duration. It is clearly apparent that in general the shorter the schedule the fewer the patients who will fail to complete treatment. A second factor is the untoward reactions (or lack of them) resulting from the antisyphilitic agent employed. Other factors which need not be considered here include patient education, case holding personnel, case holding methods employed, etc.

Schedules used in the present study are longer in duration than those employing penicillin cited (seven and one half and ten weeks as compared with six to twenty four days) and the percentage of lapsed patients is in general slightly greater. Of the 228 patients sixteen (7 per cent) are considered to have lapsed. Six of these lapsed only after they had received more than 60 million units of penicillin and probably had adequate treatment. Other things being equal it would appear that ambulatory regimens employing penicillin will prove superior to arsenical bismuth schedules from the standpoint of case holding.

#### SUMMARY AND CONCLUSIONS

1. Procaine penicillin in oil was administered semiweekly to 228 patients in the ambulatory treatment of syphilis.

2. Two arbitrary schedules of therapy have been used: 600,000 units being injected intramuscularly semiweekly for seven and one half weeks or alternatively for ten weeks.

3. In respect to toxicity one instance of suspected (but not proved) procaine intolerance was observed. No evidence of chronic procaine toxicity developed.

4. Cutaneous reactions of the type attributed to penicillin occurred in five patients (less than 2.5 per cent).

5. On the basis of preliminary evidence this type of repository penicillin seems well suited for the ambulant treatment of syphilis. The criteria considered included disappearance time of *T. pallidum*, rapidity of healing of lesions, and serologic trend in early syphilis, and the response of the abnormalities of the cerebrospinal fluid in late neurosyphilis. Final evaluation of the schedules employed in the present study must await wider application and more prolonged observation.

6. No serious reactions of the Jarisch Herxheimer type occurred.

7. From the standpoint of case holding 93 per cent of 228 patients completed treatment, 7 per cent lapsed. In this respect the ambulant treatment of syphilis with penicillin appears to be more successful than with arsenical bismuth regimens of comparable duration.

## HISTAMINE ANTAGONISTS

### XIV AN EXPERIMENTAL AND CLINICAL STUDY OF N,N-DIMETHYL-N 2 THIAZOLYL N'p METHOXYBENZYL ETHYLENEDIAMINE HYDROCHLORIDE (194 B)

THEODORE B. BERNSTEIN, M.D. and SAMUEL M. FEINBERG, M.D.  
CHICAGO, ILL.

ALTHOUGH the antihistaminic drugs currently available are valuable agents for producing symptomatic relief in the management of allergic diseases the results attained have not measured up to the earlier enthusiastic clinical claims for these substances. Their deficiencies include failure to produce relief of sufficient degree and duration, failure to benefit certain types of allergic manifestations, failure to relieve severe allergic symptoms, and the occurrence of certain toxic side reactions. For these reasons new compounds of the ethylenediamine series continue to be synthesized for experimental as well as in laboratory animals and clinical trial in human allergy.

We have been studying several of these new substances during the past year. One of them is N,N-dimethyl-N 2 thiazolyl N'p methoxybenzyl ethylenediamine hydrochloride (194 B)\*. It was found to be a good drug for clinical use, combining effectiveness with a low incidence of undesirable toxic symptoms.

Laboratory studies by Kitzes, Soudern, and Neary† have shown that compound 194-B has potent antihistaminic properties and low acute and chronic toxicity. We employed several procedures to determine the antihistaminic potency of this drug in guinea pigs. Intraperitoneal injections of 0.1 mg. per kilogram protected all animals against I.M.D. 100 of histamine (0.4 mg. base) given intravenously. The inhalation of a 2 per cent aerosol of this compound for five minutes at 5 pounds pressure released through a DeVilliss nebulizer permitted the animals to remain ten minutes or longer in an aerosol of histamine obtained from a solution of 0.5 mg. per cubic centimeter without showing dyspnea. The same animals when unprotected would have marked dyspnea in two minutes or less. The duration of protection conferred by the aerosol was about seventy five minutes. The intraperitoneal injection of 5

†Kitzes, C., Soudern, C. W., and Neary, E. R., New Antihistaminic Compounds. V. Aralkyl Derivatives of N 2 Thiazolyl N,N-Dimethylethylenediamine. I. Pharmacologic Study. (In press.)

mg of this compound per kilogram was required to give protection against the same histamine aerosol. The duration of this action was about two and one-half hours.

In a group of ten guinea pigs which were actively sensitized with horse serum, 10 mg per kilogram of this compound intraperitoneally were sufficient to prevent anaphylactic death from an intracardial shocking dose. In a control series of unprotected animals the mortality was 85 per cent.

We previously had devised a method to assay or quantitatively titrate the ability of an antihistaminic drug to inhibit the local reaction produced by histamine on the human skin. Essentially the method consists of applying dilutions of the drug to a series of scratches on the skin, and afterwards testing these sites with a dilution of histamine which had previously been determined to give half maximal reactions. Several antihistaminic agents can be assayed simultaneously on one subject, and twenty to forty subjects are used for each complete assay. Compound 194-B was shown by this method to be an effective inhibitor of the histamine flare and it compares favorably with several others tested.

The clinical results obtained in the symptomatic treatment of various allergic conditions with compound 194-B are tabulated (Table I). The group consisted of 249 patients of whom 148 had seasonal hay fever. The dosage in most instances was 50 mg, although a number used 100 mg when sufficient relief was not obtained with the smaller dosage and when side effects were

TABLE I SYMPTOMATIC RELIEF WITH 194 B

ALLERGIC DISEASE	NUMBER OF PATIENTS	SATISFACTORILY HELPED	PER CENT HELPED
Hay fever	148	94	64
Perennial rhinitis	37	15	41
Asthma	30	2	6
Cough (allergic)	12	3	25
Atopic dermatitis	9	3	33
Urticaria	9	3	33
Migraine	3	1	
Heat urticaria	1	0	
Total	249		

not a bar to increased dosage. The frequency and regularity of administration depended upon the character of the complaint. Patients with continuous symptoms, generally those with chronic perennial rhinitis, atopic dermatitis, chronic urticaria, and some with hay fever, took the medication several times daily, usually after meals. The others, whose symptoms were characterized by isolated attacks, used one dose, occasionally repeating it a few hours later if necessary. Careful and repeated observations were carried on to be reasonably certain that the symptomatic relief following medication was due to the treatment.

The best results were obtained by the hay fever patients, with 64 per cent obtaining satisfactory and consistent relief. A smaller percentage of the patients with perennial rhinitis (41 per cent) was benefited. The results

with asthma were poor and similar to what had been our experience with other antihistaminic substances. Because of the small number of the other types of allergic manifestations it is not desirable to draw conclusions until a larger number of patients is treated.

The side effects from compound 194 B were of the same nature as those produced by the older antihistaminic agents. In most instances they were mild and only rarely was it necessary to discontinue medication. Mild sedation was the most common side effect occurring in forty one patients (16 per cent). A few patients complained of nervousness (four), gastrointestinal symptoms (four) and dermatitis (3).

#### SUMMARY

The laboratory experience and clinical results produced by another recently synthesized antihistaminic agent, N,N dimethyl N 2 thiazolyl N' p methoxybenzyl ethylenediamine hydrochloride (194 B) are reported. This compound was found to have potent antihistaminic and antianaphylactic properties as determined by various experimental methods. Its clinical use was attended with favorable symptomatic relief in seasonal hay fever, but negligible improvement in asthma. Toxic side reactions were few in incidence and mild in degree.

# THE APPRAISAL OF ANTICHLINERGIC ACTIVITY BY PREVENTION OF METHACHOLINE-INDUCED FATAL BRONCHOSPASM IN GUINEA PIGS

GRAHAM CHEN, M S , Sc D , M D , AND CHARLES R ENSOR, B A , M S  
DETROIT, MICH

**P**HARMACOLOGICALLY, four etiological factors are possible in bronchial asthma (A) A local or systemic increase of histamine concentration as in allergy, (B) hyperactivity of the parasympathetic or (C) hypoactivity of the sympathetic nervous system, and (D) toxic agents acting directly on the bronchial muscle, notably the irritants. Accordingly, antihistaminic, anticholinergic, sympathomimetic, and spasmolytic substances have been employed successfully for the relief of asthmatic attacks. Due to their common effect of relaxing the bronchial muscles, all these agents with different pharmacologic actions will alleviate spasm somewhat, regardless of the cause or causes of asthma in question. Therefore it is unreasonable in rational therapy to praise one drug or one type of drug as superior to others in the treatment of bronchial asthma in general. One agent will be more efficacious than others for a particular asthmatic condition for it will specifically antagonize the causative agent or modify a disturbed physiologic function before muscular spasm occurs.

For these reasons we have in the past two years been testing compounds both for their antihistaminic and anticholinergic properties against bronchial spasm in guinea pigs. This will assist us more precisely to elucidate the pharmacodynamics of bronchial dilating drugs in the management of asthmatic conditions. In this paper there will be presented a testing procedure and the anticholinergic activities of a number of substances as determined by this method.

## EXPERIMENTAL

The procedure of Loew, Kaiser, and Moore, based on protection against the lethal effect of histamine aerosol in guinea pigs, was adapted in our work with methacholine. Acetylcholine, which has been employed with or without prostigmine by previous investigators,<sup>1, 2</sup> was found not very satisfactory as a cholinergic stimulant for the bronchial muscles. Acetylcholine in solution is not very stable, furthermore a high concentration of it is required to produce fatal bronchospasm in guinea pigs. Among the stimulants tested, acetyl beta-methylcholine chloride (methacholine) and carbamyl choline chloride were found to kill guinea pigs at very low concentrations in the mist. Owing to its pure muscarinic action and close similarity in other pharmacologic properties to acetylcholine, methacholine was used in our work.<sup>3</sup>

The capacity of the enclosed compartment for the animals is 16 liters, half a cubic centimeter of methacholine solution (1 to 200 dilution) is sprayed

into it in fifteen to twenty seconds. A total of ten minutes is allowed for the animals to breathe the methacholine vapor. The anticholinergic agent is injected intraperitoneally fifteen minutes before the test or, when given orally, thirty minutes beforehand. For each experiment a control is run on animals of the same stock without medication.

Fig. 1

## RESULTS AND DISCUSSION

In Fig. 1 are given the dose mortality curves with methacholine aerosol in percentages and in probit units. Each point was obtained with twenty-eight animals four in a group. One hundred fifty-eight micrograms of methacholine per liter of air (0.5 cc of 1 to 200 solution) which would kill around 98 per cent of animals was chosen as a challenging dose for determining the anticholinergic effect of a compound. In Table I are recorded the anticholinergic activities of various compounds some of which possess also antihistaminic or/and spasmolytic properties. The antihistaminic activities of these compounds are given

in the table for comparative studies. The data indicate that atropine is the most effective while aminophylline is the least effective agent for alleviating methacholine-induced bronchospasm in guinea pigs. The results are in good agreement with observations in man from vital capacity determinations.

TABLE I ACTIVITIES OF COMPOUNDS IN PREVENTING FATAL BRONCHOSPASM IN GUINEA PIGS RECEIVING METHACHOLINE OR HISTAMINE AEROSOL

COMPOUND	ANTIMETHACHOLINE PD <sub>50</sub> ± S.E.* (MG/KG)	ANTIHISTAMINE PD <sub>0</sub> ± S.E.* (MG/KG)

\*Intraperitoneal dose average standard error calculated by the method of Miller and Tainter.<sup>4</sup>

†Kindly made available to us by Dr. E. Jones and Dr. C. K. Banks, Chemical Division, Research Laboratories, Parke, Davis & Company.

It is of interest to note the recent publication of Hambourger and associates on the protective action of combinations of diphenhydramine and aminophylline in guinea pigs receiving methacholine aerosol.<sup>6</sup> Their determinations for the individual compounds agree with ours in that large doses of the two are required to obtain a 50 per cent protection of animals inhaling a lethal concentration of methacholine aerosol. Evidently then, measurements represent principally the anticholinergic effects of the two substances individually and in combinations. As judged from the antihistaminic activities and toxicities of diphenhydramine and aminophylline and their PD<sub>50</sub> antimethacholine doses<sup>6</sup> (Table I), it is improbable that clinically the two substances relieve bronchial asthma chiefly by virtue of their anticholinergic effect. In patients whose asthmatic condition simulates that following methacholine injection,<sup>5,7,8</sup> either atropine or epinephrine should be the therapeutic agent of choice to bring about a quick relief of symptoms.

#### SUMMARY

A procedure is described for evaluating the anticholinergic effect of a compound in fatal bronchospasm of guinea pigs induced with methacholine aerosol.

Of the compounds studied, the decreasing order of potency was as follows: atropine sulfate, Dibutoline sulfate, n-(β-dimethylaminoisopropyl) phenothiazine HCl, 2-n-propoxy-4,6-diamino-s-triazine, diphenhydramine (Benadryl), papaverine, isonipercaine, khellin, and aminophylline.

Evidently then measurements represent principally the anticholinergic effects of the two substances individually and in combinations. As judged from the antihistaminic activities and toxicities of diphenhydramine and aminophylline and their PD<sub>50</sub> antimethacholine doses<sup>6</sup> (Table I), it is improbable that clinically the two substances relieve bronchial asthma chiefly by virtue of their anticholinergic effect. In patients whose asthmatic condition simulates that following methacholine injection,<sup>5</sup> either atropine or epinephrine should be the therapeutic agent of choice to bring about a quick relief of symptoms.

#### SUMMARY

A procedure is described for evaluating the anticholinergic effect of a compound in fatal bronchospasm of guinea pigs induced with methacholine aerosol.

Of the compounds studied, the decreasing order of potency was as follows: atropine sulfate, Dibutoline sulfate, n-(β-dimethylaminoisopropyl)phenothiazine HCl, 2-n-propoxy-4,6-diamino-s-triazine, diphenhydramine (Benadryl), papaverine, isonipercaine, khellin, and aminophylline.

# FURTHER STUDIES ON ENHANCEMENT OF HETEROPHILE AGGLUTINATION TITERS BY MEANS OF SERUM DILUENT

ALBERT MILZER, PH D, AND SHIRLEY NATHAN, BS  
CHICAGO, ILL

RECENTLY we reported that heterophile and various bacterial agglutination titers were significantly enhanced by the use of serum diluent instead of saline<sup>1</sup>. This paper is a further report on the enhancement of heterophile agglutination titers by use of serum and other diluents in place of physiologic saline. Routine heterophile agglutination tests were done, as previously, comparing saline and pooled human serum diluents. Titrations using human ascitic fluid,\* horse serum,\* bovine serum,\* 20 per cent bovine albumin, 20 per cent human albumin, and 10 per cent gamma globulin diluents were also carried out.

## METHODS

The technique of Paul and Bunnell<sup>2</sup> was used in heterophile agglutination tests. The patient's serum was first inactivated by heating at 56° C for one half hour. Serial two-fold dilutions were made of the patient's serum in saline diluent, and equal parts of 1 per cent sheep cells in saline were added to each tube. The tubes were shaken and incubated at 37° C for two hours. Next they were removed and kept overnight in the icebox at 5° C. The titer was read as the highest dilution showing distinct visible clumps of erythrocytes.

Tests using ascitic fluid, horse serum, bovine serum, 20 per cent bovine albumin, 20 per cent human albumin, and 10 per cent human gamma globulin were carried out in an identical manner except that these various diluents were used in place of saline. Human serum, horse serum, and bovine serum diluents were inactivated by heating at 56° C for one half hour, and all diluents were tested for the presence of heterophile antibodies prior to use. If present, heterophile agglutinins were removed by repeated absorption with sheep cells. Often, heterophile agglutinins were detected in pooled human serum and bovine serum prior to absorption with sheep cells. A diluent and saline corpuscle control tube were included in each test. The Davidsohn guinea pig kidney absorption test for infectious mononucleosis<sup>3</sup> was carried out in a similar manner with the patient's serum absorbed with 20 per cent guinea pig kidney suspension one hour at room temperature prior to titration.

## RESULTS

Heterophile agglutination titrations comparing saline, ascitic fluid, horse serum, bovine serum, 20 per cent bovine albumin, 20 per cent human albumin, and 10 per cent human gamma globulin diluents in individuals with positive and negative clinical and hematologic† findings for infectious mononucleosis are summarized in Table I. Sheep erythrocytes suspended in saline were added to the tubes containing the various diluents. It was noted that the clumps of sheep cells in the various serum diluents were more easily dispersed on shaking than in saline.

## LABORATORY METHODS

### A COMPARISON OF EOSIN ACETONE AND PHLOXINE PROPYLENE GLYCOL DILUENTS IN EOSINOPHIL COUNTS

CAPTAIN PHILIP H. HENNEMAN, M.C. \* HILDA WALKER, A.B. AND  
MARY M. WESTENHAYER  
WASHINGTON, D. C.

THE potential value of direct chamber counts of circulating eosinophils as an adjunct in studies of adrenal activity has been demonstrated by Thoin.<sup>1</sup> Randolph examined previous methods for direct eosinophil counts in 1944 and experimented with several diluents including certain ones with a propylene glycol base. He concluded that diluents consisting of eosin, acetone and water were unsatisfactory because of lysis of leucocytes in these fluids. The present study was designed to evaluate two diluents for eosinophil counts.

The diluent used by Thoin<sup>1</sup> and a modification of Randolph's eosinophil diluent were prepared as follows:

EOSIN ACETONE DILUENT		PHLOXINE PROPYLENE GLYCOL DILUENT	
Aqueous eosin 2 per cent	50 cc	Phloxine	0.05 Gm
Acetone	50 cc	Propylene glycol	50.0 cc
Distilled water	90.0 cc	Distilled water	50.0 cc

#### METHODS

Freshly drawn venous blood was placed in bottles containing sufficient oxalate to prevent clotting. Twenty-four white cell pipettes were filled at once with blood to the 1.0 mark. Twelve of these pipettes were filled to the 1.1 mark with the eosin acetone diluent and twelve with the phloxine propylene glycol diluent. After three, eighteen and seventy-eight minutes respectively, four pipettes containing the eosin acetone diluent and four containing the phloxine propylene glycol diluent were placed in a mechanical shaker for two minutes and the eosinophils promptly counted. Thus the effect of continued contact of the blood with each diluent for five, twenty, and eighty minutes was observed. Identical studies were performed after the same oxalated blood had aged two and four hours. The oxalated blood was mixed thoroughly by gentle agitation before sampling. Both sides of a standard Spencer Bright Line counting chamber were filled from each pipette and all the eosinophils within the ruled areas counted. Thus 18/10 cubic millimeters of blood diluted 1:10 were examined.

\*From the Basic Science Department, Army Medical Department Research and Graduate School, Army Medical Center.

Received for publication April 6, 1949.

Present address: Peter Bent Brigham Hospital, Boston, Mass.

Since the phloxine-propylene glycol diluent required fifteen minutes for complete staining of the eosinophils, the blood counting chambers were filled at the five-minute periods as with the eosin-acetone method, but the actual counting was delayed until fifteen minutes of staining time had elapsed

## RESULTS

The calculated eosinophil counts performed with the two diluents are listed in Table I and diagrammed in Figs 1 and 2

TABLE I

Sample 3	177	138	177	50	50	38	11	11	0
Sample 4	156	172	150	44	27	16	27	11	5
Mean	178	150	187	62	37	27	26	8	11

EOSINOPHIL COUNTS WITH PHLOXINE PROPYLENE GLYCOL DILUENT									
TIME AFTER DILUTION OF BLOOD	5 MIN			20 MIN			80 MIN		
AGE OF BLOOD	0 HR	2 HR	4 HR	0 HR	2 HR	4 HR	0 HR	2 HR	4 HR
Sample 1	177	244	166	138	216	144	227	172	266
Sample 2	222	172	200	194	183	211	211	177	272
Sample 3	189	255	166	194	266	133	177	205	244
Sample 4	156	216	233	166	238	205	244	161	144
Mean	186	222	193	173	226	173	215	179	232

The eosin-acetone diluted blood showed a striking decrease in cell count with lapse of time after dilution of the blood. Using this diluent there was also a marked decrease in cell count with increasing age of the ovalated blood. The phloxine-propylene glycol method showed no significant change in count with lapse of time after dilution of the blood nor with aging of the ovalated blood.

The decrease in count with lapse of time after dilution of the blood with the eosin-acetone fluid was highly significant statistically ( $p < 0.001$ ) as determined by analysis of variance. The analysis further revealed that the nature of this decrease was complex. The decrease in eosinophil counts obtained with the aged blood was also highly significant ( $p < 0.01$ ). The relationship of count to age of blood was curvilinear. These results suggest that multiple factors are involved in these decreases.

Similar analysis of the values obtained with the phloxine-propylene glycol diluent revealed no significant change with time or age of blood. Hence all the phloxine-propylene glycol counts were pooled, providing a mean count of 199 eosinophils per cubic millimeter of blood with a standard deviation of 36 cells or 18 per cent. This emphasizes the large inherent error in this type of determination.

Since Randolph<sup>2</sup> observed the lysis of leucocytes in aqueous acetone diluents, the following additional study was undertaken in this laboratory. Blood was diluted with the eosin-acetone fluid and placed in a counting chamber with a thin cover slip and sealed with petroleum jelly. There was no change in the eosinophil count over a period of three hours. However, immediate examination of the cells under high magnification revealed the forma-

Fig. 1—Circulating eosinophil counts performed at three time intervals showing change in counts with passage of time and aging of oxalated blood

Fig. 2—Circulating eosinophil count performed at three time intervals after dilution showing lack of significant change in counts with passage of time and aging of oxalated blood

tion of blebs on the limiting membrane of the eosinophils followed by rupture of the cells. If the preparation was not agitated, the individual aggregates of eosinophilic granules could still be counted as eosinophils even though the cell membranes were disrupted. If the pipette containing blood and the eosin-acetone diluent was agitated after allowing several minutes for lysis of cells the granules were scattered and there was an apparent decrease in eosinophil count.

Since the phloxine-propylene glycol diluent required fifteen minutes for complete staining of the eosinophils, the blood counting chambers were filled at the five-minute periods as with the eosin-acetone method, but the actual counting was delayed until fifteen minutes of staining time had elapsed

## RESULTS

The calculated eosinophil counts performed with the two diluents are listed in Table I and diagrammed in Figs 1 and 2

## A SIMPLE METHOD FOR ASEPTIC GRINDING OF SMALL AMOUNTS OF TISSUE

F J MURRAY, PH D  
CINCINNATI OHIO

DURING the course of routine passages of mouse encephalitis viruses it was necessary to grind individual brains. The usual method for such grinding involves the use of a small pestle and mortar, previously wrapped in paper and sterilized. Where many pestles and mortars are required a considerable saving of space may be effected by use of the method here described. Probably the greatest disadvantages of using pestle and mortar are the possibilities of contamination of the material being ground and the possibility of infection of the person doing the grinding.

Fig 1—Assembly for grinding tissues

The method employed by me calls for 6 in Pyrex test tubes with 10 in glass rods fitted in the tubes through the centers of the cotton stoppers. The tube rod assemblies are sterilized in the autoclave and dried in the oven. Sterile alundum or other suitable grinding material may be added at the time the mouse brain is placed in the tube or it may be added beforehand and sterilized with the assembly.

From the Bacteriology Department Research Laboratories the Wm S Merrell Company  
Received for publication April 27 1949

When the brain and diluent have been added, the tube is held loosely in the palm of the left hand, with the thumb stretched across the bottom of the tube (Fig 1) The portion of the rod showing above the cotton plug is grasped by the right hand and is made to perform a gentle whipping motion The angle of the tube, position of the hands, etc , may be varied to the comfort of the individual employing the technique

Obviously this technique is not limited to the grinding of brains, but may be used for lungs and other animal tissues

## PRESERVATION OF VIRUSES IN A MECHANICAL REFRIGERATOR AT $-25^{\circ}\text{C}$

PETER K OLITSKY, M.D., JORDI CASALS, M.D., DUARD L. WALKER, M.D.,\*  
HAROLD S. GINSBERG, M.D. AND FRANK L. HORSFALL, JR., M.D.  
NEW YORK, N. Y.

AS A routine, many laboratory workers who employ viruses in investigations or in diagnostic procedures store infectious material in the frozen state at about  $-70^{\circ}\text{C}$  in cabinets<sup>1</sup> that are refrigerated with solid carbon dioxide. Although this way of preservation is useful and effective, it has some disadvantages. Of these, the most important are (1) the necessity for a continuous supply of solid  $\text{CO}_2$ , (2) the high annual cost of solid  $\text{CO}_2$ , and (3) the acidity caused by the diffusion of  $\text{CO}_2$  into specimens. In many geographical areas a regular supply of solid  $\text{CO}_2$  cannot be obtained. In areas where the refrigerant is readily available, the cost of constantly maintaining low temperatures with solid  $\text{CO}_2$  is considerable even when efficient cabinets are employed (the outlay may run to \$100 to \$200 per cubic foot of storage space per year). Although diffusion of  $\text{CO}_2$  into specimens can be prevented by the use of sealed hard glass containers, this procedure is cumbersome and inconvenient.

Subfreezing temperatures now can be maintained with a number of commercially available mechanical refrigerators. Certain electrically operated ones maintain temperatures in the range attained with cabinets cooled with solid  $\text{CO}_2$  but their initial cost is high and their storage capacity not large. Other less costly refrigerators can maintain temperatures in the range of  $-20$  to  $-30^{\circ}\text{C}$  and of these many provide large storage space.

The preservation of viruses for prolonged periods at  $-70^{\circ}\text{C}$  has been studied in a number of instances<sup>2,3</sup> and it is now well known that most viruses retain infectivity for long intervals when properly stored at this temperature. However, relatively little is known as to the stability of viruses at  $-20$  to  $-30^{\circ}\text{C}$ . Melnick<sup>4</sup> found that Y-SK and Ph poliomyelitis viruses as well as the TO Theiler virus retained their original titers when stored for twelve months at  $-20^{\circ}\text{C}$ . Under the same conditions the titer of Japanese B virus decreased by one thousand fold or more.

In the present investigation infectivity titrations were carried out with a number of different viruses which were stored in an electrically operated mechanical refrigerator for periods up to twelve months at temperatures ranging from  $-20$  to  $-30^{\circ}\text{C}$ . The results indicate that all of the viruses studied can be stored under these conditions for at least three months without causing any striking reduction in infectivity. With most of the neurotropic viruses full infectivity was maintained for nine months. With the influenza mumps group of viruses infectivity was much diminished although still present after twelve

\*From the Laboratories and the Hospital of The Rockefeller Institute for Medical Research.

Received for publication May 1<sup>st</sup> 1949.

Fellow in the Field of Virus Diseases of the National Research Council.

months It should be mentioned that during the study one refrigerator was once accidentally disconnected, and the other twice failed to operate properly During these periods the temperature increased sufficiently so that all specimens were thawed for an interval of less than twenty-four hours

#### EXPERIMENTAL

The following viruses were employed Eastern equine encephalitis (Rockefeller Institute strain), Western equine encephalitis (Rockefeller Institute strain), Russian Far East encephalitis (No 1 strain), Japanese B encephalitis (Nakayama strain), poliomyelitis (Lansing strain) and poliomyelitis (MEF1 strain), influenza A virus (PR8 strain), influenza B virus (Lee strain), and mumps virus (Habel strain)

The neurotropic viruses were contained in suspensions of fresh, infected mouse brains or in frozen suspensions previously stored in a CO<sub>2</sub> cabinet The suspensions stored were 10<sup>-1</sup> dilutions of brain in either 10 or 50 per cent normal rabbit serum which were placed either in screw-capped nitrocellulose tubes or in sealed Pyrex ampules Influenza and mumps viruses were contained in allantoic fluid obtained from infected chick embryos One portion of each allantoic fluid was stored in the undiluted state, the other after dilution to 10<sup>-1</sup> with normal horse serum The allantoic fluids were all kept in screw-capped nitrocellulose tubes

In every instance a number of specimens of each virus preparation were quickly frozen by partial submersion in a mixture of ethyl alcohol and solid CO before they were placed in the refrigerator at -20 to -30° C At appropriate intervals one specimen of each frozen suspension was thawed rapidly in running tap water and an infectivity titration was performed Titrations were carried out with serial decimal dilutions With the neurotropic viruses the usual intra cerebral technique in white mice was employed, and the LD<sub>50</sub> was determined In the case of influenza and mumps viruses the intra-allantoic technique in chick embryos was used, and the EID<sub>50</sub> was determined by hemagglutination tests with allantoic fluids removed after an appropriate interval

The refrigerators employed were commercially available models which had single stage compressor units and were capable of maintaining temperatures of -30° C on intermittent operation One refrigerator had a storage capacity of 20 cubic feet, the other, 16

The results of the titrations are presented in Table I It will be noted that all of the viruses which were suspended in 50 or more per cent normal serum retained infectivity throughout the entire period of observation It will also be seen that the Russian Far East encephalitis virus and the MEF1 and the Lansing strains of poliomyelitis virus retained almost their original LD<sub>50</sub> titers for a period of nine months Melnick<sup>4</sup> also showed a similar relative stability for other Lansing-type viruses The Western equine encephalitis virus showed only a slight reduction in titer after nine months of storage and the titer of the Eastern equine encephalitis virus decreased only about 1.5 log units over the same period However, the Japanese B encephalitis virus, although still infective (i.e., LD<sub>50</sub> 10<sup>2.6</sup>) after nine months, had decreased markedly in titer This latter finding is in good agreement with the results reported by Melnick<sup>4</sup>

m b Mouse brain suspension in normal rabbit serum

nrs Normal rabbit serum in saline solution

all fl Allantoic fluid

nhs Normal horse serum

EID<sub>50</sub> 50 per cent end point of virus titration in chick embryos

It will be observed that influenza A, influenza B, and mumps viruses showed only slightly reduced EID<sub>50</sub> titers after storage for three months. However after six months of storage the titers of the influenza viruses had decreased by more than 3 log units. This was true even in the case of the suspensions which had been prepared in 90 per cent normal horse serum. After storage for one year none of the three viruses kept in undiluted allantoic fluid showed any evidence of infectivity and all suspended in horse serum gave titers 3 to 4 log units lower than the original titers of the suspensions.

## DISCUSSION

It appears evident that a number of neurotropic viruses can be preserved by storage at -20 to -30° C for periods of at least nine months without much loss of infectivity. Japanese B encephalitis virus seems to be the least stable of the neurotropic viruses tested; it showed a marked reduction in titer after storage for six months at this temperature. Influenza and mumps viruses exhibited a stability under the conditions employed which was approximately of the same order as that of Japanese B virus. Their infectivity titers also were considerably reduced following storage for six months at -25° C.

It should be emphasized that of the viruses employed those suspended in 50 to 90 per cent normal animal serum retained infectivity sufficient to permit recovery easily after storage for at least nine months. Moreover when such concentrations of normal serum were used none of the virus suspensions showed any striking reduction in titer after three months of storage; only those of Eastern equine and Japanese B encephalitis exhibited a decrease of 1 or more log units. It also should be stressed that the results were obtained despite the fact that the viruses had been accidentally thawed once or twice for an interval of some hours.

For many virus studies a period of storage of three months is satisfactory. In laboratories in which a CO<sub>2</sub> refrigerated cabinet is not available, and in areas in which a supply of solid CO<sub>2</sub> cannot be obtained, electrically operated mechanical refrigerators which maintain a temperature of -20 to -30° C may prove useful.

#### SUMMARY

Numerous viruses can be preserved by storage in an electrically operated mechanical refrigerator at -20 to -30° C. The infectivity titer of a number of viruses did not diminish significantly after storage for three months. In spite of the fact that some showed a marked reduction in titer after nine months, none became inactivated if stored in the presence of an adequate amount of normal serum.

## A MACERATOR FOR SMALL SAMPLES OF TISSUE

J. CAMPBELL, PH.D., AND I. W. F. DAVIDSON  
TORONTO, CANADA

IT IS often necessary to macerate small samples of fresh tissues for analysis before extraction with solvents. Grinding in a mortar involves transfer with an increase in the volume of washings and the risk of small losses. The Waring Blender is an excellent instrument for the maceration of fresh tissues, but transfer to other vessels is necessary and is sometimes troublesome when the samples are small.

We have devised the highly efficient macerator, shown in Fig. 1, whose cutting blades are small enough to be inserted into a large sized test tube. Samples of tissue are macerated in the extraction vessel, thus obviating a transfer and increasing speed and accuracy. The instrument processes organs and tissue samples of 2 to 25 grams and, if suitably modified, much larger samples could be finely macerated.

The gear housing (A) is made from  $\frac{1}{4}$  in. by  $\frac{3}{4}$  in. brass stock bent to form a rectangle with inside dimensions  $1\frac{1}{2}$  in. by  $2\frac{1}{4}$  in. Cover plates of copper sheeting are made to match the open sides. Lubricating grease covers the inside of the housing. The mounting bar (B) is of  $\frac{3}{8}$  in. diameter brass rod 7 in. long, tapped into an end of the housing. Shaft (C) for the driving gear is coupled to an electric motor by a short length of pressure tubing. A Cenco variable speed stainer (80 to 1300 r.p.m.) is suitable for the purpose at the upper speed range.

The driving gear actuates gears  $D_1$  and  $D_2$ , counterrotating the  $\frac{1}{8}$  in. diameter by  $8\frac{1}{2}$  in. stainless steel spindles centered  $\frac{3}{8}$  in. apart. There is a step up from the driving to the driven gears of 3 to 1, the speed of the two spindles being equal. The cutter spindles are supported by a bearing (E), which is  $\frac{1}{2}$  in. above the cutter blades and is mounted on a stainless steel rod support (F)  $\frac{1}{4}$  in. diameter and  $4\frac{1}{2}$  in. long, tapped into the bottom of the housing. The cutters,  $G_1$  and  $G_2$ , 37 mm. by 11.5 mm., are formed from 24 gauge stainless steel in a modified "S" shape with cutting edges. A curved plate (H) mounted on  $\frac{3}{8}$  in. diameter rod is supported from the stand by a clamp and serves as a guide for a test tube.

The cutting blades mesh when rotated giving fine maceration. The tendency to vortex formation by one blade is nullified by the counterrotation of the other so that fluid does not mount the sides of the vessel. The long length of the blades helps to prevent the trapping of tissue above the cutters.

The instrument is simple to operate. In this laboratory it is used to macerate rat livers for the determination of total lipids. A 28 mm. by 150 mm. Pyrex test tube containing a liver (approximately 8 to 10 grams) with sufficient acetone

to cover the organ is placed so that the cutting blades are inserted to about 1 m above the solvent and the test tube is held against its guide. The motor is turned on and the vessel is slowly raised against the guide until the cutters enter the solvent and end near the bottom of the tube. Maceration is complete within one

Fig 1

minute. The tube is partially withdrawn, the motor immediately switched off, and the cutters are quickly washed with a stream of acetone from a wash bottle. After removal of the supernatant fluid the liver may be re-extracted directly in the tube by fresh solvents.

With the instrument shown, the macerating cutters can be inserted into a vessel as small as 23 mm in diameter, but it is obvious that the size and form of the cutters may be modified to suit many types of vessels and tissues or materials requiring maceration.

We wish to acknowledge the assistance of Mr J D Brown, Mr E B Johnson, and Mr J H Royce in the development of the instrument.

## THE EFFECT OF RIGID SODIUM RESTRICTION IN PATIENTS WITH CIRRHOSIS OF THE LIVER AND ASCITES

W J EISENMENGER MD E H AHRENS, JR MD, S H BLONDHEIM, MD,  
AND HENRY G KUNKEL MD  
NEW YORK N Y

LOW salt diets have been used for many years in the treatment of edema and ascites in patients with cirrhosis of the liver. Enthusiastic reports appeared in the French literature as early as 1904 claiming actual termination of ascites formation from the use of a low salt diet<sup>1 2 3</sup>. In recent years, however, emphasis on high protein high caloric diets in treatment of cirrhosis has led many physicians away from the use of low salt regimens since it has seemed difficult to devise a palatable low salt diet which is adequate in protein. Moderate restriction of salt has continued to be common practice in the treatment of ascites but results have not been striking.

Recently numerous reports have appeared dealing with the role of sodium in the formation of ascites and edema in cardiac disease<sup>4 5 6</sup>. Sodium and water retention by the kidney has been claimed as a factor in the production of ascites in cirrhosis as well as in congestive heart failure by Farnsworth<sup>7</sup>. Layne and Schenck<sup>8</sup> have applied this principle to the management of cardiac and cirrhotic ascites by means of low salt diets. Chalmers and Davidson<sup>9</sup> have shown in a preliminary study of sodium balance in cirrhosis that salt plays an important role in fluid retention. Recently the work of Whipple and co-workers<sup>10</sup> on dogs rendered ascitic by constriction of the inferior vena cava above the liver has demonstrated that ascites of purely mechanical origin can be affected markedly by variations in salt intake.

The role of hypoalbuminemia in the formation of ascites in patients with liver disease has been recognized by numerous observers<sup>11 12</sup>. Rall and co-workers<sup>13</sup> have obtained evidence that increased excretion of antidiuretic substance also plays a role in ascites formation. Recently, the work of Blake more<sup>14</sup> has demonstrated the importance of portal hypertension as a third factor in the formation of ascites. The present report represents a description of the direct relationship between the sodium content of the diet and the accumulation of ascites in thirteen patients despite the operation of the other three factors. Detailed studies of electrolyte balance in three of these patients will be published in a separate communication.

### MATERIALS AND METHODS

The thirteen patients to be discussed were admitted to the Hospital of The Rockefeller Institute at least ten days prior to the initiation of salt restriction in the diet. The diagnosis

From the Hospital of The Rockefeller Institute for Medical Research  
Received for publication May 3 1949

of cirrhosis of the liver was established by characteristic history, numerous physical examinations, x-ray studies of the esophagus and abdomen, and a wide variety of liver function tests. Ascites had been present for four to forty eight months prior to the onset of low salt therapy and had necessitated two to seventy eight paracenteses. Fluid continued to accumulate at the usual rate at the time of onset of therapy.

Fig 1—Case 1. Three paracenteses in the hospital prior to Na restriction. Immediate cessation of ascites formation on diet of 1 Gm of NaCl per day. Reversion from negative to positive nitrogen balance.

The etiology of the cirrhosis was chronic alcoholism with associated nutritional disturbance in nine of the thirteen patients. None of the patients was suffering from an enlarged, acutely decompensated fatty liver at the time of admission.

The diets used were prepared by trained dietitians who kept careful records of the daily intake of protein, fat, carbohydrate, and salt. An effort was made to provide patients with an excess of food and calculations were made from the amounts offered and refused. Protein, salt, and caloric intake were calculated from standard tables. The sodium intake was checked by direct analyses. In the detailed studies on sodium balance, direct analysis of the sodium content of the food, urine, and feces was carried out (NaCl was calculated on the basis of measurements of N). In the low salt diets, special attempts were made to keep the food palatable. Salt free bread, available for purchase, was used. No salt substitutes were administered. Where protein intake tended to be low, or where a high protein, low sodium intake was sought, whole protein supplements were added to the diet.\* As much as 50 Gm of protein per day could be provided with these palatable supplements. Serum albumin was determined by a modification of the specific immunologic method of Chow<sup>12</sup>. Instead of measuring turbidity, the antigen antibody precipitate was determined by means of the molybdenum reagent of Moore and Stein<sup>13</sup>. The Howe method with Kjeldahl digestion

\*Delcos Granules (Sharp & Dohme) Melactin (Squibb) Protinal (National Drugs)

was also used for protein determination. Osmotic pressures were determined by a specially constructed Hepp type osmometer. Determinations of serum bilirubin, bromsulfalein retention, thymol turbidity and total lipids were also carried out in all of the patients during the period of therapy. The methods employed were identical with those presented in a previous study.<sup>17</sup> Plasma chlorides were determined by the method of Van Slyke<sup>18</sup>, plasma volume, by the method of Gibson and Evans<sup>19</sup>. Sodium was determined by means of a Perkin Elmer flame photometer utilizing lithium as an internal standard.

### RESULTS

**CASE 1**—A 52 year old man with cirrhosis of unknown etiology beginning six months prior to admission and requiring six paracenteses. Physical examination showed occasional spider angiomas and a small hard liver. Laboratory tests indicated an advanced cirrhosis. The total protein was 5.7 Gm per cent with albumin 1.9 Gm per cent. Bromsulfalein retention was 37 per cent in 45 minutes. Serum esterase was 22 units. Cephalin flocculation was 2+ the thymol turbidity was 10 units and bilirubin was 1.8 mg per cent.

On admission the patient continued to accumulate ascites at a regular rate (Fig 1), necessitating three paracenteses while on an unlimited NaCl intake. This was found by analysis to average 9.2 Gm NaCl per day. Urinary excretion of NaCl was extremely low, averaging 0.04 Gm per day while fecal NaCl was 0.3 Gm per day. The patient was in negative nitrogen balance on the normal diet. This was chiefly due to the loss of ascitic nitrogen through the paracenteses.

Immediately following the initiation of a low salt diet which on analysis was found to contain between 0.8 and 1.2 Gm NaCl per day, the ascites formation ceased and the patient reverted to positive nitrogen balance as indicated in Fig 1. The urinary output approximately doubled and both the urinary and fecal NaCl concentrations fell. The serum and ascitic fluid Na levels showed a fall of approximately 3 meq per liter. After the patient remained on this diet for three months the urinary NaCl which had remained constant suddenly increased and the patient lost considerable ascites. Table I illustrates the sudden rise in the urinary NaCl despite continued NaCl restriction. The dietary intake improved progressively during this time and positive nitrogen balance increased. At the present time, six months after the initiation of Na restriction the patient is markedly improved although not entirely recovered. He now tolerates 4 and 5 Gm NaCl per day without forming ascites because of the increased urinary output of Na.

The total protein in the serum and ascitic fluid rose by 2 Gm per cent after five months on the diet.

TABLE I

DATE	NaCl GM/DAY			Na MEQ/LITER	
	FOOD	URINE	FECES	SERUM	ASCITIC FLUID
Dec 3	9.1	0.05	0.30	138	137
Dec 15	9.3	0.07	0.35	139	139
Jan 12	1.1	0.02	0.15	135	135
Feb 12	0.9	0.02	0.12	135	134
Mar 24	1.0	2.00	0.25	137	137
May 12	0.9	1.00	0.18	136	135

**Comment**—Rigid NaCl restriction caused a cessation of ascites formation, positive nitrogen balance and a rise in serum and ascitic fluid proteins. Urinary NaCl increased with the mobilization of ascitic fluid. A five month period of therapy was necessary before the patient showed signs of recovery.

**CASE 2**—Fig 2 illustrates the course of a 42 year old woman with a nutritional cirrhosis who had ascites for eight months prior to admission. She had a total of twenty nine paracenteses in that period, during which time she was at home on minimal activity. Since an

accurate record of these was kept, they are indicated in the weight curve of Fig 2 Her diet, poor at the onset of the ascites, was adequate for six months prior to admission The skin showed numerous spider angiomas and prominent liver palms The liver edge was barely palpable at the costal margin An esophagram showed esophageal varices Laboratory tests likewise pointed to an advanced cirrhosis Proteins formed by the liver were all low, plasma albumin was 2.4 Gm per cent, fibrinogen 225 mg per cent, prothrombin

Fig 2—Case 2 Ascites of eight months duration requiring thirty paracenteses. Immediate control of ascites with salt restriction. Prompt increase in urinary output and delayed rise in serum albumin.

38 per cent of normal, and esterase 13 units. Gamma globulin was elevated as indicated by a zinc turbidity of 32 units and a total serum globulin of 3.5 Gm per cent. Bromsulfalein retention was 40 per cent in 45 minutes. Ascitic fluid total protein was 1.0 Gm per cent, with albumin 0.7 Gm per cent.

On admission the patient was placed on a regular hospital diet and activity equivalent to that at home. On this regimen she continued to gain weight and ascites at her usual rate. The urinary output was small. Following a paracentesis which became necessary, she was put on a diet with NaCl restricted to 1 Gm per day. The response was immediate with a complete cessation of ascites accumulation and a rise in urinary output to about three times the previous output. This occurred despite a spontaneous decrease in fluid intake. A small amount of ascites, detectable by shifting dullness, persisted. This effect was sustained throughout her hospitalization and at home. After three months the patient was able to tolerate larger amounts of NaCl in her diet without forming ascites. She has remained well during the year since discharge and all ascites has disappeared.

A rise in serum albumin from a subnormal level of 2.4 Gm per cent to normal levels of 4 to 4.5 Gm per cent occurred.

Clinically there was marked improvement in this patient. As soon as she became adjusted to the diet she complained only of the flat taste of food without salt but this did not interfere with her eating a perfectly adequate diet. The termination of her need for paracenteses after having had thirty was a strong factor in raising her morale and insuring cooperation.

*Comment*—A low salt diet aided in restoring this patient to a fairly normal, active life, after having previously required almost weekly paracenteses for seven months. The urinary output likewise showed an immediate increase, while the serum albumin levels gradually rose to almost double the former levels within three weeks.

Fig 3—Case 3. Ascites formation controlled by NaCl restriction at 1 Gm per day. Reaccumulation of ascites on 15 to 3 Gm NaCl per day. Control of ascites again at 1 Gm per day. High protein intake (140 Gm per day) despite salt restriction to 1 Gm per day.

CASE 3—Fig 3 illustrates the course of a 54 year old wine drinker who on admission to the hospital was accumulating ascitic fluid at a regular rate. He had been hospitalized elsewhere on two occasions. Following an unexplained febrile episode he lapsed into hepatic coma for four days but gradually recovered. Three paracenteses were performed at the other hospital following the episode of coma. Since weights were available, these are illustrated in the weight curve of Fig 3. On physical examination the patient showed a small, hard liver and marked ascites with no edema. Following admission to the Rockefeller Hospital he was kept on a regular diet with normal sodium intake for three weeks. Ascitic fluid continued to accumulate and a fourth paracentesis was performed. Following the reduction of the NaCl content of his diet to 3 Gm per day there was an immediate slowing in the rate of ascites formation as is readily visible from the weight curve of Fig 3. The NaCl content was further reduced to approximately 1 Gm per day, and following a fifth paracentesis the patient ceased accumulating ascitic fluid for one month. The NaCl content of the diet was then gradually raised to 2 Gm per day. Ascitic fluid began to accumulate and the weight curve illustrated in Fig 3 can be seen to rise with progressive increments.

of salt intake. When NaCl was reduced again to 1 Gm per day, ascitic fluid again ceased accumulating and the weight curve flattened out. By means of protein supplements, as much as 140 Gm of protein were supplied a day during this latter period despite the very low NaCl intake.

Improvement on the low salt regimen was very striking. The discontinuance of paracenteses caused the patient to feel better and to eat better and resulted in a rise in the albumin concentration in the serum. The limitation of salt was very well tolerated. After three months on the low sodium diet, the patient recovered sufficiently to tolerate a normal diet at home without ascites.

*Comment*—The degree of salt restriction necessary to control the ascites in this patient was well defined at about 13 Gm a day. Limitation below this level promptly resulted in a favorable therapeutic response with control of ascites and a marked increase in urine volume. By the use of protein and carbohydrate supplements it was possible to raise the patient's protein intake to 140 Gm per day and his caloric intake to over 3,000 calories despite limitation of sodium chloride to 1 Gm per day.

CASE 4—Fig. 4 illustrates the course of a 60 year old housewife who developed hepatic cirrhosis without known cause and had been steadily accumulating ascites for four years. She had had seventy six paracenteses prior to admission, with removal of an average of 10 liters per tap followed by leakage of fluid from the wound for one to two weeks. After closure of the wound she consistently accumulated approximately 1 liter of ascitic fluid per day. Edema of the legs appeared as the intra abdominal pressure increased.

In the nine months prior to admission the patient had become progressively weaker. She had lost considerable body tissue and had had several episodes suggesting minor cerebrovascular accidents. In the course of the four years the patient had been hospitalized for all paracenteses, and the main therapeutic efforts were directed toward a highly nutritive diet with occasional trials of mercurial diuretics.

On admission she appeared chronically ill, with marked tissue wasting. The liver was slightly enlarged and hard. Laboratory findings were consistent with an advanced cirrhosis with a decrease in the proteins formed by the liver, serum albumin was 2.5 Gm per cent, prothrombin level 47 per cent of normal, fibrinogen 160 mg per cent, serum esterase 27 units. Bromsulfalein retention was 23 per cent. Ascitic fluid total protein was 1.1 Gm per cent, with albumin 0.5 Gm per cent.

On the hospital diet with unrestricted salt the patient continued to gain weight and ascites at her usual rate until two paracenteses were performed. Just before the second tap in the hospital, salt in the diet was limited to 1 Gm a day. The rate of accumulation of ascites was promptly slowed and eventually leveled off at a point just short of requiring a paracentesis. With the institution of the low salt diet, urine output which had been minimal (200 to 300 cc a day) except following mercurials approximately doubled. This occurred despite a voluntary reduction in fluid intake. Attempts to raise the fluid intake were futile, leading to nausea. This may have been due to impaired renal function presumably on an arteriosclerotic basis. Both prior to and during the period of sodium restriction the patient showed a constantly elevated nonprotein nitrogen, a urea clearance of 25 per cent, and urine specific gravity fixed at 1.010. The patient's diet averaged 60 Gm of protein and 2,000 calories daily, with NaCl limited to below 1 Gm a day.

Laboratory tests showed no change with the exception of a moderate rise in serum albumin levels, from 2.5 Gm per cent to 3.7 Gm per cent. During the entire course there were but insignificant variations in the hemoglobin levels. Clinically this patient improved for two months but then her dietary intake fell and she was returned to a normal diet. A second period on the low Na diet again proved of little permanent value and the patient died three months after returning to the normal Na intake.

*Comment*—The chronicity of this patient's illness with resultant debility and prolonged ascites plus the renal and cerebral arteriosclerotic complications provided a difficult test for this regimen. After seventy-eight paracenteses the rate of ascites formation was promptly slowed by salt restriction but the dietary intake was poor and the patient eventually died.

Fig. 4—Case 4. Ascites of four years duration requiring seventy-eight paracenteses. Effect of salt restriction in controlling formation of ascites. Increase in urine output and serum albumin level. Return of ascites and need for paracenteses on normal diet.

#### DISCUSSION

The results of rigid Na restriction have been described in detail in four of the thirteen patients studied. The remainder of the patients showed similar results with complete cessation of ascites formation when the NaCl was limited to 1 Gm per day. Higher intakes caused ascites formation in direct proportion to the NaCl given. An average critical level of NaCl intake was obtained for these patients above which ascites formation occurred. This was 1.2 Gm NaCl per day. The reason for this direct relation between NaCl intake and ascites was that the NaCl excretion in the urine was extremely low regardless of how much NaCl was furnished in the diet. The urinary NaCl excretion in eight of these patients on a diet of 7 to 9 Gm NaCl per day ranged from 0.02 to 0.13 grams. Fecal NaCl excretion was higher, averaging 0.35 Gm per day. With this low excretion of NaCl it is apparent that the large part of the NaCl intake is used to form ascitic fluid. Insensible NaCl loss was not measured but could be calculated from the NaCl balance data to be approximately 0.8 Gm per day.

Excretion of water rose in all of the patients on the low sodium diet. When there was no Na supplied in the diet for ascitic fluid accumulation water was

excreted proportional to the intake. A high fluid intake had little effect in altering daily sodium excretion.

All but one of the thirteen patients were able to tolerate the low Na regimen for at least three months without ill effects. The one exception, Patient 4, showed a fall in fluid and caloric intake on the diet. Another patient developed muscle cramps after being on the diet for five months. These were relieved by supplying Na. The patient had done well on the diet without forming ascites prior to the onset of the cramps. Serum Na levels were followed in all of the patients. A fall in serum Na of approximately 3 meq per liter usually occurred. One patient who received mercurials in addition to the low Na diet showed the greatest fall, 12 meq per liter.

Nitrogen balance studies were carried out in two of the patients. These patients were in negative balance prior to Na restriction because of the loss of ascitic nitrogen. When ascites formation ceased on the low Na diet, the patients reverted to positive nitrogen balance.

All of the patients demonstrated a rise in serum proteins on the low Na diet. Fig. 5 shows a group of determinations on the serum and ascitic fluid of one of the patients (Case 1). The rise in albumin and in colloid osmotic pressure was approximately equal in the two fluid compartments, demonstrating the equilibrium which exists. The total protein of serum and ascitic fluid rose considerably more than the albumin. Plasma volume determinations showed little change and thus did not account for the rise. Some of the other patients demonstrated a 10 per cent fall in plasma volume accounting for a portion of the protein rise. The patients who responded best to the diet and gained body weight soon after treatment was started showed a rise in serum albumin that was sometimes greater than the total protein rise. This was due to a fall in globulins. The selective rise in albumin was a sign of improvement in liver protein synthesis. This did not occur in the chart shown (Fig. 5) nor in most of the other patients. The rise in these patients of all the protein components appeared to be the result of cessation of protein loss in the ascitic fluid permitting the proteins to accumulate in the body.

The use of newly available low Na protein supplements permitted the administration of as much as 150 Gm of protein per day on the low Na diet. The patients showed considerable individual variation in their ability to take different supplements, but of those which were used there usually was one which was readily tolerated by each patient. Improvement appeared to be more rapid when the protein was kept above 100 grams. However, some of the patients responded well at a level of 70 Gm of protein per day.

The general clinical results of a three-month period on the low NaCl diet were evaluated by studying the effect of normal Na intake on ascites at the end of the three months. Four patients recovered sufficiently during this time to enable them to excrete the increased Na and they did not reform ascites. These patients gradually absorbed the remaining ascitic fluid and returned to a normal life. Eight patients were still unable to excrete larger amounts of Na and accumulated ascites on the normal diet. These patients had not regressed during the three months of Na restriction and all of them appeared

slightly improved but they had not been cured. Na restriction was reinstituted in these individuals. Three of these have since showed increased Na excretion representing loss of ascitic fluid after more than six months of therapy. Others in the group are still being treated with combined albumin, liver extract, and low Na therapy. One of these patients died of esophageal hemorrhages. Patient 4 who did not tolerate the low Na diet also died.

Fig 5—Rise in values for determinations of proteins and colloid osmotic pressure in serum and ascitic fluid following Na restriction.

In all of the patients the diet appeared to be beneficial in stopping the malignant course of events brought about by removal of protein through paracenteses in the already depleted individual thus enabling dietary therapy to become effective. The long term clinical results are difficult to evaluate but the fact that ascites formation could be completely controlled by rigid Na restriction was clearly evident.

#### SUMMARY

1 The results of rigid NaCl limitation in the diet of thirteen patients with cirrhosis of the liver and long standing ascites are presented.

2 Ascites formation ceased for three months in twelve of the thirteen patients. Urine output increased in each case commensurate with decreased fluid retention.

3 Four patients did not reform ascites when a normal NaCl intake was tried after three months; eight patients did reform ascites.

4 Serum protein levels showed a rise following therapy. This is explained primarily on the basis of retention in the serum of protein which previously had been lost in the ascitic fluid.

5 A high protein and high caloric diet could be maintained despite rigid salt limitation.

# THE HYPERBILIRUBINEMIC EFFECT OF SODIUM NICOTINATE

MARIO STFFANINI, M Sc, M D \*  
MILWAUKEE, WIS

## INTRODUCTION

NEW techniques are often instrumental in permitting important developments in the understanding of biological and clinical problems. In 1941, Villa<sup>13</sup> claimed that treatment with nicotinamide produced a striking remission of jaundice in different types of hepatic dysfunction provided the liver damage had not reached the irreversible stage. Apparently while investigating the mechanism of this therapeutic effect Matter<sup>9</sup> observed that the injection of 30 mg of sodium nicotinate intravenously in normal individuals was followed by a sharp rise of the level of indirect reacting bilirubin in serum. This technique has permitted interesting observations on some aspects of the metabolism of biliary pigments in normal and pathologic conditions.<sup>8</sup> The results obtained so far in more than twenty normal subjects and seventy eight patients with various disorders of the liver will now be reported.

## THE TECHNIQUE OF THE TEST

Ten cubic centimeters of blood are collected from the patient who has been fasting for the previous twelve hours and 30 mg of sodium nicotinate dissolved in 10 cc of saline solution are slowly injected through the same needle. The injection is followed almost immediately by a sensation of flushing and intense heat. Temporary marked vasodilatation is also observed particularly in the face and extremities. Ten cubic centimeters of blood are again collected 90, 210, and 480 minutes after the injection. The intervals have been selected because they best show the changes of serum bilirubin level during the test, both in normal and pathologic conditions. Patients may be given a light meal after the third sample of blood has been collected to avoid an excessively long period of fasting. This practice does not influence the result of the test.

The tubes containing the blood are left in the oven at 37° C for one hour and the serum is then separated by centrifugation. To prevent hemolysis (which represents one of the major causes of error in the determination of the bilirubin level) the blood must be obtained with a perfectly dry syringe and needle† by a clean venipuncture and without forcing. Total and direct reacting bilirubin are determined in each sample with the method of Jendrassik and Grof<sup>6</sup> and the value of bilirubin of the indirect reacting type is calculated by difference.

## RESULTS

*Effect of the Intravenous Injection of Sodium Nicotinate on Bilirubinemia*—Following the intravenous injection of sodium nicotinate in normal subjects the total bilirubin level of serum rises sharply, reaches a maximum value after ninety minutes and then decreases slowly, returning to normal

†Coating of syringes and needles with the film silicone (General Electric Dri-Film 9987) permits one to obtain serum free of hemolysis almost constantly. Technical details are given in a previous paper.

figures within six to eight hours. Ordinarily the rise in circulating bilirubin is due to the 'indirect reacting type' since no bilirubin of the direct reacting type appears in circulation. If the bilirubin variations are followed at regular

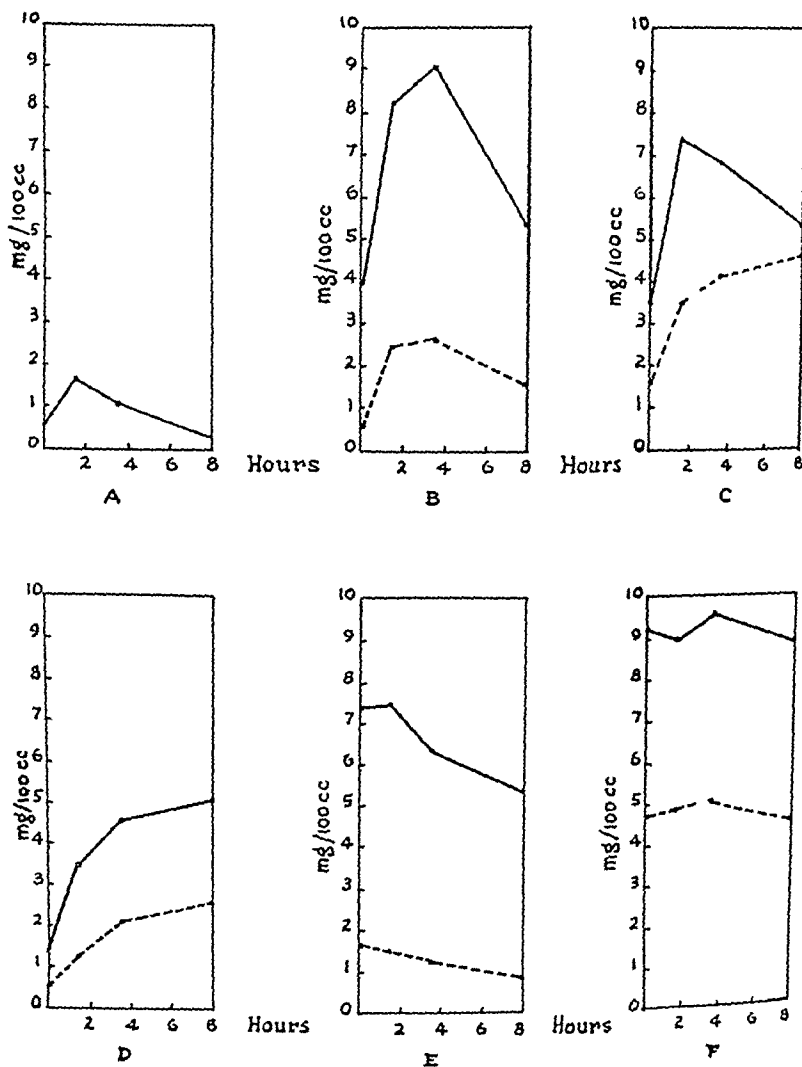

Fig. 1—Different types of hyperbilirubinemic curves obtained in normal subjects and in patients with various liver disorders following the intravenous injection of 30 mg. of sodium nicotinate.

(The continuous lines represent the level of total serum bilirubin; the broken ones the level of serum direct reacting bilirubin.)

intervals and plotted against time, a curve is obtained with a sharp, short ascending and a prolonged, slowly descending segment (Fig. 1, A shows an average normal curve, derived from the analytic values obtained in twenty-two normal subjects). Serum cholesterol and bile salts are also influenced by the intravenous injection of sodium nicotinate (Table III), but so inconsistently that their variations do not present any clear significance. This phenomenon appears to be specific for sodium nicotinate. Chemically related substances

TABLE I LEVELS OF BILIRUBIN CHOLESTEROL BILE SALTS, CHLORIDES AND URIC ACID OF SERUM IN A PATIENT WITH CIRRHOSIS OF THE LIVER FOLLOWING THE INTRAVENOUS INJECTION OF SODIUM NICOTINATE (30 MG)

*The Chologogic and Choleretic Effect of Sodium Nicotinate*—When 30 mg of sodium nicotinate are given intravenously to normal subjects in whom a Rehfuss tube has been passed previously into the duodenum a copious flow of bile begins about ten minutes after the injection. For the first five minutes

the bile collected has the characteristics of bile A, then, for about twenty minutes, of bile B, and finally of bile C. The total amount of bile which is collected in one hour's time is 200 to 250 cc, far greater than the amount obtainable through ordinary stimulation with the Meltzer-Lyon technique. If the serum bilirubin level is determined simultaneously, it appears to be only minimally increased. The same low type of hyperbilirubinemic curve is obtained when the biliary flow is stimulated with intraduodenal introduction of  $MgSO_4$ , thirty to sixty minutes before the intravenous injection of sodium nicotinate, and the bile obtained is, at least in part, extracted through the Rehfuess tube.

The first two findings suggest a direct stimulation of the bile excreting function of the liver by sodium nicotinate. This has been, moreover, proved directly from the study of a patient suffering from chronic hepatocholangitis in which a surgical biliary fistula had been therapeutically established. This case, which offered a rare opportunity of following the modifications of the bilirubin level of bile as compared with those of serum bilirubin during the performance of the sodium nicotinate test, has been presented in detail elsewhere.<sup>7</sup> Notwithstanding the presence of the fistula, the concentration of stercobilin (determined in the feces with the method of Watson<sup>15</sup>) showed a considerable amount of bilirubin still flowing into the intestine. The injection of sodium nicotinate in this patient was followed by a limited rise in the serum bilirubin level. Its consequent decrease toward the initial value was accompanied in direct time relationship by an increase of bilirubin concentration in bile.

*The Effect of the Intravenous Injection of Sodium Nicotinate on Urobilinuria*—The cholagogic and choleretic action of sodium nicotinate provides larger amounts of urobilinogen for reabsorption from the intestinal tract. This effect is further enhanced by the vasodilatation caused by the substance, particularly pronounced in the splanchnic area. A corresponding rise in the amount of urobilin eliminated could, therefore, be expected.

Studies on the changes in elimination of urobilin after the intravenous injection of sodium nicotinate have been carried out in twelve normal subjects and in a few patients with various grades of liver dysfunction. Urobilin level in urine has been determined with the original method of Heilmeyer and Krebs.<sup>5</sup> It has been found consistently that, following the intravenous injection of sodium nicotinate, the urinary concentration of urobilin rises to from five to eight times the original values, reaches a maximum value two to three hours after the injection, and then slowly returns to the normal level in twenty-four hours (Fig 2, Table IV). This rise in concentration of urobilin is roughly proportional to that of the indirect reacting bilirubin of serum, although somewhat delayed. It is greatly pronounced (ten to fifteen times the original values) in patients presenting serious liver dysfunction.

In patients in whom direct reacting bilirubin appears or increases in circulation as an effect of the injection of sodium nicotinate, a contemporaneous appearance of bilirubin or rise in its concentration is observed in the urine.

TABLE IV. MODIFICATIONS OF THE LEVEL OF TOTAL AND DIRECT REACTING BILIRUBIN OF SERUM AND OF UROBILIN FOLLOWING THE INTRAVENOUS INJECTION OF 30 MG OF SODIUM NICOTINATE

TIME AFTER INJECTION	0 MIN	90 MIN	120 MIN	180 MIN	24 HR.

Fig. 2.—The effect of the intravenous injection of 30 mg of sodium nicotinate on the level of serum indirect reacting bilirubin and the level of urobilinuria in a patient with chronic hepatocholangitis.  
(The values of indirect reacting bilirubin and of urobilin are expressed in milligrams per 100 ml of serum and urine respectively.)

*Hyperbilirubinemic Curves in Normal and Pathologic Conditions*—As described previously, the intravenous injection of sodium nicotinate in normal subjects is followed by a rise in the level of indirect reacting bilirubin of serum, which returns to normal within eight hours.

The liver cell very probably disposes of the sudden load of indirect reacting bilirubin caused by the sodium nicotinate test by transforming it to direct reacting bilirubin and certainly eliminates the latter. A curve of the type shown in Fig. 1, A is therefore obtained when both bile forming\* and bile excreting functions of the liver are normal. The curve is usually found (a) in normal subjects, (b) in patients with moderately abnormal liver function but no clinical jaundice, (c) in a few patients presenting mild clinical jaundice and a serum bilirubin level slightly higher than normal. Some of the patients of the third group may also present a small amount of circulating direct bilirubin which is only insignificantly modified during the course of the test and always returns to the initial value at the end of the eight hour period. Often, at the end of the

\*To be understood as the capacity probably possessed by the liver cell of transforming the indirect to direct reacting bilirubin of elimination and indicated by the gradual decrease of the circulating bilirubin of the indirect reacting type.

the bile collected has the characteristics of bile A, then, for about twenty minutes, of bile B, and finally of bile C. The total amount of bile which is collected in one hour's time is 200 to 250 cc., far greater than the amount obtainable through ordinary stimulation with the Meltzer-Lyon technique. If the serum bilirubin level is determined simultaneously, it appears to be only minimally increased. The same low type of hyperbilirubinemic curve is obtained when the biliary flow is stimulated with intraduodenal introduction of  $MgSO_4$ , thirty to sixty minutes before the intravenous injection of sodium nicotinate, and the bile obtained is, at least in part, extracted through the Rehfuess tube.

The first two findings suggest a direct stimulation of the bile excreting function of the liver by sodium nicotinate. This has been, moreover, proved directly from the study of a patient suffering from chronic hepatocholangitis in which a surgical biliary fistula had been therapeutically established. This case, which offered a rare opportunity of following the modifications of the bilirubin level of bile as compared with those of serum bilirubin during the performance of the sodium nicotinate test, has been presented in detail elsewhere.<sup>7</sup> Notwithstanding the presence of the fistula, the concentration of stercobilin (determined in the feces with the method of Watson<sup>15</sup>) showed a considerable amount of bilirubin still flowing into the intestine. The injection of sodium nicotinate in this patient was followed by a limited rise in the serum bilirubin level. Its consequent decrease toward the initial value was accompanied in direct time relationship by an increase of bilirubin concentration in bile.

*The Effect of the Intravenous Injection of Sodium Nicotinate on Urobilinuria*—The chologogic and choleretic action of sodium nicotinate provides larger amounts of urobilinogen for reabsorption from the intestinal tract. This effect is further enhanced by the vasodilatation caused by the substance, particularly pronounced in the splanchnic area. A corresponding rise in the amount of urobilin eliminated could, therefore, be expected.

Studies on the changes in elimination of urobilin after the intravenous injection of sodium nicotinate have been carried out in twelve normal subjects and in a few patients with various grades of liver dysfunction. Urobilin level in urine has been determined with the original method of Heilmeyer and Krebs.<sup>5</sup> It has been found consistently that, following the intravenous injection of sodium nicotinate, the urinary concentration of urobilin rises to from five to eight times the original values, reaches a maximum value two to three hours after the injection, and then slowly returns to the normal level in twenty-four hours (Fig. 2, Table IV). This rise in concentration of urobilin is roughly proportional to that of the indirect reacting bilirubin of serum, although somewhat delayed. It is greatly pronounced (ten to fifteen times the original values) in patients presenting serious liver dysfunction.

In patients in whom direct reacting bilirubin appears or increases in circulation as an effect of the injection of sodium nicotinate, a contemporaneous appearance of bilirubin or rise in its concentration is observed in the urine.

No tissue deposits of bile pigments are known to exist, at least in normal conditions,<sup>1</sup> nor is the injection of sodium nicotinate followed by changes in level of blood chlorides and uric acid (substances which are easily mobilized from tissues). Another possibility namely that the hyperbilirubinemia may be due to an exaggeration of normal blood destruction, has no clear cut experimental evidence in its favor. No changes of red blood cell and reticulocyte count follow the intravenous injection of sodium nicotinate although these changes might be very small yet significant (more important they could be masked by variations of hemoconcentration). However hyperbilirubinemic curves of normal type are usually obtained in patients with increased fragility of erythrocytes.\*

Our findings suggest that the increase of indirect reacting bilirubin of serum is due to the increased reabsorption from the intestine of a biliary pigment (possibly mesobilirubin). This tentative conclusion is based on strong but, so far, indirect evidence (a) the powerful cholagogic and choleretic effect of sodium nicotinate and (b) its pronounced vasodilatory action on the vessels of the splanchnic area. As a result the reabsorption from the intestinal tract of components of bile is greatly increased. (Exaggerated reabsorption of a chromogenous bilirubin derivative—urobilinogen—following the intravenous injection of sodium nicotinate is shown by the corresponding changes in elimination of urobilin.) Further evidence shows that availability of bile in the intestine and hyperbilirubinemic effect of sodium nicotinate are directly related as proved by two main findings (a) the hyperbilirubinemic effect of sodium nicotinate is limited or absent in normal subjects when biliary flow is first stimulated by means of  $MgSO_4$  and the secreted bile extracted as completely as possible by means of a Rehfuess tube passed into the duodenum (b) patients with complete biliary obstruction do not present any hyperbilirubinemic response to sodium nicotinate.

The conclusion suggested is not supported by the accepted theories on the metabolism of biliary pigments. However the Italian school of Zoja<sup>16</sup> has strongly claimed that serum bilirubin of the indirect reacting type represents reabsorbed mesobilirubin which has escaped the hepatic filter through lymph channels or the portacaval anastomoses. Notwithstanding the demonstration by Colangiuli<sup>3</sup> that mesobilirubin and indirect reacting bilirubin behave in a similar manner with various chemical reagents the theory still awaits more conclusive evidence and is not generally accepted. It would however offer an explanation of our findings since the increased flow of bile and the vasodilatation induced by sodium nicotinate could exaggerate the reabsorption of mesobilirubin and consequently raise the serum level of indirect reacting bilirubin.

The increased elimination of urobilin which follows the intravenous injection of sodium nicotinate is another finding of clinical interest and practical

A very low hyperbilirubinemic curve was observed in a patient with Verlhof's disease recently splenectomized. This finding is difficult to interpret and thus does not specifically support or deny the view that exaggerated blood destruction is the cause of the hyperbilirubinemia due to sodium nicotinate.

\*No hyperbilirubinemia follows the intravenous injection of nicotinamide which is only slightly less active than sodium nicotinate in increasing the biliary flow but has not possessed any vasodilatory effect. This indirect evidence would suggest that the hyperbilirubinemia depends more on the vasodilatory action than on the cholagogic and choleretic effect of sodium nicotinate.

importance The effect is probably due to a double mechanism (a) the presence in the intestinal tract of a large amount of urobilinogen available for reabsorption, due to the cholagogic and choleretic effect of sodium nicotinate, (b) the vasodilatory effect of the substance on the splanchnic vascular area, which increases the possibility of the chromogen being adsorbed directly into the general circulation through portacaval anastomotic vessels The coordination of these two mechanisms explains the magnitude of the increased elimination of urobilin in the urine after intravenous injection of sodium nicotinate From a clinical viewpoint the observation shows that *large quantities of urobilin may appear in the urine even when no liver damage or hyperhemolysis can be demonstrated* This last finding indirectly confirms earlier experiments of Mell<sup>10</sup> who was able to show in dogs that the rise of pressure within the portal system (determined with experimental occlusion or direct compression of the portal vein, or pneumothorax of the right side) causes increased elimination of urobilin When the pressure within the portal tree is increased, an amount of urobilinogen greater than normal reaches the general circulation and is finally eliminated as urobilin A similar mechanism can be cited to explain the pronounced urobilinuria of clinical conditions (pneumothorax of the right side, pylethrombosis, early cirrhosis of the liver) in which liver dysfunction is absent or too limited to account for the finding It could also explain the daily fluctuations and the postprandial increase of physiologic urobilinuria

The findings presented in this paper might have possible diagnostic and therapeutic applications That the sodium nicotinate technique could be used as a test of liver function is obvious The technique, producing a prompt and conspicuous rise of the serum indirect reacting bilirubin, tests the ability of the hepatic cell to dispose of a sudden and large load of bilirubin and evaluates both the bile-forming and the bile-excreting functions of the liver Compared with the tolerance tests of exogenous bilirubin or with other techniques in which a rise of the serum bilirubin level is determined indirectly by the injection of different substances (epinephrine, biliary salts, desoxycorticosterone acetate) or other methods (ingestion of fats and carbohydrates, diathermy and roentgen irradiation of the hepatic and splenic areas), the sodium nicotinate test has the advantage of causing a prolonged and conspicuous hyperbilirubinemia with a technique both simple and safe Unfortunately, studies on seventy eight patients presenting various liver disorders show the pattern of the hyperbilirubinemic curve after intravenous injection of sodium nicotinate to present no definite correlation with the anatomic or clinical diagnosis of the case, the total hepatic function evaluated with a "profile" of liver function tests, or the results of any other individual test This finding is not attributable to an intrinsic defect of the sodium nicotinate technique, but to the fact that bilirubin excretion is widely dissociated from other functions of the liver It may remain normal even in cases of serious cellular damage, or be involved early in rather benign conditions The results of the test, therefore, cannot be used as an indication of the total function of the liver nor considered as a means of differential diagnosis between obstructive and hepatocellular jaundice, since a diag

nostically typical curve (first type) is obtained only in cases of complete obstruction of the biliary tract. The sodium nicotinate technique remains mainly a test of the bilirubin excreting function of the liver. Under certain conditions, it may also be useful in the prognostic evaluation of jaundice. For example in cases of infectious hepatitis still with evident jaundice the test may give a normal result, indicating the restoration of a normal excretion of bilirubin and forecasting the regression of the icterus at an early date. In other cases jaundice may be due rather to sluggishness than insufficiency of the bilirubin excreting function as in icteric malaria. The sodium nicotinate curve will then show a normal pattern.

Sufficient evidence has been given to show that sodium nicotinate when administered intravenously exercises a powerful cholagogic and choleretic action. This effect has been proved by means of duodenal intubation in normal subjects and in a patient with surgical biliary fistula. Experiments utilizing the same techniques have also shown that intravenous nicotinamide or sodium nicotinate or nicotinamide administered by mouth in therapeutic doses also possess the same action although slightly less pronounced. Although these findings suggest a possible therapeutic use of both substances in jaundice which has not yet reached the irreversible stage, much more additional evidence is required before these conclusions can be given practical clinical application.

This communication should be considered of a preliminary character and the results presented here certainly do not exhaust the possibilities of experimental and clinical investigation offered by the sodium nicotinate test. It is unfortunate that the related observations cannot be completed and integrated with animal experimentation because no hyperbilirubinemia can be determined in dogs and rabbits with the technique. However, further work in human beings is contemplated, employing this test, to obtain more information on the normal and pathologic metabolism of biliary pigments.

#### SUMMARY AND CONCLUSIONS

1 The intravenous injection of 30 mg. of sodium nicotinate in normal subjects is followed by (a) a rise of the serum level of indirect reacting bilirubin, which reaches a maximum after about ninety minutes, then slowly returns to the initial value within six to eight hours, (b) almost immediate stimulation of the secretion and excretion of bile (bilirubin), (c) increased elimination of urobilin which reaches a maximum two to three hours after the injection and returns to normal values in about twenty four hours.

2 In pathologic conditions two main modifications of the hyperbilirubinemic effect of sodium nicotinate are observed (a) a failure of the bilirubin level to return to normal values within the experimental period of eight hours (b) the appearance in circulation of bilirubin of the direct reacting type. Their various combinations characterize different types of curves obtained in patients with liver disorders. These curves are not consistently related to the anatomic or clinical condition of the patient. Therefore the hyperbilirubinemic effect cannot be utilized as a test of liver function or for the differentiation between hepatogenous and obstructive jaundice.

3 The interpretation of the ascending part of the hyperbilirubinemic curve is complex, experimental evidence suggests that the rise in level of the indirect reacting bilirubin in serum might be due to increased reabsorption of meso bilirubin from the intestine. The descending part is in direct relationship to the bile-excreting function of the liver.

4 The increased elimination of urobilin is very likely due to the increased reabsorption of urobilinogen, because of the vasodilatory, chologogic and choleretic effects of sodium nicotinate. The finding proves that large quantities of the chromogen may appear in the urine even when no liver damage or hyperhemolysis can be demonstrated.

5 Both sodium nicotinate and nicotinamide, when given intravenously or orally, exert a powerful choleretic and chologogic effect.

# CHOLESTEROL DESOXYCHOLIC ACID A STABLE ANTIGEN FOR USE IN A FLOCCULATION TEST FOR LIVER DYSFUNCTION

## I COMPARISON WITH THE HANGER CEPHALIN CHOLESTEROL TEST

MAJOR ARTHUR STEINBERG \* SANITARY CORPS UNITED STATES ARMY  
RESERVE CORPS  
PHOENIXVILLE, PA

SINCE the introduction of the Hanger test<sup>1,2</sup> it has found many proponents.<sup>3,4</sup> I had an opportunity to employ this test as well as other liver function studies in a large series of cases in military personnel.

There were a few pitfalls associated with the cephalin cholesterol flocculation test as it was first performed by me. Bacterial contamination was found to give rise to false positives especially in an overheated room. Furthermore the reaction was photosensitive.<sup>11</sup> The latter was reported also by Neefe and Reinhold.<sup>12</sup> To avoid bacterial contamination sulfanilamide was dissolved in the 0.85 per cent saline in a concentration of 1:1,000 and later a 1:10,000 solution of Merthiolate was employed. With both of these agents there was found no interference with the sensitivity of the reaction. To avoid the false positives observed with exposure to light especially direct sunlight the tubes were kept in a dark cupboard.

It was observed early that there was a considerable disparity of results obtained in the Hanger tests when parallel tests were set up with two commercial antigens, Wilson and Difco. The former seemed to be much less sensitive. It appeared likely that such variation between the two antigens may have been due to differences in the cephalin. Previously Mateer and co-workers had indicated that the state of the cephalin affected the sensitivity of the test.<sup>6,14</sup> Later Lippincott and associates<sup>1</sup> reported a discrepancy of results obtained in patients with vivax malaria employing the Difco and Wilson antigens. These authors also found the Wilson antigen to be less sensitive.

Kabat, Hanger, Moore and Lindow<sup>16</sup> showed that false positive tests were obtained with known negative sera when the sera was inactivated for thirty minutes at 56° C. This observation also was made by me in using similar heat inactivated sera.

There is no attempt made in this paper to detract from the value of the Hanger reaction as a liver function test in fact adequate confirmation of the reliability of the test is presented herein. This investigation was undertaken because of the following: (1) the instability of the cephalin in the preparation of the antigen; (2) the difficulty in preparing the antigen or the expense in purchasing commercial preparations of the antigen; and (3) the lack of availability

From the Valley Forge General Hospital

Received for publication April 1949

Present address: Physicians and Surgeons Laboratory 193 Spruce Street, Philadelphia 3 Pa.

of the antigen or the components for its preparation in overseas hospital installations. An attempt was therefore made to prepare a similar antigen from readily available compounds, but one that would be stable. Cephalin is an unstable phospholipid, which readily undergoes oxidation. It appeared likely that the chief function of this substance in the preparation of the Hanger antigen was to render the antigen more soluble in the aqueous media employed in the flocculation test. This fact was also suggested by MacLagan,<sup>1</sup> who, during the development of the thymol turbidity test, suggested that the turbidity obtained with the sera of patients manifesting parenchymatous liver disease was due primarily to phenol and its substitution products. He showed a definite relationship between the molecular weight, solubility, and the precipitating power. He indicated that higher homologues such as cholesterol failed to give positive results because of their lack of solubility.

Consequently, I sought a stable substance of known chemical composition that would increase the solubility of cholesterol. Veisz and Kúthy<sup>18, 19</sup> demonstrated that free bile acids have the ability to keep fatty acids and other acholic components in aqueous solution. This appeared to be accomplished by the formation of coordination compounds and was confined to the alkaline side of the neutral point. These authors also showed that lecithin and other substances exert an influence of their own on solubility in a mixture and may supplement the effect of the bile acids. The enhanced solubility of cholesterol in bile and bile acids solutions was mentioned as early as 1868 by Kuehne.<sup>20</sup> Finally, diffusion experiments by Schoenheimer and Hidada<sup>21</sup> showed that cholesterol was more strongly associated with desoxycholic acid than any other bile acid.

Hence, desoxycholic acid was selected as the compound of choice, to replace cephalin in the Hanger antigen. Desoxycholic acid has been used in the preparation of a variety of coordination compounds, including the phenanthrene hydrocarbons. It has the property of forming loose compounds with steroids, thereby broadening the solubility range of the combined substance. Initially a coordination compound of cholesterol-desoxycholate was prepared by fusing one molecular weight each of cholesterol and desoxycholic acid with the aid of heat. A cholesterol-desoxycholate was also prepared by the method of Downie, Stent, and White<sup>22</sup> by crystallization from petroleum ether. Subsequently a simpler preparation was devised, which eliminated the necessity for the formation of this coordination compound entirely.

#### METHOD

*Preparation of the Stock Antigen*—1.2 Gm of chemically pure desoxycholic acid were dissolved in 16 cc of absolute alcohol with the aid of gentle heating, then 0.6 Gm of chemically pure cholesterol was dissolved in this solution of desoxycholic acid. This yields an alcoholic solution of cholesterol which was of the same concentration as that of Hanger. This stock antigen was stored in a tightly stoppered bottle in the refrigerator.

*Preparation of the Cholesterol Desoxycholic Acid Emulsion*—The working antigen was prepared by placing 30 cc of N/60 NaOH in a small beaker and heating to about 70° C. The flame was removed and 1 cc of stock antigen was added, a drop at a time, with constant stirring. The mixture was then slowly brought just to the boiling point with constant stirring. The resultant emulsion was then allowed to cool to room temperature and transferred to two 15 cc centrifuge tubes. These were centrifuged at 1,500 rpm for five

minutes to remove any coarse particles. The supernatant milky emulsion was then poured off and stored in a stoppered test tube. This emulsion keeps for days in the refrigerator.

*Procedure*—To 4 cc of phosphate buffer of pH 7.8 in a small test tube or 15 cc centrifuge tube such as Hanger employed, was added 0.2 cc of serum. The contents were then mixed by inverting several times. Then 1 cc of antigen emulsion was added and the contents were vigorously shaken, stoppered and allowed to stand. The tubes were examined at twelve, twenty-four and forty-eight hours for flocculation and were reported as negative, +, ++, +++, +++++, as in the Hanger test. Two control tubes were prepared at the same time. One contained known negative serum and the other contained just the buffer and emulsion in the same proportions as in the test. Flocculation of ++ or more in forty-eight hours was considered positive.

Parallel Hanger tests were performed in all sera tested. Simultaneous thymol turbidity, icterus index, serum bilirubin, albumin/globulin ratio, cholesterol, total and esters, alkaline phosphatase and, in many instances, bromsulphalein, heterophile antibody, and urine urobilinogen were also carried out. These latter will be reported in a subsequent paper.<sup>26</sup>

There were 600 tests performed on 485 individuals. The type of cases utilized are depicted in Table I.

TABLE I CASES STUDIED

DIAGNOSIS	NUMBER OF PATIENTS	NUMBER OF TESTS
Infectious hepatitis	142	174
Obstructive jaundice	14	22
Cirrhosis of liver	5	12
Cholecystitis	8	8
Infectious mononucleosis	38	66
Vivax malaria	82	116
Miscellaneous	28	34
Normal	168	168
Total	485	600

Where possible the sera of these patients were tested during the various phases of the disease, i.e., at the onset, during subsidence, during recrudescence, and following clinical recovery. The diagnoses in the various cases were based on appropriate laboratory studies and clinical evaluation.\*

## RESULTS

The results obtained in the individual cases will be published subsequently together with the other laboratory data mentioned previously. A summary of the data is herein presented.

The results obtained in the sera of patients in various stages of infectious hepatitis are shown in Table II.

TABLE II FLOCCULATION TESTS IN CASES OF INFECTIOUS HEPATITIS

NUMBER OF CASES	NUMBER OF TESTS	% HANGER POS	% CDF* POS	CLINICAL STAGE
56	76	96	97	Active (acute)

CDF, cholesterol desoxycholic acid flocculation test.

†Icterus index serum bilirubin normal.

I am indebted to many medical officers from the 1st and General Hospital, the 13th General Hospital, The Valley Forge General Hospital, especially Lt. Col. I. Pilot, Col. Frank Sinclair, deceased, Lt. Col. E. A. Gall, Capt. Mack Elber, Lt. Col. R. R. Huffer, Major Jacobson, Dr. H. I. Segal, and Dr. F. R. Schechter for their cooperation, encouragement, and for the clinical diagnosis in the cases studied in this presentation.

Physically, the flocculant of the cholesterol desoxycholic acid flocculation test appears to be finer and to pack more firmly. An effort will be made to perform these tests subsequently.

The evidence reported herein would suggest that the Hanger and cholesterol desoxycholic acid flocculation tests could be employed interchangeably in the diagnosis and follow up of cases of hepatocellular diseases.

#### SUMMARY

1 A new antigen is described in which desoxycholic acid was substituted for cephalin in the cephalin cholesterol flocculation test.

2 There were 600 tests on 475 patients carried out employing the cholesterol desoxycholic acid (C D I) and the cephalin cholesterol flocculation test with 94 per cent agreement.

3 The cholesterol desoxycholic acid flocculation test compared closely with the Hanger test in specificity and sensitivity. The mechanism of action in the two tests appeared to be closely related.

4 The cholesterol desoxycholic acid flocculation test appeared to be of advantage in regard to stability, ease of preparation and economy.

## A CRYOGLOBULIN PRESENT IN HIGH CONCENTRATION IN THE PLASMA OF A CASE OF MULTIPLE MYELOMA

ROBERT M. HILL, PH.D., STUART G. DUNLOP, PH.D., AND  
RICHARD M. MULLICAN, M.D.  
DENVER, COLORADO

THE first reported case of a reversible cold precipitation of plasma protein is that of Wintrobe and Buhl<sup>1</sup> (1933). This and other cases that have been reported since that time are summarized by Lerner and Watson (1947), who give the relevant bibliographies. In their paper a new case is described which is particularly valuable because of the completeness of the studies. An extensive physical chemical study of the protein is described in a separate paper by Lerner and Greenberg.<sup>2</sup> All of these cases gave immediate gross precipitation of protein on cooling the plasma and resolution of the precipitate on warming. Because of this property Lerner and Watson have suggested the name "cryoglobulin" for this class of proteins.

Since the publication of the paper of Lerner and Watson, a case with Raynaud's syndrome having a protein of this class in the plasma was reported by Hansen and Faber<sup>3</sup> (1947). Olhagen<sup>4</sup> (1948) has also described three cases that merit special mention. All three gave spontaneous crystalline precipitates, although the crystal structure was not the same in any two cases. In Case I (diagnosis myeloma, total plasma protein 10.1 Gm per cent) the content of spontaneously precipitating protein was 1.4 Gm per cent of plasma. In spite of this high concentration it did not precipitate immediately on cooling, and after warming to 37° C. redissolved slowly (twenty to thirty minutes). There is a question whether Olhagen's Case II (diagnosis myeloma, total protein 13.0 Gm per cent) should be listed as a cryoglobulin because the precipitation was "on the whole independent of the outer temperature but slightly faster in the cold." The spontaneous precipitation of crystalline protein appeared first after 24 hours and amounted to 0.8 Gm per cent of plasma. The electrophoretic pattern of this plasma showed 75.6 per cent of the total area in the gamma globulin peak. This is reminiscent of the case of Holmberg<sup>5</sup> in which precipitation could be prevented by anaerobic collection. The stimulus to precipitation seemed to be the loss of CO<sub>2</sub> on exposure to air. Olhagen did not find anaerobic collection a factor in his Case II and does not suggest a cause for the protein precipitation. Olhagen's Case III (probably "a myeloma diagnosis in spite of the negative marrow and x-ray findings") was complicated by renal insufficiency and high blood nonprotein nitrogen. There was no hyperproteinemia (total protein 7.4 Gm per cent). The spontaneously crystallizing protein amounted to 0.6 Gm per cent of plasma; it precipitated immediately on cooling and redissolved promptly on warming to 37° C. A urinary protein was electrophoretically identical with the cryoglobulin of the plasma.

From the Departments of Biochemistry, Bacteriology, and Pathology, University of Colorado Medical Center.

Received for publication March 3, 1949.

Wertheimer and Stein<sup>7</sup> were the first to suggest a classification of "cold fraction" plasma proteins. They made a systematic search for such proteins following their discovery of a "cold fraction" in the plasmas of dogs infected with kala-azar. "Cold fractions" were classified by them as Grades 1, 2, 3, 4, and 5. Grade 1 was defined as including those plasmas showing "turbidity marked but no precipitate" after standing twenty-four hours in the refrigerator at 7 to 11° C, Grades 2 and 3 were intermediate and Grade 4 included plasmas showing a "marked precipitate easily estimable by quantitative methods." Grade 5 was reserved for reversible cold fractions of a nonprotein nature, usually cholesterol, of which these authors found a considerable number. Investigators are warned against mistaking Grade 5 cold fractions for cold-sensitive proteins. Five cases of kala-azar in human beings were investigated, two of which showed Grade 4 cold fractions while the other three showed Grade 3 precipitations. This indicates that large quantities of cold sensitive plasma proteins may be a common occurrence in this disease to be found for the searching. Eight cases of endocarditis lenta all showed cold fractions of Grades 1 to 3, with one showing Grade 4. Grades 1 to 3 were found in four cases of nephrosis. In the twenty-seven cases studied, Grade 5 precipitates (nonprotein reversible cold fractions) were found in six.

A more extensive and more systematic search for cold-sensitive plasma proteins was reported by Lerner, Barnum, and Watson<sup>8</sup> (1947). These authors examined the serums from one hundred twenty-one patients with a variety of pathologic conditions and from forty controls. Their work is the basis for a very practical classification of cryoglobulins according to the time of appearance on standing at 5° C and according to the amount of precipitate formed. Grade 1 includes plasmas containing a trace to 6 mg per cent of cryoglobulin appearing between twenty-four hours and one week, Grade 2 includes plasmas containing 6 to 25 mg per cent appearing in twenty-four hours, Grade 3 includes plasmas containing more than 25 mg per cent of cryoglobulin appearing immediately on cooling. In one hundred twenty-one cases examined they found twelve cases of Grade 2 and eighteen cases of Grade 1 cryoglobulinemia. None were found among the forty controls. No case of Grade 3 cryoglobulinemia was found because of the systematic search, the one case listed was the first seen by these authors and was apparently the stimulus for the later work. The behavior of lipid precipitates was found to be "entirely different from the cryoglobulins." It should be emphasized that the Grade 3 cryoglobulinemia of these authors, the grade including the heaviest precipitation, corresponds to Grade 4 of Wertheimer and Stein<sup>7</sup>. In our search of the literature, we have found, including our own, fifteen cases of cryoglobulinemia that would be classified as Grade 3 according to the classification of Lerner, Barnum, and Watson.<sup>8</sup>

#### CASE REPORT

In the present paper we are reporting some properties of the plasma and of a cryoglobulin separated from the plasma of a person (Patient O. O.) suffering from multiple myeloma. The patient, a white woman, 55 years of age, entered Colorado General Hospital

Fig 1—X ray of left shoulder showing extensive destruction of head of left humerus and osteolytic process in the left scapula and clavicle.

Fig 2—Plasma cell myeloma of left humerus. Note prominent nuclei, often eccentric, sometimes double with heavy coarse margined chromatin and large conspicuous nucleoli. Hematoxylin and eosin stain. ( $\times 600$ )

on Aug 7, 1945 For the past seven years she had suffered from severe sensitivity to cold Death occurred the following September 9 Autopsy revealed plasma cell myeloma involving the bone marrow, chiefly of the left humerus, scapula, and clavicle The bone of the head and neck of the humerus was extensively destroyed by massive proliferation of cells with the morphology of plasma cells, chiefly in the plasmoblast stage (Figs 1 and 2)\*

#### RESULTS

*Properties of the Plasma*—When the blood of Patient O O was first drawn it was found to solidify quickly in the needle and syringe even though large amounts of anticoagulant were used However, when the syringe and needle were warmed before use and the sample of drawn blood was kept warm, it remained liquid indefinitely with no more than the usual additions of anti-coagulant When heparinized blood was kept at 37 to 40° C throughout the process of centrifugation it separated into three layers an upper layer of apparently normal plasma, a middle, clear, almost water-white layer, and a lower layer of cells On cooling, the upper layer remained liquid The middle layer, however, congealed to a pearly white translucent solid In a sample of 75 ml of blood, the volumes of the three layers were upper, 30 ml, middle, 28 ml, and lower, 17 milliliters Thus the middle layer of cold sensitive material accounted for 37 per cent of the total volume of the blood When the middle layer solidified on cooling the top layer could be poured off and, with distilled water, could be washed off completely from the surface of the solid middle portion On warming, the middle layer again liquefied and could be pipetted from the surface of the cells This separation was accomplished on five different samples drawn on five different days Following a whole blood transfusion the separation into three layers never again occurred though the whole blood or plasma solidified on cooling as before After dilution with distilled water the cryoglobulin of these latter samples separated on cooling first as a thin gel which then quickly broke up as a flocculent precipitate and could be purified by resolution in warm water from which it again precipitated on cooling Solidification on cooling to about 32° C and liquefaction on rewarming to 38° C was repeated on the same sample of whole blood fifteen times without any apparent changes in its properties

Fractional plasma protein analyses were carried out by means of a micro-modification<sup>10</sup> of the method of Howe These and other analytic data are collected in Table II The urine was free from protein at all times

In dilute solution the cryoglobulin was precipitated solely in the globulin fraction This was not true in high concentrations and it is probable that the high 'fibrinogen' fraction on Aug 28, 1945, contained a large amount of cryoglobulin

The viscosity of the plasma was measured at different temperatures with the Ostwald viscosimeter Exactly 3 ml of the plasma were used in the instrument which was then placed in a water bath at 45° C and allowed to stand for thirty minutes to come to thermal equilibrium After several determinations of viscosity were made at this temperature, the bath was cooled quickly with crushed ice and a new temperature level established By repeating this procedure, the data for viscosity changes with temperature were obtained

\*The pathologic aspects of the case have been reported\*

In Fig. 3 the curve for the plasma of Patient O O is compared with the average curve for three normal plasmas measured in this laboratory and the average curve for three normal plasmas and the curve for one hyperproteinemic plasma (9.2 Gm per cent) reported by Jochims<sup>11</sup>. The viscosity of the plasma of Patient O O is more than five times that of the average normal plasma at 38° C and rapidly increases to infinity at 32° C. If the viscosity of normal

Fig. 3—The changes of viscosity with temperature of the plasma of Patient O O. A case of hyperproteinemia reported by Jochims. D the average of three normals reported by Jochims (O) and F the average of three normals examined in this laboratory. Curve B is the log of the viscosity of the plasma of Patient O O showing a break at about 34° C.

plasma is plotted against the logarithm of the temperature, a continuous straight line is obtained. When the viscosity of the plasma of Patient O O is so plotted, two straight lines are obtained. The position of the break in the semilogarithmic curve suggests that the change in state of the cryoprotein on cooling begins when the temperature reaches 34° C.

**Chemistry of the Cryoglobulin**—A large sample of whole plasma was diluted and cooled in the icebox for several hours. It was then centrifuged with the centrifuge tubes packed in ice. The cryoglobulin separated in this way was quickly and completely dissolved when placed in warm (40° C) distilled water. The solution was again cooled in the icebox to reprecipitate the cryoglobulin. In this way the sample was purified by ten reprecipitations from distilled water. A small sample of the final product was dried to a pure white powder which gave strong biuret, xanthoproteic, Millon, and Acree-Rosenheim tests and a negative Molisch test. The bulk of the product was redissolved in warm distilled water and mixed with an equal volume of

95 per cent ethyl alcohol and placed in the icebox. Amorphous material began to precipitate at once and after three days needlelike crystals appeared (Fig 4). These were at first presumed to be crystals of the cryoglobulin because of the similar crystals found by Wintrobe and Buell<sup>1</sup> and the protein crystals reported in the case of myeloma of von Bonsdorff, Groth, and Packalen.<sup>12</sup> However, the crystals proved to be not protein but cholesterol ester (method of Schoenheimer and Sperry<sup>13</sup>) with no free cholesterol and no

Fig 4—Crystals of cholesterol ester separated from purified protein after standing in the cold room three days in 50 per cent ethyl alcohol ( $\times 60$ )

nitrogen or phosphorus present. The crystals must represent a "lightly bound" lipid fraction in the protein molecule because although they were not removed by ten resolutions in and precipitations from distilled water, they were removed by treatment in the cold for three days with 50 per cent ethyl alcohol. The quantity of crystals was approximately 2 per cent of the cryoglobulin.

The remaining amorphous protein was dried and subjected to repeated extraction with a 1:2 mixture of ethyl alcohol and ethyl ether. This treatment yielded an additional 0.17 per cent of material which proved to be 20 per cent cholesterol ester and 70 per cent fatty acid. Again no free cholesterol was present and only a trace of lipid phosphorus.

Four samples of the extracted and dried protein were subjected to micro-Kjeldahl analysis<sup>10</sup> and were found to contain 15.2, 15.2, 15.2, and 14.9 per cent nitrogen respectively, with an average of 15.13 per cent. Phosphorus and purines were not present in detectable quantities.

Another sample was assayed for amino acids by microbiologic methods essentially those of Stokes, Gunness, Dreyer, and Caswell<sup>14</sup> and Stokes and Gunness.<sup>15</sup> Nine amino acids were determined with *Streptococcus faecalis* (American Type Culture Collection No. 9790) and the tenth, phenylalanine, with *Lactobacillus delbrueckii* LD 5 (American Type Culture Collection No. 9595).

In Table I these assays are compared with assays, taken from the literature of some normal plasma protein fractions and with Bence Jones protein. The cryoglobulin shows an amino acid pattern suggesting relationship to the beta or gamma globulins.

TABLE I. AMINO ACID ANALYSES OF CRYOGLOBULIN COMPARED WITH ANALYSES OF NORMAL PLASMA PROTEINS AND BENCE JONES PROTEIN

All of the analyses the physical properties and the behavior toward Na<sub>2</sub>SO<sub>4</sub> fractionation of this cryoglobulin are compatible with its classification as a pseudoglobulin. It differed from other cryoproteins that have been described in its higher concentration in the plasma and the higher temperature at which it precipitated on cooling. After removal of the cryoglobulin the remaining plasma appeared to be qualitatively normal though the albumin concentration was low and the globulin and fibrinogen were high (Table II).

# IMMUNOCHEMICAL ESTIMATION OF THE RATE OF DISAPPEARANCE OF TRANSFUSED GAMMA GLOBULIN FROM THE BLOOD IN TWO CASES OF HYPOPROTEINEMIA

AARON BENDICH, PH D,\* AND ELVIN A KABAT, PH D †  
NEW YORK, N Y

SEVERAL cases have been reported in which an unusually low serum gamma globulin was observed electrophoretically<sup>1-5</sup> In two of these, reported in detail elsewhere,<sup>3, 4</sup> an opportunity was presented to follow by immunochemical methods the disappearance of gamma globulin from the blood after a transfusion of plasma The quantitative precipitin method has been used by several investigators for the estimation of various serum proteins<sup>6, 7</sup> and more recently a micromodification<sup>8</sup> has been applied to the determination of the gamma globulin and crystallizable albumin in human cerebrospinal fluid<sup>10</sup> The latter technique was applied in this study and indicated a "half-life" of 3 to 4 days for gamma globulin

In one of the patients, the ability to form antibodies was tested by subcutaneous injection of blood group A substance<sup>11, 12</sup> and of a mixture of six type-specific pneumococcal polysaccharides<sup>13, 14, 15</sup> The degree of utilization of dietary amino acids for tissue synthesis was evaluated in the second patient by determining the rate of excretion of N<sup>15</sup> in the urine after ingestion of a known amount of isotopic glycine<sup>16</sup>

## EXPERIMENTAL

One patient, E B, was a 31 year old woman Her case history has been presented by Homburger and Petermann<sup>3</sup> in connection with a detailed description of a new syndrome, familial idiopathic hypoproteinemia Despite a constant high protein diet, the gamma globulin level remained low No evidence of inefficient utilization of dietary protein could be found Proteinuria was absent The rate of synthesis of serum protein was found to be normal<sup>3</sup> The general clinical picture was negative

A small blood sample (E B<sub>2</sub>) was taken before the intravenous injection of 975 ml of normal donor plasma Blood samples were then removed two hours later and after one, three, five, and nine days

Determination of the gamma globulin in the transfused plasma and in the serum samples was carried out as previously described<sup>10</sup> except for the addition of appropriate dilutions of the serum samples to 10 ml portions of calibrated rabbit antiserum to purified and electrophoretically homogeneous human gamma globulin (gamma globulin of Deutlich and co-workers<sup>17</sup>) and measuring the quantities of specifically precipitable nitrogen The equivalent amounts of gamma globulin are found by interpolation on the calibration curve Dilutions of the serum samples of 1:50 to 1:200 were required to ensure that all analyses were carried out in the region of antibody excess (as is necessary for the immunochemical method to be valid) The results are listed in Table I

After immunization	0.003 $\mu$ g	0.001 $\mu$ g	0.005 $\mu$ g	0 $\mu$ g	0 $\mu$ g	0.018 $\mu$ g	0.004 $\mu$ g

The second patient B V, a 33 year old female mechanic, showed a generalized nonspecific lymph node enlargement in 1937 which was radiosensitive and disappeared on treatment in August, 1938. The albuminuria noticed in 1938 did not reappear. With the exception of edema of the lower extremities the clinical picture was negative. An intake of 90 Gm of protein per day was required to maintain nitrogen balance. For fifteen days before and for the duration of the experiment (Jan 9 to 23, 1948) the daily protein intake was about 1.0 Gm per day. A detailed case history will be given elsewhere.<sup>4</sup> The patient died on March 13, 1948, from a brain hemorrhage, and a giant follicular lymphoma was found on autopsy.

One half liter of normal plasma was injected intravenously after a blood specimen (B V) had been taken. Additional blood specimens were removed two hours, one, three, five, nine and fourteen days later for total protein and gamma globulin analyses. As in the case of E B, serum samples prepared from the bleedings were diluted appropriately. The gamma globulin determinations are listed in Table I. Duplicate analyses were performed throughout.

Manufactured by E. R. Squibb and Co. New Brunswick, N. J.

\*The vaccine was obtained through the kindness of Professor Michael Heidelberger.

†By Mrs. Marie DiLapi in Dr. Heidelberger's laboratory.

To obtain information concerning the efficiency of utilization of dietary glycine,<sup>16</sup> B V received orally 540 mg of glycine<sup>18</sup>\* containing 32 per cent excess N<sup>15</sup>. Total daily urine collections were made for three days. Isotope determinations† indicated that 42, 52, and 60 per cent of the dietary isotope had been eliminated twenty four, forty eight, and seventy two hours after ingestion.

## RESULTS

From Table I it may be seen that injection of the plasma caused almost a doubling of the gamma globulin concentration in the blood serum of both subjects, although there was a very much smaller increase in total serum protein. In both instances, it required about nine days for the gamma globulin to return to the preinjection level, and about three to four days for the initial increase in gamma globulin to be reduced by one-half, indicating a "half life" for the injected gamma globulin of about 3 to 4 days.

As for the response of E B to injection of pneumococcal specific polysaccharides, the data in Table II reveal no measurable antibody to types III and V and extremely little to type I. The greatest response was to type VII. The values for types II and VIII are probably significant.

## DISCUSSION

Although many electrophoretic studies on plasma proteins have been carried out, only very few instances of low gamma globulin have been recorded. Perhaps the first record is that by Forbes in 1944<sup>1</sup> of a hypoproteinemic woman. The gamma globulin studied electrophoretically was unaffected by ingestion or intravenous injection of Amigen. Following a plasma transfusion, this patient eliminated most of the plasma protein she had received intravenously in eight days. Kiebs<sup>2</sup> described a 15-year-old girl suffering from malnutrition who showed a general hypoproteinemia with an electrophoretically determined gamma globulin level of 0.15 Gm per 100 ml plasma. This returned to about normal (0.65) on dietotherapy. Two other cases of hypogammaglobulinemia, in children, have been cited by Stein.<sup>3</sup>

In the present study, an attempt has been made to consider the possible metabolic basis for the low gamma globulin levels. It has been seen that a decreased gamma globulin due to low protein intake may be restored to normal when the proper protein intake is maintained.<sup>2</sup> This explanation obviously does not apply to the two patients studied, for they were kept on protein intake levels far in excess of that required for nitrogen balance without affecting their serum gamma globulin.

The present study showed that on transfusion of an amount of plasma sufficient to double the circulating serum gamma globulin, this component returned to its original level at a rate indicating a "half-life" of 3 to 4 days. Unfortunately, the procedure does not lend itself to a comparison in normal subjects since it would not be possible to raise the gamma globulin level significantly by transfusing normal plasma into a normal subject. It therefore becomes necessary to compare the "half-life" of gamma globulin

\*Obtained through the kindness of Dr. David Rittenberg.

†Carried out by Mr. I. Sucher in Dr. Rittenberg's laboratory.

found by this method with that found by other methods. A "half life" of about two weeks has been found for human serum globulin by isotope studies.<sup>13</sup> <sup>1</sup> footnote, p. 317

The specificity of the immunochemical method, as applied to the estimation of gamma globulin has been considered previously.<sup>10</sup> Deutsch and co-workers<sup>19</sup> have found extensive cross reactions with human gamma<sub>1</sub> and gamma<sub>2</sub> globulin. Very recently it has been reported<sup>20</sup> that several preparations of human gamma<sub>2</sub> globulins react alike with rabbit anti-gamma<sub>2</sub> serum. Since immunochemical determinations of serum gamma globulin were consistently higher than the electrophoretic values Jager, Smith, Nickerson and Brown<sup>20</sup> inferred that other serum proteins (probably globulins) cross reacted with the antiserum. The individual values obtained in this investigation therefore probably represent all constituents reactive with antibody to gamma<sub>2</sub> globulin. There is however general agreement between the values reported here and those for gamma globulin obtained on the same serum samples (from E. B.) by electrophoresis,<sup>3</sup> from which the same "half life" can be calculated.

To determine antibody production one of the patients (E. B.) received injections of the blood group substance<sup>11, 1</sup> and several type specific pneumococcal polysaccharides.<sup>13, 11, 12</sup> There was no response to the A substance and very little or no anti SI, SIII and SV formed. The patient did however form antibodies against types II, VIII and VII although the antibody levels reached were not striking. These data while below average do not differ sufficiently to be abnormally low. It might be of interest in this connection to compare these findings with the report<sup>1</sup> that rabbits showed a lower capacity to produce agglutinins against *Escherichia typhosa* when made hypoproteinemic by low protein diets or plasmapheresis.

When the high protein diet of the second patient (B. V.) is taken into account, the rate of excretion of isotope in the urine after ingestion of a single small dose of isotopic glycine<sup>16</sup> suggests a rather normal utilization for protein synthesis.

#### SUMMARY

1. The rate of elimination of transfused gamma globulin from the blood stream of two patients with idiopathic hypoproteinemia was followed immunochemically by the quantitative precipitin method.

2. The "half life" of transfused gamma globulin in these patients was found to be three to four days.

The authors wish to acknowledge the cooperation and advice of Dr. George Bosworth Brown, Dr. Freddy Homburger, Dr. Mary I. Petermann, and Dr. Richmond W. Smith.

## SENSITIZATIONS TO THE FACTOR Rh IN NEGROES

ROBERT K. WALLER, M Sc, M D, AND MARION WALLER, B A  
RICHMOND VA

THE literature on Rh sensitizations in Negroid races is exceedingly sparse, and with the exception of one report by Wiener and Wexler<sup>1</sup> no systematic study of this problem has come to our attention. In that report, three cases of erythroblastosis fetalis in Negroes are described, none due to Rh and two due to apparent sensitizations against the factors A or B. The inference is made that in this group of people there might be a better placental barrier or there may exist a lower sensitivity to the antigen Rh. In a subsequent personal communication to one of us (R. K. W.) it was pointed out that the intentions of that paper were actually to report three unusual cases and to arouse interest in the subject matter and not to make any generalized statements concerning Rh sensitizations in Negroes.

It is the purpose of this paper to describe our experience with isoimmunization in Negroes taken at random from the obstetric clinic of the Medical College of Virginia.

### MATERIALS AND METHODS

During the past two years 3115 consecutive obstetric clinic patients were examined for blood groups Rh factor and presence of isoantibodies. Those found to be negative with anti D (Rh<sub>0</sub>) serum were checked at approximately monthly intervals for antibodies. Whenever possible, specimens of cord blood were obtained at the time of delivery. Presence of antibodies was determined simultaneously by the saline agglutination, 20 per cent bovine albumin, and antiglobulin<sup>2</sup> techniques. The cord specimens were grouped and typed, the cells studied with the antiglobulin technique for antibody coating and the respective sera searched for antibodies with the methods mentioned. The children born of immunized Rh negative mothers were checked with the routine hematologic methods as well as the antiglobulin technique.

### RESULTS

As shown in Table I over 86 per cent of patients were Negroes. The incidence of d (Rh<sub>0</sub> negative) in Negroes and Caucasians was 73 and 17.4 per cent respectively. Among the 197 Rh negative Negroes, eight were found to be sensitized to Rh and among the seventy three Caucasians three were shown to have Rh antibodies. If one expresses these figures in per cent of d (Rh negative) (see Table II) one finds that 4.06 per cent of the Negroes and 4.1 per cent of the Caucasians were sensitized. However in relating the number of sensitized patients to the total number in each racial group it may be

From the Department of Clinical Pathology, Medical College of Virginia.  
Received for publication May 13 1949

TABLE I

	NEGROES	PER CENT	CAUCASIANS	PER CENT
D (Rh <sub>0</sub> pos)	2499	92.7	346	82.6
d (Rh <sub>0</sub> neg)	197	7.3	73	17.4
	2696		419	

shown that 0.3 per cent of the Negroes and 0.7 per cent of the Caucasians had developed Rh antibodies. The ratio of Negro to white Rh negatives in this series is 1.24, and the corresponding ratio of sensitized patients, 1.27.

TABLE II

d (Rh <sub>0</sub> NEGATIVE)	NEGROES	CAUCASIANS
Total number of Rh negative patients	197	73
Patients sensitized	8	3
Per cent sensitized	4.06	4.1
Per cent sensitized of entire racial group	0.3	0.7

As shown in Table III, all of the Negro patients were multiparas. One subject (Patient 2) had a definite history and another (Patient 4) a questionable history of erythroblastosis in a previous pregnancy. In four of the eight cases a history of transfusion was elicited. Only Patient 6 received transfusions preceding the first pregnancy. All but one (Patient 8) showed a consistent absence of Rh agglutinins. In five patients the outcome of the pregnancy is known, and at the time of birth all were described as clinically

TABLE III

\*Previous to first pregnancy.

†These cells were saturated with incomplete maternal antibody so that they failed to be agglutinated in vitro by anti-Rho agglutinating sera.

normal. There was not a single instance of incompatibility of the major blood groups. However, on laboratory examination the four cord and/or peripheral blood specimens belonging to Rh positive children showed antibody coating to a varying extent (antiglobulin technique).

## CASE REPORTS

CASE 1—The clinical appearance of this infant at birth was that of an entirely normal full term baby. Its red blood cells however were 'blocked' so that they gave the reaction of Rh<sub>+</sub> negative cells with agglutinating sera. The antiglobulin reagent gave a 4+ reaction on cord and peripheral cells and incomplete antibodies could be demonstrated in the cord serum. Hemoglobin and red blood count shortly after birth were 13.6 grams and 4.3 million respectively. This child was discharged on the third postnatal day because of 'apparent' lack of involvement. The subsequent course is summarized in Table IV.

As can be seen from Table IV, this infant's hemoglobin dropped markedly after its discharge and the infant was brought back to the hospital only because the mother had been warned of the possible complications. There was no evidence of jaundice at any time. Despite four transfusions, the hemoglobin value persistently dropped as long as antibodies could be demonstrated to be attached to the red cells (i.e. approximately seven and one half weeks postpartum).

CASE 2—This infant was apparently normal at the time of delivery but on the eighth day was noticed to be jaundiced, pale and in acute respiratory distress. On admission hemoglobin was 2 grams and red blood count 610,000 per cubic millimeter. Erythrocytes gave a 4+ antiglobulin reaction but were not completely 'blocked'. Incomplete anti-Rh antibodies could be demonstrated in the serum. The subsequent course is summarized in Table V.

## III

25	4+	13.6					
27	4+	17.0	5.4	5,300	0		
51	1+	9.9					
71	Neg	11.0					

As in the first infant, the intensity of the antibody coating of the red cells seemed to parallel the clinical course. It is of interest that the mother of this child lost her four previous children from erythroblastosis. Her ninth and tenth children were severely jaundiced and lived for six and twelve days respectively. Her eleventh and twelfth pregnancies terminated in nine months with stillbirths.

TABLE V CASE 2

POSTNATAL DAY	ANTIGLOBU LIN TEST	HGB	R B C	COMMENTS
8	4+	2.0	610,000	150 c.c. transfusion (whole blood)
9	1+	2.0		35 c.c. washed cells
10	1+	14.0

16	3+	18.8		Patient dehydrated
19				120 c.c. whole blood
21	Neg			
29	Neg			Peripheral blood appeared entirely Rh negative
31	1+	13.5		Patient clinically well
38	Neg	13.0		Discharged, living and well since

CASE 3—This infant also was described as clinically normal at birth. Its hemoglobin was 12.0 grams, with a red blood count of 3.8 million per cubic millimeter. Antiglobulin reaction was 4+. Red cells from the cord as well as from the baby's peripheral circulation were completely "blocked" and the cord serum contained incomplete antibodies. Because of our experience with previous similar cases, a replacement transfusion of 500 c.c. was given on the first postnatal day. Antiglobulin reaction after the transfusion was 1+. On the third day hemoglobin had risen to 16.4 grams with a weakly positive antiglobulin test. Thirty days after the replacement transfusion the baby was discharged from the hospital with a hemoglobin of 11.2 grams, red blood count of 4.0 million per cubic millimeter, and a negative antiglobulin reaction. The baby has remained well since.

CASE 4—This child was clinically Rh<sub>0</sub> negative (dCe, rh') and consequently not affected by the maternal antibodies which were anti D (Rh<sub>0</sub>) in specificity. Antiglobulin reaction on cord cells was negative and the infant remained well despite a somewhat low hemoglobin (12.6 grams) at birth. It is of interest that on a six week post partum sample of the mother's blood, anti rh' (anti C) agglutinins could be demonstrated.

CASE 5—This baby was born of a mother possessing a very low incomplete Rh antibody titer. At the time of birth the baby appeared normal and has remained so. Its hemoglobin was 15.6 grams and the antiglobulin reaction on cord cells was only 1+. There were no free antibodies demonstrable in the cord serum. On the fiftieth post partum day the hemoglobin had dropped to 10.0 grams and no antibodies could be detected on the surface of the red cells.

CASE 6—As yet undelivered.

CASE 7—This was a normal full term child which has remained well according to the mother. This child was not available to us for testing.

CASE 8—The outcome of this case is unknown to us but because of low parity and the low titer of incomplete antibodies in the third trimester, experience indicates that this child probably was not affected.

CASES 9, 10, and 11—These are the cases observed in Caucasians and are listed only because they occurred within our present series.

#### DISCUSSION

Because of our findings that Negroes can be apparently immunized against Rh with the same frequency as Caucasians we proceeded to check our hospital statistics for clinical erythroblastosis in the two races over a period of eight years. These findings are summarized in Table VI.

TABLE VI

YEAR	NUMBER OF HOSPITAL CASES OF ERYTHROBLASTOSIS FETALIS		TOTAL HOSPITAL BIRTHS	
	CAUCASIANS	NEGROES	CAUCASIANS	NEGROES
1941	0	0	697	639
1942	0	0	828	823
1943	0	0	980	850
1944	5	0	1 064	825
1945	3	1	1 267	952
1946	2	0	1 490	1 222
1947	7	1	1 649	1 522
1948	10	5	1 460	1 870
Total	29	7	9 500	8 931

From Table VI it can be seen that over the eight year period erythroblastosis was diagnosed in Caucasians at a rate of 1 out of approximately 300 births. For the Negro race this figure, however, was only 1 in 1 300 cases. The ratio of frequency between the two groups is 1.4. It can also be seen that as the years passed the frequency of the diagnosis rose with increasing knowledge of the Rh factor. The majority of cases have been diagnosed during the past two years over which period our study has extended.

The incidence of erythroblastosis reported by various authors ranges from 1/150 to 1/568 (see Table VII) with an average incidence of about 1/300+. However it is to be noted that in most statistics cited the Negro cases have been included in the total group.

TABLE VII INCIDENCE OF ERYTHROBLASTOSIS

AUTHORS	YEAR	INCIDENCE
Diamonds <sup>3</sup>	1945	1/150
Londer Ponder and Levine <sup>4</sup>	1948	1/169
Schwartz and Levine <sup>5</sup>	1943	1/200
Lotter <sup>6</sup>	1947	1/252
Javert	1942	1/438
Wolfe <sup>8</sup>	1940	1/568

In order to ascertain whether the difficulty in finding cases of erythroblastosis in Negroes was shared by other institutions, a questionnaire\* was sent to seven departments of pediatrics in regions with large Negro populations. Four of these institutions reported cases and gave the frequency of Negro births. These are summarized in Table VIII.

TABLE VIII

	CASES OF ERYTHROBLASTOSIS FETALIS, HYDROPS, OR ICTERUS GRAVIS IN NEGROES	DUE TO Rh?	NUMBER OF NEGRO BIRTHS
1 Duval County Hospital, Jacksonville, Fla (H A Carithers)	None	—	488 per yr
2 Tulane University, New Orleans, La (R V Platou)	5	Yes, 2 due to AB incompatibility	6,000 per yr
3 Duke University, Durham, N C (G Taylor)	1	Yes	535 per yr
4 Louisiana State University, New Orleans, La (M E Wegman)	3	Yes, also Hr	6,500 per 2 yr

\*Through courtesy of Dr Lee E Sutton, Jr Professor of Pediatrics Medical College of Virginia

In this survey seven cases are reported out of 13,523 births if one takes into account only those hospitals which stated their incidence of Negro births and only those cases which were proved to be due to Rh incompatibility. This frequency of about 1 in 1,900 births approximates the incidence in our institution (1/1,300).

It remains to be explained why only one case of erythroblastosis is diagnosed in 1,300 births if the rate of immunization to the factor Rh among Negroes is 1 in approximately 330 (0.3 per cent).

As stated by Levine,<sup>9 10 11</sup> the true incidence of erythroblastosis fetalis in any given population can be expected to be proportional to the frequency of negative reactions with anti-D (Rh<sub>0</sub>) serum. That this apparently holds for immunizations against the Rh factor can be seen from our figures (see Tables I and II). The reasons for the failure to find the expected number of cases of erythroblastosis in Negro infants are probably numerous.

First, not all immunized mothers will have sufficiently potent antibodies to produce clinical symptoms in their offspring.

Second, a certain proportion of these mothers will have Rh negative, unaffected children.

Third, the pigmented skin makes the diagnosis of icterus and anemia very difficult.

Fourth, in our institution Negro multiparas usually stay in the hospital for only twenty-four to forty-eight hours after delivery, which will remove their offspring from clinical observation during the time symptoms may develop (Cases 1 and 2).

Fifth many stillborn infants are not autopsied, and erythroblastosis is probably undiagnosed

Sixth, because marked jaundice was unusual in our group and severe anemia rather common, many cases may have been diagnosed in the past as anemia of the newborn

Whether or not the disease is actually less severe in Negroes cannot be ascertained from this short series

#### SUMMARY

On the basis of a study of 3,115 consecutive obstetric clinic patients of which 86 per cent were Negroes presumptive evidence is submitted that Rh negative Negroes are sensitized at the same rate as Caucasians. The total number of sensitized patients is shown to be directly proportional to the frequency of the Rh<sub>0</sub> negative reaction in a given population. The incidence of affected Negro children in our series was about 1/900 pregnancies. Reasons are suggested for the failure to diagnose erythroblastosis in Negroes at the expected rate.

We wish to thank Dr H H Ware, Jr Professor of Obstetrics, and Dr Lee E Sutton, Jr Professor of Pediatrics, for their kind permission to use the cases cited.

## NEBULIZED PYRIBENZAMINE IN NASAL AND BRONCHIAL ALLERGY

SAMUEL M. FEINBERG, M.D., AND THEODORE B. BERNSTEIN, M.D.  
CHICAGO, ILL.

THE usefulness of the antihistamine drugs in alleviating the symptoms of nasal allergy is now well established. It is the general experience, however, that many patients fail to be relieved and certain symptoms, such as blocking of the nasal passages, are particularly resistant to these drugs. Among possible explanations for the failure to achieve the desired effect by oral therapy is that an insufficient concentration of the compound reaches the nasal tissues. The toxicity of the present series of antihistamine substances limits the amount which may be given orally to produce a higher nasal concentration. Since in earlier investigations we demonstrated<sup>1, 2</sup> that small quantities of the antihistamine compounds when applied to the skin would inhibit the histamine and allergic reaction, it was considered likely that the topical use of these drugs would be effective in skin<sup>3</sup> and respiratory allergy.

In 1945 we began to experiment with nasal drops of antihistamine drugs. We found that a concentration of Pyribenzamine as low as 0.5 per cent was irritating to the nose and particularly the pharynx of many patients. Recent reports<sup>4, 5</sup> claimed favorable results with such drops. The ordinary nasal spray was also objectionable for similar reasons, although both techniques were helpful in some instances. We finally adopted the technique of administering a nebulized solution from a nebulizer (DeVilbiss No. 40) with an attached nasal piece. This provides an aerosolized mist which is nonirritating and reaches the nasal and pharyngeal tissues most readily.

A 2 per cent buffered solution of Pyribenzamine was found the most generally useful concentration. These topical treatments were not employed routinely for the relief of seasonal hay fever or allergic rhinitis, but were confined to those patients who either were not getting sufficient results from oral antihistamine therapy or who could not tolerate the latter. A number of these patients owed their resistant nasal obstruction to the repeated use of topical vasoconstrictors. Although at times the effect of this nebulization was immediately noticeable, more commonly it was not apparent until later, and particularly after several treatments had been given. In other words, the action of this therapy in these severe cases of nasal congestion is more of a preventive nature and requires repeated administration.

A nebulized mist of 2 per cent Pyribenzamine, released by about half a dozen squeezings of the bulb of a DeVilbiss No. 40 nebulizer, and repeated every two or three hours, produced benefit in twenty-seven out of thirty-four patients with the type of nasal congestion described. This relief had not been obtained in the same patients with the oral use of Pyribenzamine or other

antihistamine compounds. Of two patients who failed to respond to a 2 per cent solution one responded to a 5 per cent concentration. It should be emphasized that the effect of vasoconstricting drops is more marked and more dramatic than this therapy in relieving nasal obstruction. However the marked congestion which frequently follows the shrinking effect of the repeated use of potent vasoconstrictors is a penalty which frequently is responsible for the continuation of the nasal blocking. The topical antihistamine therapy does not produce this deleterious effect and for that reason is preferable in these difficult cases.

In bronchial allergy the antihistamine drugs orally are much less effective than in nasal allergy. Acute or severe asthma is almost never relieved by these drugs while moderate wheezing may be helped. In spasmodic cough due to bronchial allergy without dyspnea these compounds orally are effective in about one third of the patients. From our experience with topical treatment in these cases we have the feeling that here too the major difficulty probably is the presence of a greater amount of a chemical mediator than can be combated by oral administration of antihistamine drugs. We have employed aerosols of various antihistamine drugs using varying strengths of solutions and various methods of application. Here we wish to record briefly only the results with Pyribenzamine solution as nebulized with the ordinary hand nebulizer or oxygen pressure.

Out of fifty seven patients with asthma, most of whom did not respond to Pyribenzamine by mouth ten obtained effective relief and thirteen had slight relief with a 2 per cent Pyribenzamine aerosol. It should be emphasized that the vast majority of this group were ambulatory patients appearing at the office and presenting a moderate rather than severe asthmatic state. A 1 per cent aerosol was effective in three out of eight patients while a 5 per cent aerosol was effective in five out of nine patients. The spasmodic cough without dyspnea appeared to respond better than the true asthma. Twelve out of sixteen patients reacted favorably. In most instances this type of therapy was less effective than aerosol therapy with epinephrine or isopropyl epinephrine. In several cases of cough the antihistamine aerosol gave better results than these bronchodilators. The main advantage of the use of the antihistamine drugs by aerosol however rests on the much lower toxicity of these solutions and their consequent safety in frequent use as compared with the other aerosols and the antihistamine drugs orally.

#### SUMMARY

The results of the application of aerosolized 2 per cent Pyribenzamine solutions to the nose and bronchi indicate that this is a useful adjunct method in the treatment of selected cases of nasal and bronchial allergy.

## THE ADAPTABILITY OF MICE TO THE LABORATORY DIAGNOSIS OF TUBERCULOSIS

ROBERT A. PATNODE, M.S. \* MARTIN M. CUMMINGS, M.D.,†  
AND GEORGE A. SPENDLOVE, M.D.‡  
ATLANTA, GA

THE mouse is ordinarily considered to be resistant to induced tuberculous infection. In reviewing the literature one is at once impressed by the lack of detailed information regarding experimental tuberculosis in mice. Moreover reports by the various investigators reveal a wide divergence of opinion relative to the existence of any reliable and constant characterization of the infection in these animals.<sup>1-10</sup>

Recent studies have stimulated interest in the possibility of using mice for the evaluation of antituberculosis agents<sup>11-15-22</sup> and for the identification of virulent acid fast bacilli. The latter investigations conducted by Dubos and associates,<sup>16-19</sup> have shown that pigmented (line 1 dba and C 57) strains of mice appeared to be more susceptible to tuberculous infection than other strains examined and, moreover young cultures grown diffusely in certain liquid media were found to be extremely infective for the mice. It was observed too that deficient (corn meal) diets<sup>17</sup> and also concurrent infection with pneumotropic viruses<sup>18</sup> appeared to accelerate the course of pulmonary tuberculosis in mice.

In light of this recent work the Tuberculosis Evaluation Laboratory has undertaken a series of experiments designed to evaluate the reliability of mouse inoculation tests with special emphasis upon their usefulness in the routine laboratory diagnosis of tuberculosis.

### MATERIALS AND METHODS

*Mice*—Mice of the C57 black and dba strains<sup>16</sup> were obtained from Rockland Farms and at the time of inoculation varied in age from 2 to 11 weeks. Immediately after inoculation the mice were placed in metal cages with wood shavings and wire mesh tops in most instances four or six animals per cage. In the preliminary experiment to be reported and for general maintenance the mice were fed regularly a diet of mouse pellets† and water, but in all subsequent experimental work corn meal‡ was substituted at the time of inoculation.

*Cultures*—For preliminary work in the development of techniques, standard strains§ of human (H37 Rv), bovine (Ravenel) and avian (Kirchberg) tubercle bacilli were used. These stock cultures were maintained in a Tween albumin medium|| patterned after the liquid medium of Dubos<sup>6</sup> in which, after six to seven days, growth appeared as a diffuse, fairly homogeneous suspension containing 0.2 to 0.3 mg. of bacilli (dry weight) per milliliter of medium. Saprophytic acid fast bacilli were used in certain of the experiments as

controls, and these consisted of organisms recently isolated in this laboratory from sputum specimens. They were avirulent for the guinea pig. The timothy bacillus (*Mycobacterium phlei*) was not used in mouse infection tests involving the liquid medium, since observations here had shown it to grow in a nonacid fast form. A similar observation has previously been reported by Dubos and co-workers<sup>19</sup> in regard to another avirulent strain (H37 Ra). One BCG (Holm) strain was also used, as well as several organisms recently isolated on modified Lowenstein's medium from sputa and gastric washings.

**Inoculation and Autopsy**—Cultures grown diffusely in the liquid medium were inoculated into mice in 0.05 ml volumes, either directly or diluted to the desired dosage with sterile saline. The modes of infection utilized were (a) intravenously in the tail vein or (b) intracerebrally in the left hemisphere while the animal was under ether anesthesia. Growth from the surface of Lowenstein slants was prepared for mouse inoculation by grinding a weighed sample in a sterile mortar with sterile saline in such a manner that the desired dosage was suspended in 0.05 milliliter. Autopsies were performed on all animals dying during the experimental period (these deaths were attributable, in some part, to intercurrent infections) as well as on all survivors, the latter being sacrificed at the conclusion of the experiments, usually one to four weeks after infection. Evaluations of virulence were based upon the ability of the organisms to proliferate and invade spleen, lung, liver and, in the case of intracerebral inoculations, brain tissue. For purposes of these evaluations, impression smears were prepared from the organs listed and stained by the Ziehl-Neelsen technique, special care being taken, in the case of brain tissue, to prepare smears from the cerebral hemisphere opposite the site of inoculation so that some measure of the degree of spread of the infection within the brain would be available. Arbitrarily, three lengths of each smear were examined microscopically and a record was kept of the total number of acid fast bacilli seen. To express more graphically the extent of the bacterial invasion, the following microscopy code was adopted, based upon the total bacterial count:

1 - 20	= +
21 - 50	= ++
51 - 100	= +++
101 or more	= ++++

Gross lung lesions were designated as being either present (+) or absent (-).

In all instances in which the virulence of the organisms had not been determined previously, guinea pig controls were inoculated simultaneously in the right thigh by the subcutaneous route. The extent of infection was recorded in the following manner, according to the distribution of gross lesions noted at the time of autopsy and confirmed by the demonstration of acid fast bacilli microscopically:

Inguinal lymph node	= Tub 1
All lymph nodes	= Tub 2
Lymph nodes + spleen	= Tub 3
Lymph nodes + spleen + liver	= Tub 4
Lymph nodes + spleen + liver + lungs	= Tub 5

**Experiment 1**—The first experiment was set up with the purpose of deriving a standard technique of mouse inoculation and autopsy for use in subsequent experimental work.

Twenty-four dba mice, 10 to 11 weeks of age, were used, half of which were inoculated intravenously and half intracerebrally. Within each series of twelve mice, six received 0.01 mg and six, 0.0001 mg of an H37 Rv culture grown in the Tween albumin medium and injected in a total volume of 0.05 milliliter. In this preliminary experiment it was reasoned that it might be of some value for future comparisons with mice transferred to the deficient diet, to maintain the present animals on regular mouse pellets. At intervals of one, two, and four weeks, two mice in each series of six were killed and autopsied. The lungs of all animals were examined carefully for gross lesions, and at the same time im-

pression smears of lung tissue were stained and examined for the presence of acid fast bacilli. Supplementary smears were prepared of brain tissue in the case of those mice inoculated intracerebrally and of spleen and liver in those inoculated intravenously.

**Results of Experiment 1** Results presented in Table I reveal that bacilli inoculated intravenously in a dose of 0.01 mg can be recovered in lung, liver and spleen smears as early as one week after inoculation. Lung smears, however, appeared to be inferior from the standpoint of the number of organisms that could be demonstrated early (one to two weeks) in the disease. With the smaller dose (0.0001 mg) there was noted a marked superiority for spleen smears, the only organ in which bacilli could be detected in one week. This superiority was present fairly consistently through the entire experiment.

The results of the intracerebral inoculations are summarized in Table II. As in the case of infection by the intravenous route, the initial time of appearance of pulmonary involvement was in fairly close relationship to the size of the inoculum. However, invasion of the cerebral hemisphere opposite the site of inoculation was detectable in the first week regardless of the dosage.

It will be noted that in none of the mice could macroscopic lung lesions be demonstrated nor were there any deaths as a result of the tuberculous infection.

On the basis of results obtained in this preliminary study the intracerebral route of inoculation was adopted in all subsequent experiments since by this method pulmonary involvement was shown to take essentially the course observed after infection by the intravenous route. Moreover, the former technique was preferred because of the relative ease and rapidity with which it can be performed.

\*One mouse died in twenty-four hours and was eaten by survivors so that no tissue examination was possible.

*Experiment 2*—In this experiment an attempt was made to determine (a) whether tubercle bacilli of all three types are virulent for the mouse, and (b) whether there is any perceptible difference between the three types in respect to their mouse pathogenicity. Young (7 day old) cultures growing diffusely in the Tween albumin medium were used throughout. Strains of tubercle bacilli tested consisted of an avian (Kirchberg), a human (H37 Rv), a bovine (Ravenel), and an acid fast saprophyte recently isolated from sputum and avirulent for the guinea pig. With each strain, six mice of the C57 strain, 4 weeks of age and maintained on a diet of corn meal and water from the time of infection, were inoculated intracerebrally with 0.05 ml of undiluted culture (approximately 0.01 mg dry weight). At one, two, and four week intervals some of the animals were sacrificed and autopsied, at which time the lungs were examined for evidence of gross lesions. Impression smears were prepared of brain, spleen, and lung tissue. Five of the twenty four mice died during the experimental period.

*Results of Experiment 2* As indicated in Table III, all three virulent types produced much the same picture on autopsy. As early as seven days there were signs of marked multiplication of tubercle bacilli in the brain tissue and an invasion of the spleen. In two weeks bacilli were present in large numbers in the lung smears of all animals examined, but only in those inoculated with the bovine strain were there grossly visible lung lesions. These lesions appeared first in those mice killed at the end of two weeks. In none of the six mice inocu-

lated with the saprophyte was it possible to recover acid fast bacilli by smear from the spleen or lung and only an occasional organism was observed in the brain tissue

The results presented in Table III reveal, then, that the C57 mice were susceptible to the three types of virulent tubercle bacilli inoculated intracerebrally. Any conclusion, however, regarding the adaptability of the mice to the type determination of tubercle bacilli could hardly be justified on the basis of the present findings. There were observable differences from the standpoint of certain criteria (deaths, gross lung lesions, relative numbers of bacilli and their time of appearance) but these were not thought to be significant enough for type differentiation.

*Experiment 5*—In the foregoing experiments the results appeared to be encouraging enough to warrant further investigations particularly in respect to a search for a practical application of mouse infection tests in the routine laboratory diagnosis of tuberculosis.

Most laboratories today utilize the classical solid egg media, or modifications of them, in the primary isolation of tubercle bacilli from pathologic material. In order to simulate routine conditions all cultures tested in the experiment to be described were grown on a modified Lowenstein medium as recommended by Holm<sup>21</sup>. In all, twenty-five strains of acid fast bacilli were studied and these included twenty primary isolations from sputum specimens and one from a gastric washing. For purposes of control cultures of standard human (H37 Rv) bovine (Ravenel), saprophytic (timothy), and attenuated mammalian (BCG, Holm) organisms were also included. Mice of the C57 and dba strains (7 to 10 weeks of age) were inoculated intracerebrally with 0.01 mg. of bacilli suspended in 0.05 ml. of sterile saline. Guinea pig controls received the same dosage subcutaneously in the right thigh. The mice were maintained on a diet of corn meal and water from the time of infection, three to four animals of the same age and strain being used for each of the twenty-five cultures.

As shown in Table IV, bacilli cultivated on the solid medium appeared only in the brain tissue of certain of the mice sacrificed at the end of one week. This suggested that these animals might have been killed prematurely and for that reason the period of infection for survivors, was extended to twenty-one days in the remainder of the experiment. At the time of autopsy, impression smears were made of brain, lung and spleen tissue and a record was kept of the presence of macroscopic pulmonary lesions. The guinea pig controls were killed and autopsied at the end of six weeks.

*Results of Experiment 3* Table IV shows that twenty-one of the twenty-five strains studied proved to be virulent for the guinea pig according to the usual criteria. In the mice which had received the corresponding organism in the same dosage, there was, in general, evidence of bacterial proliferation within the brain tissue as well as an invasion of spleen and lung. It will be noted, however, that there occurred some marked inconsistencies at autopsy within groups of animals which had received the same culture in supposedly the same dosage. This phenomenon had been observed, but to a lesser extent in the preceding experiments. Of the factors which might be postulated to have had some bearing on these discrepancies, any one or a combination, of the following might conceivably have been responsible: (a) inconsistent dosage because of the presence of clumps of bacilli in both mechanically triturated suspensions and cultures grown, diffusely, in liquid media<sup>18</sup>, (b) the impossibility, in intracerebral inoculations, of depositing organisms in the same position within the

brain of every mouse and the relationship this might possibly have to the rate of bacterial spread (c) the usual errors of random sampling encountered in the selection of material for smear and in the choice of fields in microscopic examinations and finally (d) it can be assumed with some degree of certainty that mice even though they be of the same age and strain probably vary considerably in their native susceptibility to tuberculous infection.

From an analysis of the data presented in Table IV it can be concluded nevertheless that in the strains of acid fast bacilli examined and on the basis

of the evaluation procedure established for the determination of pathogenicity in the present study, there was evidence of close correlation between virulence for mice and virulence as measured by classical guinea pig tests

*Experiment 4*—The results presented in the preceding experiments indicated that a combination of rapid, diffuse culture in a liquid medium, plus subsequent mouse inoculation, would reduce considerably the time required for the diagnosis of tuberculosis in the routine laboratory. Experiment 4 was designed to explore this possibility.

A recent report by Foley<sup>23</sup> described the successful use of the Dubos medium for the rapid, primary isolation of tubercle bacilli from various pathologic materials. Special note, however, was made of the fact that the medium supports the growth of a variety of nonacid fast organisms. Of considerable interest, then, was the work of Goldie<sup>24</sup> in which the addition of penicillin (0.5 to 2 units per milliliter) to the Dubos medium was advocated in light of its suppressive effect on the growth of contaminants.

For this experiment a total of nine sputum specimens was selected at random. A direct smear was prepared of each specimen and a 2 ml portion was prepared for culture according to the classical NaOH concentration technique.

With a sterile Pasteur pipette, approximately 0.25 ml of each neutralized (2N HCl) sediment was inoculated into a tube containing 5 ml of the Tween albumin medium, to which had been added penicillin in the amount of 2 units per milliliter. To serve as controls, identical inocula of each sediment were spread evenly over the surface of two tubes of the Lowenstein medium.

After incubation periods of eight, ten, fourteen, fifteen, and twenty one days certain of the Tween albumin cultures were prepared for animal inoculation by first centrifuging 3 ml samples at 3,000 r.p.m. for forty five minutes. The supernatant fluid was discarded and 0.5 ml of sterile saline was added to the sediment. Dba mice, varying in age from 8 to 11 weeks and maintained on a diet of corn meal and water from the time of inoculation, were inoculated intracerebrally with 0.05 ml of the saline suspension, four animals being used for each of the nine cultures. The experimental period was twenty one to twenty six days, at the end of which time all the mice were sacrificed and autopsied according to the technique described in the preceding experiments. Four of the thirty six mice died during the observation period. Guinea pig controls received 0.05 ml of the saline suspensions subcutaneously in the right thigh and were autopsied after an infection period of six weeks.

It is interesting to note that a preliminary examination of the direct smears of the original sputum specimens revealed that five were positive for acid fast bacilli, whereas four were negative.

*Results of Experiment 4* The results are summarized in Table V. It can readily be seen that penicillin in a concentration of 2 units per milliliter in the Tween-albumin medium was toxic to the tubercle bacilli contained in the experimental inocula. These results stand in sharp contrast to those of Goldie previously described, but would appear to coincide well with the investigations of Kirby and Dubos<sup>25</sup> which revealed that small inocula of tubercle bacilli are highly susceptible to concentrations of penicillin as low as 1 unit per milliliter in Tween-albumin medium. Reports of results from other laboratories,<sup>26</sup> where comparative studies have been made, have advised against the routine use of liquid media in the isolation of tubercle bacilli from pathologic material. Such findings bear out the observations of Dubos<sup>27</sup> who, following a recent evaluation of his own medium, concluded that, "It would appear unwise to formulate in final form the composition of media best adapted for diagnostic work until more is known of the growth requirements of the different strains of tubercle bacilli which occur in pathological material."

TABLE V RESPONSE OF DBA MICE TO THE INTRACEREBRAL INOCULATION OF PRIMARY SPUTUM CULTURES IN TWENTY ALBUMIN-PENICILLIN (2 UNITS/ML) MEDIUM SUMMARY OF RESULTS OBTAINED WITH 9 RANDOM SPUTUM SPECIMENS

MICROSCOPY (DIRECT SMEAR)	AUTOPSY FINDINGS		LOWENSTEIN CULTURE CONTROLS (WITHOUT PENICILLIN)
	ANIMALS INOCULATED WITH TWEEN ALBUMIN-PENICILLIN CULTURES		
	MICE (21-26 DAYS)	GUINEA PIGS (42 DAYS)	
Number positive = 5	-	-	+
Number negative = 4	-	-	-

All five positive cultures were shown to be virulent human type tubercle bacilli by subsequent guinea pig inoculation

Further investigations into the possibility of deriving a more perfect combination of rapid diffuse culture from pathologic material with mouse confirmation await then the formulation of a reliable liquid medium with the ability to initiate growth of minimal inocula of tubercle bacilli quickly and uniformly and of equal importance the ability to eliminate all contaminating microorganisms

*Experiment 5*—The final study in the present series was devoted to an evaluation of the adaptability of mice to the isolation of tubercle bacilli directly from pathologic material. A survey of the literature reveals that investigations of this nature have been neglected. Only recently<sup>18</sup> has there been reported the successful establishment of a tuberculous infection in mice by the injection intracerebrally of 0.01 ml of sputum obtained from tuberculous patients.

In the following experiment two routine sputum specimens (S-2205 and S-2206) were prepared for mouse inoculation according to the procedure previously outlined (Experiment 4). After neutralization with 2N HCl approximately 0.25 ml of the sediment was seeded on each of two Lowenstein slants and the balance was transferred aseptically to an inoculating bottle containing 1 ml of sterile distilled water. Mice of the DBA strain 2 to 5 weeks of age were inoculated intracerebrally with 0.05 ml of this suspension, four animals being used for each specimen. All mice were maintained on the deficient diet during the experimental period. The unused portion of each suspension was inoculated subcutaneously into the right groin of a control guinea pig. Infection periods and autopsy techniques for both mice and guinea pigs were essentially those described in the preceding experiments.

As can be seen from the data presented in Table VI these two digested (NaOH) and neutralized (HCl) sputum specimens proved to be extremely toxic to the mice. Only three of the eight animals inoculated survived the twenty-one day infection period. It might be worth mentioning that one additional unrecorded sputum sample killed all four mice instantly. In an effort to determine whether this toxicity might be due to some factor present in untreated material the balance of this study was confined to an observation of the effect on the mice of clear etherized urine specimens which ordinarily require no NaOH homogenization. Each specimen was first centrifuged at 3000 rpm for fifteen minutes following which the supernatant fluid was removed. Procedures for culture and for mouse and guinea pig inoculations were identical with those outlined for the sputum specimens. In Table VI these specimen numbers are preceded by the letters BF. This study was terminated when

it was recognized that the untreated urines were similarly toxic to the mice. Of a total of thirty-six animals, twenty (55 per cent) died during the experimental period.

TABLE VI RESULTS OF THE INOCULATION OF ROUTINE CLINICAL SPECIMENS SIMULTANEOUSLY INTO MICE, GUINEA PIGS, AND CULTURE MEDIA, MOUSE DOSAGE = 0.05 ML OF DILUTED (DISTILLED WATER) SEDIMENT INTRACEREBRALLY

BF 292	Urine	2/4	0	0	0		K 42	-	

\*In this and subsequent tables this numeral indicates the average of the 0 to ++++ ratings of the individual mice. Autopsies were not performed on those mice which died at the time of inoculation.

†K=killed the numeral indicates the number of days after inoculation.

‡For explanation see text.

In light of the fact, however, that in one instance (S 2206) the results following mouse inoculation were confirmed by guinea pig inoculation and culture and in another (S 2205) the results indicated a possible superiority for mouse inoculation had the infection period been extended, it was thought that it might be of some value to attempt to minimize or perhaps eliminate the toxic manifestations by introducing certain changes in the technique. With this in mind a new series of ten random pathologic specimens was prepared for animal inoculation and culture by the NaOH concentration technique. Procedures for animal inoculation, autopsy, and culture were identical to those described with the exceptions that sterile physiologic saline was substituted for distilled water as a diluent, the volume of the intracerebral inoculum was reduced from 0.05 ml to 0.03 ml, and the infection period for mice was extended to six weeks.

*Results of Experiment 5* The results are summarized in Table VII. It will be noted that two of the specimens (BF-223 and G-180) killed all four mice instantly. As shown in the table, a total, then, of seventeen (42 per cent) mice died during the six-week infection period. This indicated only a slight reduction in the casualty rates in spite of the modified technique and it seems reasonable to assume that this persistently high percentage of premature deaths will markedly limit the usefulness of mice in the isolation of tubercle bacilli directly from pathologic materials by the methods described. Moreover, the failure, in two instances (S-1365 and G-179), of definitive mouse confirmation of the guinea pig and culture results would seem to indicate that the extended infection period was of no particular advantage. It is interesting to note at this point that the pronounced toxicity of clinical specimens for mice recently has been observed in another laboratory.<sup>28</sup>

*Experiment 6*—A final experiment was devised to test the possibility of rendering pathologic materials less toxic for the mice by (a) increasing the volume of saline diluent and (b) washing the sediment. For this purpose six microscopically positive sputum specimens were digested (NaOH) and concentrated and to each neutralized (2N HCl) sediment were added 4 ml of sterile physiologic saline. Half (2 ml) of each sediment was then transferred aseptically to a sterile centrifuge tube and the material centrifuged for fifteen minutes at 3000 r.p.m. After removal of the supernatant fluid the material was resuspended in 2 ml of fresh sterile saline and a portion of each (washed and unwashed) sediment was used for the inoculation of mice guinea pigs and culture media. The intracerebral mouse inoculum was 0.03 ml and the infection period was twenty-one days.

The data summarized in Table VIII reveal a sharp reduction in the number of nontuberculous deaths among the mice. Only eleven (22 per cent) animals died during the twenty-one day experimental period. All of these deaths occurred within a period of from one to fourteen days after inoculation. However an examination of the findings also reveals that in none of the mice was there evidence of generalized tuberculosis (note the absence of both gross and microscopic lung pathology) although guinea pig results had indicated the presence of virulent tubercle bacilli in all but one specimen (S 976). Moreover it would appear that in general the degree of infection among mice inoculated with washed sediments was less than that in the group receiving unwashed material. It seems probable then that some diminution in the number of bacilli occurred as a result of the dilution and washing techniques employed. This disadvantage although probably slight in the case of specimens containing large numbers of organisms would gain increasing significance in the case of those materials containing only a few bacilli. Any significant number of failures would constitute then, what is probably the most valid objection to this method as a practical means of using mice for the isolation of tubercle bacilli directly from pathologic materials.

A recent study of particular significance which should be considered here is that of Milzer and Levine<sup>29</sup> who, using pigmented strains of mice, reported several successful isolations of tubercle bacilli from clinical specimens (sputa and feces) ten to fifteen days after the intraperitoneal inoculation of suspensions containing gastric mucin, rather than saline, as a diluent. No mention was made of any toxic effect on the mice.

#### DISCUSSION

From time to time in the past, and with renewed vigor in recent years, the possibility has been suggested that mice might be found useful in certain types of investigations in the field of tuberculosis. Only one of these types of investigation has been considered here, namely, the detection of virulent tubercle bacilli in pathologic materials. It should be emphasized that sporadic attempts to develop techniques whereby the mouse might conceivably supplant the guinea pig as a criterion of virulence have been made ever since the discovery of the tubercle bacillus by Koch in 1882. It is probably because marked discrepancies were revealed by the various workers that nothing of a practical nature has materialized. In addition, certain other objections have been raised against the mouse as a test animal in the diagnosis of tuberculosis. It has been suggested,<sup>9</sup> for example, that the failure of the mouse to develop tuberculin sensitivity renders the detection of spontaneous tuberculous infections in mice impossible. This disadvantage gains increasing significance in light of the work of Glover,<sup>10</sup> who determined that the inhalation, by mice, of as few as fifty to one hundred virulent tubercle bacilli resulted in the establishment of recognizable tuberculous foci. Guinea pigs, on the other hand, can and should be tuberculin tested before use to rule out the presence of spontaneous disease.

Another serious criticism of the general adaptation of mice for tuberculosis diagnostic work results from the finding by certain investigators<sup>7</sup> that among human strains of tubercle bacilli there are encountered some which are not of equal virulence for both guinea pig and mouse. Until it can be demonstrated,

through extensive and painstaking investigation, that there exists an exact parallel between virulence for mice and virulence for man, it is doubtful that mouse infection tests will gain general recognition. The objection might be raised, too, from observations made in this laboratory and in others,<sup>11</sup> that the inoculation of mice with virulent tubercle bacilli is not always followed by a constant and predictable degree of infection among animals receiving identical dosages of the same organism.

It was the purpose of the present study to (a) verify some of the more practical laboratory findings concerned with mouse infection tests, and (b) to establish criteria for evaluating the reliability of such tests, some of which will be discussed here briefly.

That different strains of mice vary markedly in their susceptibility to induced tuberculosis has been observed by Dubos and co workers<sup>16</sup> and it was on the basis of their findings that pigmented (C57 and dba) rather than white animals were used exclusively in the experimental work reported herein. As noted by the Rockefeller group<sup>16</sup> however, "It is probable that unrecognized variations in the culture, the season of the year and other uncontrolled factors have an appreciable influence on the course and outcome of the experimental infection." In addition it is probable that individual mice of the same strain differ from others in the group as a result of certain as yet unknown factors. These might make mandatory a more thorough investigation of identical strains of mice obtained from different breeders. Pending the completion of such studies it would perhaps be wise for each laboratory to maintain a constant and reliable source of mice to eliminate the necessity of re-evaluating new and untried groups of animals.

Another source of variation is the enhancing effect, on tuberculous infections, of a deficient (essentially corn meal and water) diet which has been demonstrated for albino and pigmented mice<sup>17</sup> as well as rats.<sup>21</sup> This experimental evidence was convincing enough to warrant the inclusion of such diets in studies carried on by this laboratory in order to increase susceptibility of our mice to the test infections.

With respect to the mode of inoculation the intracerebral rather than the intravenous technique was preferred here because of its simplicity and the relative ease with which it can be mastered by the average technician.

The size and time relationships of dosage, all too frequently lost sight of in tuberculosis diagnostic work, should be given careful consideration in mouse infection tests. On the basis of investigations conducted here and in other laboratories, a dosage of 0.01 mg. has been arbitrarily adopted for use with cultures of tubercle bacilli. It was felt that the ideal dosage should be one which facilitates an early (one to three weeks) detection of proliferation in the case of pathogens without being so overwhelming as to produce false positives in the case of saprophytes, a phenomenon which though yet to be demonstrated with mice is not unknown in guinea pigs. It can be seen from the experimental results presented that tubercle bacilli can be detected in the various organs by smear even though gross evidence of their presence is lacking. This facilitates

early diagnosis. However, gross pulmonary lesions should be examined microscopically in every instance in order to exclude confusion due to spontaneous diseases closely simulating tuberculosis. Such conditions have been demonstrated in rats.<sup>32</sup> In addition, in two instances in our laboratory pulmonary lesions indistinguishable macroscopically from tubercles have been observed in mice at autopsy in which a diligent search failed to reveal the presence of acid fast bacilli.

Finally, in regard to the minimum number of animals indicated for valid results, it is recommended that at least four mice be inoculated with each culture to compensate not only for inconstant degrees of tuberculous infection among the animals but also for deaths due to intercurrent infections.

#### SUMMARY

The susceptibility of pigmented strains of mice (dba and C57) to tuberculosis induced by the intracerebral and intravenous inoculation of virulent human tubercle bacilli has been confirmed.

In these studies, tubercle bacilli of the human, bovine, and avian types were of similar virulence for mice following inoculation by the intracerebral route. An acid-fast saprophyte failed to produce a progressive disease.

In a comparative study involving a series of twenty-five strains of acid-fast bacilli there appeared to be a high degree of correlation between virulence for mice and virulence as measured by classical guinea pig tests.

Preliminary studies indicated that a combination of rapid, diffuse growth in a liquid medium of the Dubos type plus subsequent mouse inoculation would reduce considerably the time required for the laboratory diagnosis of tuberculosis. Penicillin, added to a Tween-albumin medium in a concentration of 2 units per milliliter with the purpose of suppressing the growth of contaminants, proved to be toxic to the tubercle bacilli contained in experimental inocula consisting of digested and neutralized sputum specimens.

Both treated (NaOH) and untreated routine clinical specimens were shown to be extremely toxic when inoculated (intracerebrally) directly into mice in an attempt to recover tubercle bacilli, therefore the routine use of mice as a primary diagnostic procedure is not practical by the methods described.

The theoretical and practical aspects of mouse infection tests are discussed in some detail.

The authors are grateful to Dr. Martin Frobisher, Jr., for his helpful technical suggestions and assistance in presentation of the material.

## THE SEROLOGIC RELATIONSHIP OF FUNGUS ANTIGENS

S B SALVIN, PH D  
BETHESDA, Md

THE reported concurrence of pulmonary calcification and skin sensitivity to histoplasmin<sup>1-5</sup> has led to the suggestion that infection with *Histoplasma capsulatum* is frequently nonfatal. This depends on the theory that sensitivity to histoplasmin results from a past or present infection with *H. capsulatum*. Emmons and co-workers<sup>6, 7</sup> have demonstrated, however, that a positive skin reaction to histoplasmin may appear in animals experimentally infected with either *H. capsulatum*, *Blastomyces dermatitidis*, *Coccidioides immitis*, or *Candida albicans*. Howell<sup>8</sup> demonstrated by skin tests the extensive cross reaction between histoplasmin and blastomycin in guinea pigs infected with *H. capsulatum* and *B. dermatitidis*.

Several workers started serologic investigations with the hope that the information therefrom would aid in the diagnosis of a mild or severe form of histoplasmosis. I<sup>9</sup> described the use of the whole yeastlike cell as a complement fixation antigen, and found it more specific than histoplasmin. Tenenbein and Howell<sup>10</sup> found that both histoplasmin and blastomycin, when used as complement fixation antigens, produced positive reactions in the presence of sera from animals experimentally infected with *B. dermatitidis* or *H. capsulatum*. Fixation was stronger with the homologous than with the heterologous antigen. Saslaw and Campbell,<sup>11</sup> using the sera of rabbits hyperimmunized with heat-killed antigens, found cross reactions between the yeastlike phase of *H. capsulatum* as antigen and anti-*B. dermatitidis* serum, but more especially between the yeastlike phase of *B. dermatitidis* and anti-*H. capsulatum* serum.

With the indication that antigens from the yeastlike phase appeared to be more specific than those from the mycelium, but with little knowledge of the extent of cross reactions between fungus antigens and of the identity of factors in the various antigens, further study of the serologic relationship between fungus antigens seemed desirable. Accordingly, experiments were initiated to determine by complement fixation methods the specificity of and relationships between antigens from *H. capsulatum*, *B. dermatitidis*, *C. immitis*, *C. albicans*, *Aspergillus fumigatus*, and *Mucor corymbifer*. The first four fungi were chosen for study since Emmons and associates<sup>6, 7</sup> had already established their positive immunologic relationship, in that guinea pigs infected with one of them were capable of showing positive skin reactions to histoplasmin. The last two were included for study because, although pathogenic, they had not been shown as having any relationship to *H. capsulatum* by skin test and because they were so decidedly different morphologically from *H. capsulatum*.

From the Laboratory of Infectious Diseases, National Institutes of Health.  
Received for publication May 16, 1949.

## MATERIALS AND METHODS

**Complement Fixation Test**—The complement fixation test, originally described by Bengston<sup>12</sup> was similar to the one reported in a previous paper.<sup>9</sup>

**Fungi**—One strain of each of the six fungi was employed in these studies. Strain 6521 of *H. capsulatum* originally was isolated from a dog<sup>13</sup>, strain 6046 of *B. dermatitidis* from a human patient in Alabama, strain 6210 of *C. immitis* from a human patient in Arizona, strain 3148 of *C. albicans* from a human patient with endocarditis, strain 5225 of *A. fumigatus* from a penguin, and strain 217 of *M. corymbifer* from a pig. The antigens from *H. capsulatum*, *B. dermatitidis* and *C. albicans* were whole yeastlike cells, which had been killed by suspension in 0.5 per cent formalin for eighteen hours, washed in saline, centrifuged, and then stored in a concentrated form at 2 to 5°C in 1:10,000 Merthiolate. Since the sporangial phase of *C. immitis* has not been grown extensively in culture, the broth filtrate from mycelial growth (i.e., coccidioidin) was used as the antigen. Washed spores served as the antigens for *A. fumigatus* and *M. corymbifer*. *H. capsulatum* was grown in the yeastlike phase in a semifluid peptone medium<sup>14</sup>, *B. dermatitidis* in a semifluid medium containing a mixture of amino acids plus serine<sup>15</sup>, *C. albicans* in Sabouraud's dextrose broth, and *A. fumigatus* and *M. corymbifer* on Sabouraud's dextrose agar. The antigens were assayed against homologous immune sera at irregular intervals to check their binding power and anti-complementary action.

**Antisera**—Forty adult albino rabbits were inoculated (a) intravenously with living yeastlike cells (e.g., ten rabbits with *H. capsulatum* and ten with *B. dermatitidis*), (b) intraperitoneally with a suspension of live conidia (e.g., fourteen rabbits with *C. immitis*) or (c) intravenously with increasing dosages of formalin-killed yeast cells (e.g., six rabbits with *C. albicans*). The rabbits were not inoculated with live cells of *C. albicans* because infection with this agent produced rapid death in such animals. The groups of rabbits that were inoculated with one of the live strains were bled once a week thereafter until the termination of the experiment. The sera that were used for the absorption studies were pools from these and other similar bleedings. Only those sera with positive titers with the homologous antigens were included in these pools. Attempts to produce hyperimmune anti-*A. fumigatus* and anti-*M. corymbifer* sera of significantly high titer were unsuccessful, with the result that these two types of sera were not used in the absorption tests in the present study.

## EXPERIMENTS AND RESULTS

Individual sera from thirty-four rabbits experimentally infected with *B. dermatitidis*, *C. immitis* or *H. capsulatum* and bled once a week were titrated against their homologous antigens. Those sera which fixed complement in the presence of the homologous antigen were tested against the three heterologous antigens (Figs 1 to 3). The *B. dermatitidis* antigen induced the formation of antisera only 8 per cent of which (seven of ninety-two sera) fixed complement with the heterologous *H. capsulatum* antigen and none of which reacted with the *C. albicans* or *C. immitis* antigens. The titers with the *H. capsulatum* antigen against the anti-*B. dermatitidis* serum were noticeably lower than those with the *B. dermatitidis* antigen (Fig 1). However, *B. dermatitidis* was weaker as an antibody-producing antigen than the other antigens, as evidenced by the fact that its antisera had much lower titers than the other antisera, when each was tested against its homologous antigen (Figs 1 to 3). The *H. capsulatum* antigen induced antisera which fixed complement in equal quantity with the homologous and the *B. dermatitidis* antigens, although the antibody titers with the latter were slightly lower (Fig 2). None of the anti-*H. capsulatum* sera reacted with the antigens from *C. albicans* and *C. immitis*. The

This antigen was obtained from Dr. C. E. Smith, Stanford University School of Medicine, San Francisco, Calif.

*C. immittis*-infected animals produced antisera which reacted not only with the homologous antigen but 63 per cent of which also reacted with the *B. dermatitidis* antigen and 6 per cent with the *H. capsulatum* antigen. The antibody titers with *B. dermatitidis* and especially with *H. capsulatum* antigens were

Fig 1—Reactivity of anti *B. dermatitidis* sera with homologous and heterologous antigens. Note: No positive titers were produced with *C. immittis* and *C. albicans* antigens.

Fig 2—Reactivity of anti-*H. capsulatum* sera with homologous and heterologous antigens. Note: No positive titers were obtained with *C. albicans* and *C. immittis* antigens.

much lower than with the homologous antigen. No fixation occurred in the presence of the *C. albicans* antigen. The pooled serum from the rabbits hyperimmunized with the *C. albicans* antigen had an antibody titer of 1:256 with the homologous antigen, of 1:16 with the *H. capsulatum* antigen, and of 1:2 with the *B. dermatitidis* antigen. No titer was obtained with the *C. immittis* antigen.

Thus *B dermatitidis* antigen may be considered as forming the most specific antibody (of the four tested) although its complement fixing antigen was the least specific. *H capsulatum* induced the formation of a slightly less specific antibody than *B dermatitidis* while *C albicans* and *C immitis* produced antisera that cross reacted to the greatest extent with heterologous antigens. It may be noted here that the serum titers were relatively low even with the homologous antigens a characteristic common to most fungus antisera.

Fig. 3—Reactivity of anti *C immitis* sera with homologous and heterologous antigens. Note: No positive titers were obtained with the *C albicans* antigens.

Further information on the interrelationship of the fungal antigens was sought in studies involving absorption of antisera with both homologous and heterologous antigens. Pooled rabbit antisera were absorbed with an antigen from one of six fungal species namely *H capsulatum*, *B dermatitidis*, *C albicans*, *C immitis*, *A fumigatus* and *M corymbifer*. The antigens from the first three species were whole yeastlike cells killed by 0.5 per cent formalin. In the case of *C immitis* the antigen used for absorbing antibody was mycelium grown for three weeks at 25° C. killed in 0.5 per cent formalin washed in saline and ground thoroughly in a ball mill. The antigens from *A fumigatus* and *M corymbifer* were spores washed off agar slants, rewashed in saline, killed in 0.5 per cent formalin, then washed and resuspended in saline. The serum was absorbed with homologous antigen until either no serum titer remained or additional absorption produced no change in titer. Twice the amount of antigen used in the foregoing experiments was employed in the absorption of heterologous antisera. In the tests involving *A fumigatus* and *M corymbifer* the sera were absorbed and reabsorbed until they started to become anticomplementary. The experiments were repeated three times with different sera with similar results obtained except where indicated.

When the anti-*B dermatitidis* serum was absorbed with its homologous antigen (Table I), a similar decrease in titer of the serum was shown with both the *B dermatitidis* and the *H capsulatum* complement-fixing antigens. This result indicates that the *B dermatitidis* antigen induces the formation of one antibody or one group of antibodies which is completely responsible for the serologic reaction between anti-*B dermatitidis* serum and *H capsulatum* antigen. Absorption with the *C albicans*, *C immitis*, or *H capsulatum* antigen resulted in partial removal of reactivity with the homologous *B dermatitidis*

TABLE I INFLUENCE OF ABSORPTION ON COMPLEMENT FIXATION TITERS OF RABBIT ANTISERA

‡Throughout this paper '0' indicates no fixation in a serum dilution of 1:2

complement fixation antigen and almost complete removal with the *H capsulatum* complement-fixing antigen. The *C albicans* antigen seemed to have relatively strong absorptive qualities for the anti-*B dermatitidis* serum especially when it is noted that this antigen did not fix complement with this serum. Apparently there was not sufficient *C albicans* antigen in the serologic test to produce a reaction in the presence of the heterologous antiserum. Thus, the antibodies induced by the *B dermatitidis* antigen appear to contain a factor or factors which are capable of combining in varying degrees, depending on the species, with the preceding three heterologous antigens. *A fumigatus* and *M corymbifer* absorbed no significant amount of antibody from the anti-*B dermatitidis* serum, and therefore probably have no antigenic similarity with *B dermatitidis*.

Although anti-*C albicans* serum fixed complement in the presence of *B dermatitidis* and *H capsulatum* antigens in low titers, absorption with the homologous *C albicans* antigen removed the cross reactions with these two heterologous antigens (Table II). Thus, the *C albicans* antigen contains a factor that is the same in serologic reaction as the one in *B dermatitidis* and *H capsulatum* antigens that causes fixation of complement in the presence of anti-*C albicans* serum. Absorption with either *B dermatitidis* or *H capsulatum* antigens resulted in the removal of antibody from anti-*C albicans* serum, as shown with the *C albicans*, *B dermatitidis*, or *H capsulatum* complement fixation antigens. When the antiserum was absorbed with *C immitis* antigen, only part of the antibody was removed. These two observations indicate that the

anti *C. albicans* serum has a substance that can react well with *B. dermatitidis* and *H. capsulatum* antigens and to a more limited extent with *C. immitis* antigen. Because of their failure to absorb any antibody from anti *C. albicans* serum, *A. fumigatus* and *M. corymbifer* antigens were considered unrelated to the *C. albicans* antigen.

TABLE II INFLUENCE OF ABSORPTION ON COMPLEMENT FIXATION TITERS OF RABBIT ANTISERA

ANTIGEN	ANTI <i>C. ALBICANS</i> SERUM						
	UNABSORBED	ABSORBED WITH					
		<i>B. DERMATITIDIS</i>	<i>H. CAPSULATUM</i>	<i>C. ALBICANS</i>	<i>C. IMMITIS</i>	<i>A. FUMIGATUS</i>	<i>M. CORYMBIFER</i>
<i>C. albicans</i>	256	0	0	0	64	256	256
<i>B. dermatitidis</i>	2	0	12	0	12	2	2
<i>H. capsulatum</i>	16	0	0	0	8	8	16
<i>C. immitis</i>	0	-	-	-	-	-	-

Anti *C. immitis* serum after absorption with its homologous antigen still partly reacted with the *B. dermatitidis* and *H. capsulatum* complement fixation antigens (Table III). Thus, there are nonspecific factors in the anti *C. immitis* serum which react serologically with the *H. capsulatum* and *B. dermatitidis* antigens, but not with the homologous antigen. Absorption with *B. dermatitidis* and *H. capsulatum* antigens resulted in almost complete loss of antibody capable

<i>C. albicans</i>	0	-	-	-	-	-	-

These paradoxical residual titers to the heterologous or nonspecific antigens after the complete removal of the homologous antibody may represent a nonspecific complement fixation. The antigen and absorbed serum both slightly anticomplementary may remove enough complement to produce a pseudo complement fixation.

of reacting with either the two foregoing antigens or the *C. immitis* antigen whereas repeated absorption of the anti *C. immitis* serum with *C. albicans* antigen produced only a slight decrease in antibody. No absorptive qualities were shown by the antigens from *A. fumigatus* and *M. corymbifer*.

Finally, when the anti *H. capsulatum* serum was absorbed with the homologous antigen, the titer with *B. dermatitidis* complement fixation antigen was greatly reduced (Table IV). The anti *H. capsulatum* serum may then be

TABLE IV. INFLUENCE OF ABSORPTION ON COMPLEMENT FIXATION TITERS OF RABBIT ANTISERA

ANTIGEN	ANTI- <i>H. CAPSULATUM</i> SERUM						
	UNABSORBED	ABSORBED WITH					
		<i>B. DERMATITIDIS</i>	<i>H. CAPSULATUM</i>	<i>C. ALBICANS</i>	<i>C. IMMITIS</i>	<i>A. FUNIGULUS</i>	<i>M. CORYMBIFER</i>
<i>H. capsulatum</i>	64	0	0	32	32	32	64

<i>C. albicans</i>	0	—	—	—	—	—	—
<i>C. immitis</i>	0	—	—	—	—	—	—

considered as containing a factor common to *H. capsulatum* and *B. dermatitidis* antigens. This common factor in the anti-*H. capsulatum* serum is completely responsible for the reaction with the homologous antigen, since absorption with *B. dermatitidis* produced a reduction in antibody equal to that produced by the homologous antigen. *C. albicans* and *C. immitis* antigens reduced titers only partially, whereas *A. funigulus* and *M. corymbifer* antigens had no effect.

#### DISCUSSION

The term 'antigen' may be referred to (a) as the substance that induces the formation of antibody or (b) as the substance that reacts with antibody in a serologic test. On application of the first definition to the serologically interrelated fungi, *B. dermatitidis*, *C. albicans*, *C. immitis*, and *H. capsulatum*, the antigen from *B. dermatitidis* may be considered the most specific of the four, since it produced an antiserum that reacted only with the homologous antigen and to a much more limited extent with *H. capsulatum* antigen. However on the application of the second definition, it was the least specific serologic antigen since it fixed complement not only with its homologous antiserum but also with the three heterologous antisera. Similarly, *H. capsulatum* antigen produced a relatively specific antiserum in that it reacted about equally with its homologous antigen and the *B. dermatitidis* antigen. As a complement fixation antigen, it was conversely nonspecific since it fixed complement with the three heterologous antisera. The antigens of *C. albicans* and *C. immitis* meted the formation of antibodies that reacted with three of the four antigens studied, although as serologic antigens reactions with the homologous antisera alone were obtained.

Since absorption of a serum with a homologous antigen resulted in a reduction of titer with a heterologous antigen, and since each antigen was capable of absorbing at least some of the antibody from each of the heterologous antisera, a common factor or factors must be present in the antigens of the four species. Hence, the antigen from any of these fungi is inherently capable of reacting serologically with any one of the four antisera, although in the complement fixation tests with both pooled and individual rabbit sera the antisera from *C. albicans* and *C. immitis* did not react with heterologous antisera. However, others<sup>16, 17</sup> have reported that the sera of rabbits immunized against *B.*

*dermatitidis* fixed complement in the presence of *C albicans* antigen. No indication of a serologic cross reaction between the complement fixing antigen of *C immitis* and a heterologous antiserum has been found in the literature. Why in a previous series of experiments<sup>9</sup> cross reactions between anti *B dermatitidis* serum and *H capsulatum* yeastlike cells as antigen were not obtained is in doubt, although the reason may lie in differences in the strains used.

Of interest is the failure of *A fumigatus* and *M corymbifer* antigens to absorb significant amounts of antibodies from any of the antisera under study—a characteristic probably due to the antigenic dissimilarity between *A fumigatus* and *M corymbifer* on the one hand and *B dermatitidis*, *C albicans*, *C immitis* and *H capsulatum* on the other. This apparent lack of antigenic relationship is especially striking since *M corymbifer* is more closely allied morphologically and taxonomically to *C immitis* than either *B dermatitidis*, *C albicans* or *H capsulatum*, while *A fumigatus* is closer to the latter three species than *C immitis*.

The serologic specificity of the four related antigens was paralleled by their antigenic potency—the more specific the antigen the greater its antibody-inducing powers. Thus *C albicans* and *C immitis* antigens produced the highest titered sera whereas *B dermatitidis* antigen induced sera of low titers. This high titer of a serum may partly be the basis for the reaction with heterologous antigens. Frequently the binding power of the *B dermatitidis* antigen was about the same or only slightly higher than the anticomplementary action with the result that four units of the antigen could not be used and the lot had to be discarded.<sup>18</sup>

With each of the antigens of *B dermatitidis*, *C albicans*, *C immitis* and *H capsulatum* capable of cross reaction with the sera of each other, a positive complement fixation titer in an unknown rabbit serum might theoretically be due to an antibody produced by one of the other fungi. However the antigens may still be considered to be of value in the differential diagnosis of mycotic disease, when it is emphasized (a) that fixation of complement with a heterologous antigen was generally at very low serum dilutions i.e., 1/8 and below, and (b) that the titer of a serum was usually distinctly higher with the homologous than with a heterologous antigen. Several sera from an animal with a suspected mycotic disease should be collected and tested over an extended period of time, and if titers are low they should be tested with all four antigens.

#### SUMMARY AND CONCLUSIONS

Complement fixation methods were employed in the determination of the specificity of and the relationship between antigens from *Aspergillus fumigatus*, *Blastomyces dermatitidis*, *Candida albicans*, *Coccidioides immitis*, *Histoplasma capsulatum* and *Mucor corymbifer*. Sera from animals experimentally infected or hyperimmunized with one of the pathogenic fungi were absorbed with each of the six fungal antigens. Also sera from experimentally infected rabbits were examined by complement fixation tests to determine the extent of their reactions with homologous and heterologous antigens.

*A. fumigatus* and *M. corymbifer* were probably antigenically unrelated to the other four species, since they failed to absorb antibodies from any of the heterologous antisera. Although *B. dermatitidis* antigen was the least specific complement-fixing antigen of the four remaining, it produced the most specific antibody. Its antiserum reacted with the homologous antigen and slightly with the *H. capsulatum* antigen, and was absorbed by the *H. capsulatum* antigen and to a lesser extent by the *C. albicans* and *C. immitis* antigens. *H. capsulatum* antigen produced serum that reacted about equally with homologous antigen and *B. dermatitidis* antigen, and that was absorbed by *B. dermatitidis* antigen and to a lesser extent by the *C. albicans* and *C. immitis* antigens. The latter two antigens produced sera that fixed complement with and were absorbed by two of three heterologous antigens, namely, *B. dermatitidis* and *H. capsulatum* antigens.

# THE ELECTROCARDIOGRAM OF NORMAL AND MALARIA INFECTED MONKEYS

ARTHUR RUSKIN, M D AND R H RIGDON, M D  
GALVESTON, TEXAS

PRELIMINARY to the study of comparative effects of intravenous quinine dihydrochloride in normal and malaria infected monkeys,<sup>1</sup> it was incumbent upon us to establish the variations of the electrocardiogram in these two groups of animals. The available data appeared inadequate. Lloyd<sup>2</sup> noted for seventeen *Macacus rhesus* monkeys averages for the P R interval of 0.08 sec, the QRS width 0.04 sec, the Q T length 0.20 sec, and electrocardiographic patterns similar to those of man. DeWaart and Storm<sup>3</sup> published the following norms for some fifteen *Macacus irus* monkeys. P R intervals from 0.54 to 0.088 sec, QRS widths from 0.02 to 0.044 sec, and the angle of the QRS axis from +50 to +75 degrees. They established the empirical validity of the Einthoven triangle for the monkey as for man and claimed that the P and T waves were always positive and the S T intervals isoelectric as in man and not as in the dog. We considered it necessary to establish the electrocardiographic findings in a larger series of normal monkeys with the addition of the chest lead. No detailed electrocardiographic observations in malaria infected monkeys were found in the literature.

## MATERIALS AND METHODS

In this study twenty seven normal *Macaca mulatta* monkeys weighing 2 to 7 kilograms, were strapped on their backs to an animal board. Leads I, II, III, and an apical chest lead (corresponding to IV F) were obtained in the usual manner with a Cambridge electrocardiograph. Repeated tracings were taken in some instances on different days, for a total of thirty four observations, to determine the variations in single monkeys and to establish the normal electrocardiographic range. Twelve monkeys infected with *Plasmodium knowlesi*, on which normal electrocardiograms were obtained previously, had electrocardiograms with four leads similarly taken on twenty two occasions during varying stages of the infection. The course of the disease was followed by counting the number of red blood cells and the number of parasitized cells per 100 erythrocytes in the peripheral blood.

## EXPERIMENTAL RESULTS

The electrocardiograms of normal monkeys presented heart rates varying from 170 to 280 beats per minute, P R intervals from 0.06 to 0.10 sec, QRS intervals from 0.02 to 0.05 sec, Q T intervals from 0.14 to 0.20 sec, the QRS axis angle  $\alpha$  from +50 to +115 degrees. A single auricular ectopic beat was the only arrhythmia noted. We found (Table I) a flat T<sub>1</sub> in nine of thirty four observations, a negative T<sub>1</sub> in one instance, flat T in three, negative T in three, flat T<sub>4</sub> in two and negative T<sub>4</sub> in two instances. S T depression, particularly in Leads II and III of 1 mm or more was noted in eight of twenty seven monkeys. In two monkeys a negative and flat T<sub>1</sub> was found on different

Malaria	6	3	1	1	0	0	3	12	22

days, in two other instances negative and flat T<sub>2</sub> waves were similarly noted, in one other instance the T<sub>3</sub> was flat and negative on two different occasions.

Malaria-infected monkeys presented heart rates in the same range as the normal monkeys with the exception of one monkey with a rate of 159 beats per minute. The atrioventricular and intraventricular conduction times had the same limits as in the normal animals. The Q-T intervals (electrical systoles) were in the upper range of normal controls, in only one severely infected monkey was a Q-T interval of 0.23 sec. present, with a heart rate of 159 beats per minute. Two animals, one with moderate and one with severe parasitemia and anemia, showed marked left axis deviations, -40 and -48 degrees. In all others the axes were within the normal range. No arrhythmias were noted in the malaria-infected animals.

From Table I it will be seen that, in general, the proportion of negative T waves in the malaria-infected monkeys was the same as in the normal controls, nor were these negative T waves and depressed S-T segments in the malaria-infected monkeys present particularly in the more severely infected animals. In two of three animals presenting negative T<sub>1</sub> waves they were flat on other occasions, and the same variations were seen in these two monkeys before their malarial infection (Fig. 1).

#### DISCUSSION

It is clear from our observations of the electrocardiogram in twenty-seven normal *Macaca mulatta* monkeys, which is the largest group so far published, that the variability, particularly in the recovery portion (ST-T segment) of the normal tracing, is much greater than heretofore realized. Hence, if one followed the human standards of electrocardiographic criteria for the monkey, many of our findings in the malaria-infected cases would be classed as abnormal. On the other hand, comparing their tracings with the ones obtained before the infection with *P. knowlesi*, one comes to the conclusion, as did Sprague<sup>4</sup> in thousands of cases of human malaria, that the electrocardiogram is unchanged in the vast majority of instances.

Three electrocardiographic observations in malaria-infected monkeys revealed deviations from the normal variants. Two of these involved leftward changes in the axis which are difficult to interpret. The Q-T interval tended to be in the upper ranges of normal, and in one instance was somewhat prolonged, even considering the relatively slow heart rate. This might indicate the mildest form of myocardial malfunction or fatigue, which may be so expressed under other circumstances. The failure to show significant electrocardiographic abnormalities in malaria-infected monkeys is thoroughly consistent with the absence of specific pathologic lesions in the hearts of malaria-infected monkeys<sup>5</sup> and of human beings with malaria.<sup>6</sup>

In some instances of severe anemia there are seen electrocardiographic changes suggestive of coronary insufficiency and nonspecific myocardial damage presumably correlated with anoxemia fatty degeneration and even dilatation of the heart all of which may occur in severe malarial infection. The ST and T segment variations in our malaria infected monkeys however did not

Fig 1—Before malaria the T wave was flat and ST and ST-T segments were depressed in this monkey. T was either negative or diphasic on different occasions. With red blood counts of 588, 36 and 158 on the tenth, twelfth and twenty-third day (day before death) of malarial infection respectively, the electrocardiogram was not significantly changed except for the variations in  $T_a$  as noted also before malaria and progressive prolongation of the QT interval from 0.16 to 0.18 seconds. Stethogram on the day before death was normal.

differ significantly from those of the controls. Nor did we see any prolongation of the PR interval. Our lowest attained red blood cell count 16 million per cubic millimeter may not have been low enough to cause significant anoxic electrocardiographic changes. In several instances stethographic (Fig 1) fluoroscopic and roentgenographic examinations of the heart showed no murmurs, gallop rhythm or significant cardiac dilatation in severe and even fatal cases of malaria.

#### SUMMARY AND CONCLUSIONS

1 The normal electrocardiogram of the *Macaca mulatta* monkey is between that of the dog and man. The variability includes negativity of the T waves in Leads I, II and IV F and displacement of the ST segments from the iso electric line.

2 The electrocardiogram of malaria infected *Macaca mulatta* monkeys does not differ from that of the controls in the great majority of instances. The

rare exceptions include marked (left) axis deviation and slight prolongation of the Q-T interval. No typically anovemic electrocardiographic changes were demonstrated, even in monkeys showing red blood cell counts only 25 per cent of normal.

3 The absence of significant electrocardiographic alterations in monkeys infected with *P. knowlesi* is consistent with the known pathologic changes in malaria in monkeys and with the findings of others in a large series of cases of malaria in human beings.

# LETHAL EFFECTS AND ELECTROCARDIOGRAPHIC CHANGES PRODUCED BY QUININE DIHYDROCHLORIDE IN MALARIA INFECTED MONKEYS

R H RIGDON, M D, AND ARTHUR RUSKIN, M D  
GALVESTON, TEXAS

INTEREST in the lethal effects of quinine on monkeys infected with malaria developed recently when it was observed that some animals died following an intravenous injection of quinine, while the same amount had no noticeable effect on other monkeys<sup>1</sup>. This observation brought to mind the controversy of fifty or sixty years ago as to whether the mortality rate was greater in cases of severe malarial fever treated with or without quinine. Deaderick<sup>2</sup> stated that the mortality rate was 25.9 per cent in 1,821 cases of blackwater fever treated with quinine while it was only 11.1 per cent in 1,006 similar cases not treated with quinine. Several workers have warned against the intravenous injection of quinine in human beings. Brahmachari<sup>3</sup> advised that in all cases of malarial fever in which the blood pressure was low, quinine dihydrochloride, when given intravenously, should be injected slowly, and accompanied by either pituitrin or adrenalin. Maxey<sup>4</sup> warned that if the patient is already suffering from circulatory embarrassment, or the severe hypotonia sometimes associated with chronic estivo autumnal infections, the added burden produced by the well intended therapeutic effort may result in a fatal outcome instead of improvement.

Large doses of quinine given intravenously to human beings directly depress the heart and lower the blood pressure<sup>5</sup>. The disturbance in heart action seems to reach its maximum in somewhat less than two minutes as 95 per cent of an intravenous dose of quinine is removed from the blood stream within five minutes<sup>6</sup>. Respiration and pulse rates are stimulated by small doses and depressed by larger ones. Death occurs usually in coma from cessation of respiration<sup>5</sup>.

In this experimental study observations were made first, to determine whether quinine dihydrochloride is fatal in smaller doses when given to monkeys with a severe malarial infection than when given to normal monkeys, and, second, to determine the electrocardiographic effects produced by quinine in these two groups of animals.

## MATERIALS AND METHODS

Thirteen normal *Macaca mulatta* monkeys, weighing from 2 to 7 kilograms, were injected intravenously with doses of quinine dihydrochloride varying from 20.6 to 82.8 mg per kilogram. A total of nineteen injections of quinine was given to these monkeys. Eleven animals infected with malaria were given quinine dihydrochloride in doses varying from 18.7 to 41.3 mg per kilogram. A total of twenty one injections of quinine was given to these monkeys.

From the Laboratory of Experimental Pathology and the Heart Station Department of Internal Medicine University of Texas Medical Branch

Aided by a grant from the John and Mary R. Markle Foundation

Received for publication May 16 1949

The quinine was always given intravenously, over a period of thirty to forty seconds. The preparation contained 0.5 Gm of quinine dihydrochloride in each cubic centimeter, or 0.477 Gm of quinine in combination.

*Plasmodium knowlesi* was used to infect these monkeys. The course of the disease was followed by red blood cell counts and by counting the number of parasitized red cells per 500 erythrocytes in the peripheral blood. Electrocardiographic tracings were taken at varying times during the infection.

The electrocardiograms were obtained with the monkeys on their backs with each extremity tied to an animal board. Leads I, II, III, and an apical chest lead (corresponding to IV F) were made. A series of tracings was taken for the control, and during the time of the injection of the quinine lead II was recorded. Four more sets of tracings were obtained immediately, two, four, and ten minutes later. The total number of tracings made for this study, including the normal controls, was 215.

## RESULTS

Table I shows the effect of different amounts of quinine dihydrochloride when given intravenously to normal and malaria-infected animals. The maximum amount of quinine that could be given to a normal monkey without producing death was approximately 55 mg per kilogram body weight. Ten malaria-infected monkeys died with doses of quinine varying from 20.8 to 41.3

Six monkeys with malaria were given the same amount of quinine intravenously one to four times preceding the last injection of the identical amount of quinine which resulted in their immediate deaths (Table II). These monkeys lost some weight during their disease, however, this factor alone apparently cannot account for their response to the same quantity of quinine at different intervals. Monkey 28 survived 100 mg (27.4 mg per kilogram) of quinine on four different occasions and died following the fifth injection of 87 mg (27.1 mg per kilogram). The anemia was severe at the time of death in each of these six monkeys. Fig. 1 shows the correlation between the anemia, parasitemia, and the periodic intravenous injections of quinine in Monkey 7.

The monkeys given the larger amounts of quinine first showed respiratory difficulties beginning about sixty seconds following the time of the injection. Respirations markedly decreased and frequently stopped for varying intervals following which time the monkeys gasped irregularly. During this period cyanosis and slowing of the heart occurred and in such animals death usually followed in two to ten minutes. With a slightly smaller dose of quinine the monkeys developed severe convulsions preceded and followed by twitchings of different groups of muscles. Cyanosis was frequently marked during the apnea and convulsions. Some of the monkeys that had severe convulsions died

five to fifteen minutes later. The animals that survived the convulsions were unable to stand when returned to their cages thirty to sixty minutes following the injection of the quinine. Gradually these monkeys improved and twelve to eighteen hours later appeared normal. With the smaller doses of quinine no clinical changes were observed.

Fig 1—Monkey 7. There is a progressive and rapid increase in the degree of parasitemia and a corresponding decrease in the number of red cells in the typical case of malarial infection in the monkey. Death occurred immediately following the third intravenous injection of 2 cc of quinine. Death following the injection of quinine may be correlated with the anemia.

The electrocardiographic effects of quinine given intravenously in both normal and malaria-infected monkeys were usually maximum immediately after the completion of the injection. All the intervals usually returned to normal in six to thirty minutes, with the exception of the Q-T interval. This was prolonged for indefinite periods of time following larger doses of quinine in both normal and malaria-infected monkeys. Not infrequently, however, the Q-T interval was 0.1 to 0.2 seconds shorter than the control duration at ten minutes after the injection of small doses of quinine in normal monkeys (Fig 2). ST segment deviations and T-wave reversals occurred after quinine in both normal and malaria-infected animals.

The effects of near-equivalent doses of quinine in three representative normal and subsequently malaria-infected monkeys are shown in Table III. In

are compared in Fig. 2 and the maximum deflections of the aortic flow and intracranial pressure are shown in Table III of the electrical study and the deflection in the heart rate. In general it may be said that the same dose of

The effects on the three electrocardiographic intervals of the various doses of quinine used in both the normal and malaria-infected animals respectively are plotted in Fig 3. By contrasting the two groups, a graphic illustration is provided to show that smaller doses of quinine produce greater cardiodepressive effects in malaria-infected monkeys than in normal animals. These electro-

Fig 3.—The variation of the prolongation by varying doses of quinine of the atrioventricular and ventricular conduction times and the Q-T interval in normal and malarial monkeys. Much larger doses of quinine usually failed to prolong the electrocardiographic intervals in normal monkeys than smaller doses did in malaria-infected animals.

cardiographic findings thus corroborate the clinically observed effects on the respiratory and neuromuscular systems and the higher mortality in malaria-infected monkeys than in the normal monkeys following equivalent doses of quinine.

It should be emphasized that the electrocardiographic changes induced by quinine in normal and infected monkeys vary only in degree and not in kind. The pattern following large and sublethal doses is as follows: prolongation of the intervals, slowing of the rate, auricular standstill with increasingly slower idioventricular rhythm, not infrequently periods of ventricular tachycardia and ventricular ectopic beats, rarely auricular fibrillation or flutter with varying A-V block. All of these changes are reversible in animals that recover.

from these severe cardiac effects as in those that survive respiratory arrest and convulsions lasting several minutes

The electrocardiographic findings in monkeys that died were typified by increasing intraventricular block and ventricular slowing and asystole (Fig 4). Frequently, however, respiratory failure was followed by reversal of the severe

Fig 4—Monkey 7. Partially reversible electrocardiographic effects of a relatively small dose (21.7 mg per kilogram) of quinine in a malaria infected monkey (parasitemia 1.7 per 500 R-B-C red blood count, 4.1 million). Marked slowing of the rate, ventricular ectopics preceding and following ventricular tachycardia, reversal of the conduction defects twenty five minutes after quinine administration.

electrocardiographic manifestations, so that only slow sinus rhythm with fairly short P R QRS, and Q T intervals accompanied or followed by five to twenty minutes 'clinical death'.

The rapid accession and recession of cardiac effects produced by quinine also noted by previous observers<sup>6</sup> were emphasized in our experiments. As an example, nearly identical conduction defects followed small (e.g. 20 mg per kilogram) doses of quinine repeated in ten minutes at which time the effects of the first dose were usually completely gone. Larger (e.g. sublethal) doses required up to thirty or more minutes for complete reversal. Auricular arrhythmias and prolonged Q T intervals tended to persist following such dosage for the longest period of time. Gallop rhythm was noted stethographically only once in seven observations. Fluoroscopic and roentgenologic studies in a few monkeys revealed no significant enlargement of the cardiac chambers.

## DISCUSSION

In this study no attempt was made to establish the minimal lethal dose of quinine, either for normal monkeys or for animals in varying stages of malarial infection. Although the number of animals used in these experiments is too small for statistical purposes, the data would indicate that a monkey with a severe malarial infection is more susceptible to the action of quinine than a monkey with a less severe malarial infection. It would appear from our data that the susceptibility to quinine is related more closely to the anemia than it is to the degree of parasitemia. Of course, the anemia in malaria results from the destruction of the red blood cells by the parasites. In an untreated animal there is a close correlation between the degree of parasitemia and the anemia. However, when quinine is given the parasitemia may decrease without an immediate increase in the number of red blood cells.

It is well known that the salts of quinine frequently are lethal when given intravenously. McCarrison and Cornwall in 1918,<sup>7</sup> while studying the pharmacodynamics of quinine in sheep, showed that "all the salts of quinine employed caused a profound fall of blood pressure not accompanied by a cessation, or even much diminution in the strength, of the heart's beat, except in the two instances in which the respiratory center failed." The fall of blood pressure is usually recovered from in four or five minutes but the period of cardiovascular depression may last for a considerable time." These investigators also emphasized the fact that "the respiratory center is more gravely affected than the cardiac center." Macey<sup>8</sup> noted in human patients given rapid intravenous injections of quinine symptoms simulating the early findings in our monkeys: Dizziness, sweating, hypotension, dilated pupils, twitchings of the face lasting three to ten minutes, and possible convulsions were, in his experience, danger signals.

The electrocardiographic findings in normal and malaria-infected monkeys have been reported by us in a previous paper.<sup>8</sup> There is little variation from normal in the electrocardiographic pattern of monkeys with a severe malarial infection. The changes in a monkey with a severe malarial infection given a lethal dose of quinine are similar to those in a normal monkey given a lethal dose of quinine, although the quantity of quinine given to the malaria-infected animal is only about one-half that necessary to produce death in the normal monkey. The conduction times and electrical systole are more markedly prolonged in quinine-treated monkeys with a severe malarial infection than in normal animals and, also, those monkeys with a less severe malarial infection. The occasional shortening of the Q-T interval seen ten minutes after the injection of quinine parallels the same finding in isolated rabbit hearts following quinidine.<sup>9</sup>

The questions may be asked: Is the effect of quinine only directly on the myocardium and the conduction system, or are the resulting electrocardiographic changes aggravated by anoxemia and the depressive action of quinine on the medullary centers? It would appear to us that anoxemia is not the primary mechanism in the cardiac response since monkeys with a severe malarial infection are anoxic, and then electrocardiographic responses are essentially

the same as those of normal monkeys. The direct cardiac effects of quinine and the relative coronary insufficiency resulting from anemia, hypotension, and respiratory insufficiency, however, may be additive.

A second problem in the mechanism of death in these malaria infected monkeys is the relationship of anemia to the action of quinine on the respiratory center. The manner of death is the same in monkeys with a severe malarial infection given a small amount of quinine as it is in a normal monkey given twice as much quinine. In man it is well known that the respiratory volume and the cardiac output are increased in cases of severe anemia. This implies increased work and fatigue of both the respiratory center and the heart. Large doses of quinine markedly depress both the heart and respiratory centers, especially in monkeys with a severe anemia. The electrocardiographic changes in dogs with a severe and irreversible anoxia<sup>10</sup> are similar to our findings in monkeys following a lethal dose of quinine. As previously stated, the electrocardiograms were essentially normal in our monkeys with a severe malarial infection, although they were anoxic. This apparent discrepancy in the electrocardiographic changes in these dogs and monkeys may be explained by the fact that the degree of anemia in our malaria infected monkeys apparently had not reached the irreversible stage, while the dogs studied by Swann<sup>10</sup> were in extremis at the time the tracings were obtained. Experiments are now in progress to study the relation of anemia to the effects produced by quinine.

#### SUMMARY

1 Monkeys with a severe anemia resulting from *P. knowlesi* infection succumb to a smaller dose of quinine given intravenously than normal animals or those with a less severe anemia.

2 The electrocardiographic changes following equivalent doses of quinine in malaria infected monkeys follow the same pattern as in normal monkeys, but show evidence of greater cardiodepression.

## A NEW INTRAMUSCULAR PREPARATION OF QUINIDINE (QUINIDINE GLUCONATE)\*

SAMUEL BILLET, M D , AND JOHN URBACH, M D  
PHILADELPHIA, PA

THE object of this communication is to report our experience with the use of an intramuscular preparation of quinidine which we believe has certain advantages over that at present available. The value of quinidine in the treatment of certain cardiac arrhythmias is well recognized. In most of these, the preparation available for oral use, quinidine sulphate, is adequate. However, in certain acute or paroxysmal arrhythmias, the abnormal rate and rhythm may cause cardiac pain, intense palpitation, dyspnea, vomiting, a shocklike state, and even death. In these conditions where quinidine is of recognized efficacy, parenteral administration, because of its more rapid absorption and certainty of effect, has certain advantages over oral administration. In addition, other indications for parenteral administration are vomiting and diarrhea, moderate or severe grades of congestive failure when absorption by mouth is slow and uncertain, and the presence of any condition (postoperative, for example) which might prevent the patient from taking food by mouth.

The intravenous preparations of quinidine which are available are quinidine hydrochloride and quinidine lactate. Our experience with the intravenous preparations is limited to relatively few patients because of their possible harmful effect.

We have had a rather extensive experience with the intramuscular preparations of quinidine over a period of years. We have found the intramuscular method to be a satisfactory and a relatively safe one for administration of this drug. Sagall, Horn, and Riseman<sup>1</sup> have shown that following an intramuscular injection of 5 grains of quinidine hydrochloride, a definite response is observed in fifteen minutes and occasionally in five minutes. The maximum effect of the quinidine injected intramuscularly was obtained in one and one-half hours. As far as we are aware, the only intramuscular preparation at present available is that reported by Stumiek, Riseman, and Sagall,<sup>2</sup> in which quinidine hydrochloride is buffered with urea and antipyrine. We have found this preparation to be quite satisfactory. However, in some of the lots which we have had prepared, the salt has settled out and some of the injections have been painful.

We have recently used quinidine gluconate for intramuscular injection and have found the results obtained to be quite satisfactory. The formula for this preparation is

From The Division of Cardiology, Philadelphia General Hospital and The Robinette Foundation, University of Pennsylvania.

This work was aided by a grant from the United States Public Health Service.

Received for publication May 24, 1949.

Fig 1.—1. G. V. 62 year old man. Diagnosis: arteriosclerotic heart disease congestive heart failure and diabetes. (Lead CR.) Upper strip shows evidence of digitalis intoxication. Many extrasystoles are noted three of them occurring in succession. Lower strip four hours after  $7\frac{1}{2}$  grains of quindine gluconate had been given intramuscularly shows only occasional ventricular extrasystoles and a return to a predominantly normal rhythm.

B. M. D. 48 year old woman. Diagnosis: rheumatic heart disease mitral stenosis cardiac enlargement and auricular fibrillation. (Lead CR.) Upper control strip shows auricular fibrillation with a ventricular rate of about four hundred per minute. Middle strip one hour after 6 grains of quindine gluconate had been given intramuscularly shows that the auricular rate has slowed to three hundred per minute with the production of auricular flutter. The slowing of the auricular rate in auricular fibrillation is a characteristic quindine effect. Lower strip eleven hours after quindine gluconate had been given shows a return of the auricular fibrillation.

C. A. D. 48 year old man. Heart normal. Lead CR. was taken. Seven and one half grains of quindine gluconate were administered intramuscularly and electrocardiograms repeated at fifteen minute intervals for three hours and at one hour intervals thereafter. The segments of the record are from right to left: control fifteen minutes thirty minutes two hours two and three quarter hours and twenty four hours after quindine was administered. Note the initial effect of quindine action observed in the tracing taken fifteen minutes after injection. Note the notched T wave and the slight lengthening of the QT interval which continues for several hours. The tracing taken twenty four hours after the injection shows a return to normal with absence of quindine effects.

The molecular weight is 520.55, it contains anhydrous quindine 62.3 per cent and gluconic acid 37.7 per cent. It occurs as a white dextrorotatory powder which is soluble in nine parts of water. The solution is neutral or slightly alkaline in reaction.<sup>3</sup>

This preparation has been used by us in various cardiac states in fifteen patients some of whom received as many as ten injections of 150 mg. at varying intervals. This preparation appears to have some advantages over that mentioned. The solution is stable, the preparation is relatively simple in type, it results in no irritation at the site of the injection, and the administration of

other compounds (for example, antipyrin, the action of which may be unwanted and undesirable) is not necessary. Characteristic quinidine effects were obtained clinically. These consisted of abolition of ventricular extrasystoles, slowing of the auricular rate in auricular fibrillation, and the production of characteristic changes in the T waves and Q-T intervals in patients with normal sinus rhythm. We have obtained observable effects within fifteen minutes following the injection of a 5 to 7½ grain dose of the drug (Fig 1, A, B, and C).

#### SUMMARY

Our experience with an intramuscular preparation of quinidine (quinidine gluconate) has been reported. The solution is stable, is simple in type, and results in no irritation at the site of the injection. A characteristic quinidine effect is observed in a relatively short period of time after injection, as early as fifteen minutes after a dose of 5 to 7½ grains. Absorption by the intramuscular route is certain, uniform, and relatively safe. This route of administration is suggested for those patients in whom a rapid effect is required or in whom its administration by the oral route is not considered feasible.

# STUDY OF COMPLETE PARENTERAL ALIMENTATION ON DOGS

H C MENG, M D PH D, AND FRANCES EARLE, B A  
NASHVILLE, TENN

THE present study was undertaken in an effort to improve the nutritional status of patients who cannot receive food by mouth but who must be fed parenterally. Such patients require a nutrient supply not only adequate in caloric content but also one which contains sufficient water, minerals, vitamins, carbohydrate, protein and fat. Each of these six nutritional elements requires the presence of the other five before it can be properly utilized.

Intravenous feeding of glucose saline, some of the vitamins and amino acids or protein hydrolysate has been common practice for some time but has not proved to be completely satisfactory because of the lack of fat. It has been difficult to obtain a fat emulsion suitable for intravenous use and the literature contains only five reports<sup>1-5</sup> of attempts to use parenteral alimentation using all three of the energy producing foodstuffs. In these reports either the diet was incomplete or the period of feeding too short for adequate evaluation of results.

Recent work<sup>6</sup> has led to the development of a stable fine fat emulsion which is believed to be suitable for intravenous use and should overcome the difficulties described. A complete intravenous diet was prepared using this emulsion and a protein hydrolysate. It was administered to dogs over a period of ten weeks during which time they received food exclusively by vein.<sup>7</sup> Results were generally very satisfactory but the animals showed intermittent hematuria and a mild anemia.

It was felt that the hematuria might have been due to the mechanical difficulties in voiding. The present study was carried out in an attempt to avoid the previous difficulties and demonstrate the possibility of maintaining animals completely healthy by complete parenteral alimentation.

## EXPERIMENTAL PROCEDURES

The fat emulsion used in this experiment was prepared as described in the previous communication.<sup>6</sup> However its composition was altered slightly. It is shown in Table I.

Five healthy adult dogs were used in this experiment. The animals were confined in individual metabolism cages which permitted a quantitative collection of urine. In the control period they were fed a complete basal diet (Table II) which furnished 80 calories per kilogram of body weight per day of which 50 per cent came from carbohydrate, 16 per cent from protein, and 34 per cent from fat. Immediately following this period, four animals (Dogs B, R, C, and M) were given a diet containing the same amount of carbohydrate, protein, and fat, but it was infused exclusively by vein. Carbohydrate was furnished in the form of glucose, protein in the form of Amigen<sup>\*</sup> and fat as 10 per cent olive oil emulsion.

From the Department of Physiology Vanderbilt University Medical School.

This investigation was supported in part by a research grant from the Division of Research Grants and Fellowships of the National Institute of Health, U. S. Public Health Service and the Committee of Scientific Research, American Medical Association.

Received for publication March 3 1949.

Amigen a protein hydrolysate was furnished through the courtesy of Dr. Warren M. Cox, Jr., Mead Johnson & Company, Evansville, Ind.

\*Liver Injection U S P obtained from Division of Wilson and Company, Inc., Chicago.  
 III One milliliter (10 U S P units) was given weekly.

†Folvite, a product of Lederle Laboratories Division, American Cyanamid Company, New York, N. Y. Two milliliters (15 mg per milliliter) were given every week.

The effects of complete parenteral alimentation on hematologic changes, body weight, nitrogen balance, "water balance", liver function, total plasma protein, plasma nonprotein nitrogen, and urinary sugar and albumin were followed. The same studies also were carried out for three or four weeks prior to the injections.

Methods of chemical determinations and hematologic study performed in this experiment are as follows. The nitrogen content of urine and diet was determined by the semimicro Kjeldahl method. The nitrogen content of feces was calculated as 12 per cent of the urinary nitrogen excretion based on the previous experimental results.<sup>9</sup> The nitrogen balance in the three day period was determined. The "water balance" was simply measured by the differences between the volume of fluid intake (water by mouth or water by mouth plus infused fluid) and the volume of urinary output. It also was conducted over a three day period. A blood sample for hematologic study was drawn on Monday morning before the infusion started in all instances (approximately thirty to forty hours after the previous injection of the six day a week schedule). Blood hemoglobin was determined by Sahli's method. Red and white blood cells were counted in the accepted manner and the hematocrit was obtained by centrifuging the oxalated blood in a Wintrobe tube for half an hour at 2500 revolutions per minute. Body weight was obtained just prior to the blood sampling for hematologic study every Monday.

The methods used for determining total plasma protein, plasma nonprotein nitrogen, rose bengal dye clearance test, serum phosphatase, and urinary sugar and albumin were the same as described in the previous communication.<sup>9</sup>

A solution containing 10 per cent Amigen, 15 per cent glucose and the required minerals and vitamins was mixed and infused as one solution. The olive oil emulsion was infused separately and in all instances was infused before the other mixture. Daily infusion was completed in approximately nine to ten hours (three to four hours for fat emulsion and six to seven hours for Amigen, glucose, vitamins and minerals). The infusion rate of glucose, protein and fat was approximately 1.4, 0.55 and 0.86 Gm. per kilogram of body weight per hour respectively.

During infusion, the animals remained in the individual cages. The use of the swivel of Jacobs<sup>10</sup> with modification permitted the animal complete freedom of movement during the infusion. Infusions were carried out by introducing polyethylene tubing\* (0.025 by 0.004 in.) into the external jugular vein. The tubing was left in the vein for two to five weeks. The dogs were infused for four weeks and then sacrificed for histologic study.

## RESULTS

*General Appearance*—All animals (Dogs P, R, C, and M) which received complete parenteral alimentation including the fat remained healthy, lively and in good spirits throughout. Their hair was smooth and shining. However, Dog Y, which received no fat, appeared very emaciated and apathetic. Its hair was very coarse and dry and epilation was starting to occur on the hind legs. The conditions are shown in Figs. 1 and 2.

*Hematologic Studies*—In Table V are shown the hematologic values of the five animals (Dogs B, R, C, M, and Y) determined during the control period. Table VI presents the average deviation of the weekly hematologic findings of Dogs B, R, C, and M during the experimental period from those determined during the period of control. The deviations of the weekly findings during the experimental period of Dog Y are also shown in Table VI.

\* Polyethylene tubing was obtained from the Irvington Varnish and Insulator Company, Irvington, N. J.

The differences in white cell count and hemoglobin determination in Dogs B, R, C, and M during the entire four-week period of complete parenteral alimentation with the fat were not significant. However, these dogs showed a slight fall in red cell count after the fourth week and a slight fall in hemato

*Body Weight and Nitrogen Balance*—All four animals (Dogs B, R, C, and M) receiving complete parenteral alimentation maintained or slightly increased body weight during the period of infusion. However, Dog Y which

received the same nutrient medium but without the fat lost 14 per cent of its initial weight. The nitrogen balance was slightly variable during the period of infusion. Some of the animals showed negative balance during the first

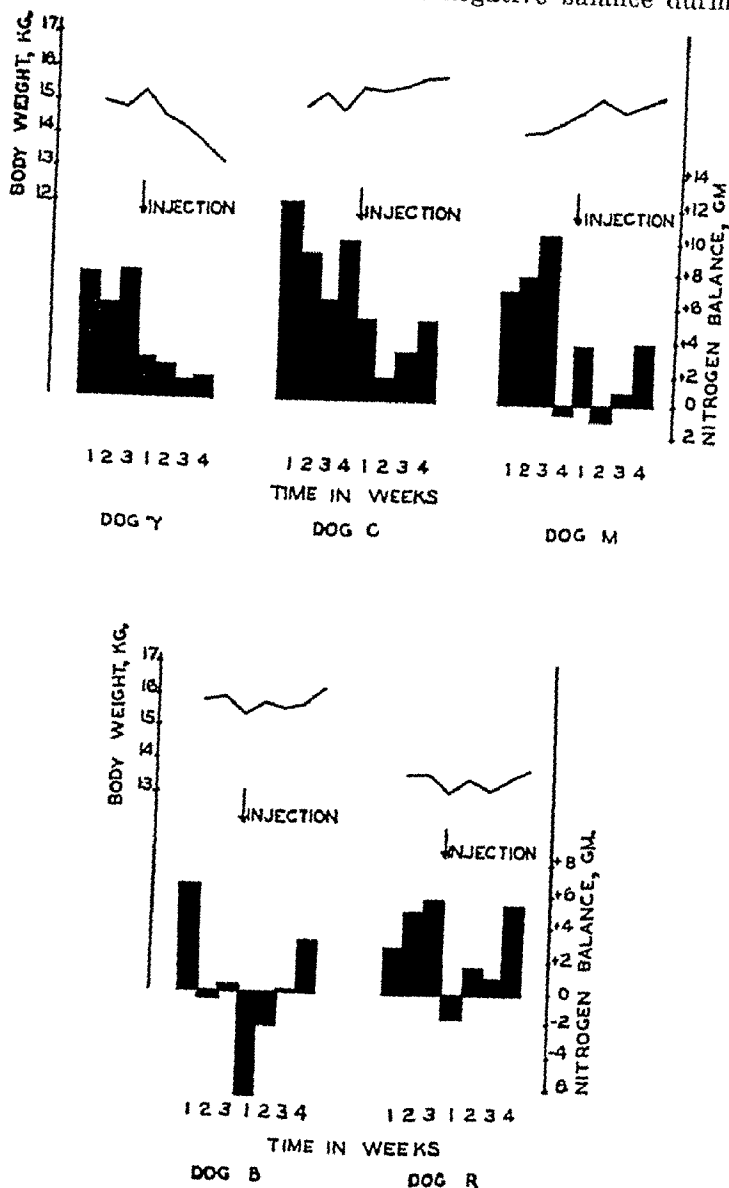

Fig 3—Showing the nitrogen balance and change in body weight during the complete parenteral alimentation period (Dog Y received no fat in the nutrient medium) similar to those during the control period

(Dog R) or second (Dog M) or both first and second (Dog B) weeks of infusion. However, negative balance also was observed on Dogs B and M during the second and fourth week respectively of the control period. The nitrogen balance of Dog Y during infusion was less positive than that during the control period. The results are shown in Fig 3.

"*Water Balance*"—During the control period the average "water balance" of the three day interval scheme for Dogs B, R, C, and M was +818 ml (ranging from 634 to 985 ml). The same animals averaged +1,447 ml (ranging from 969 to 1,938 ml) for the experimental period. The same change took place in Dog Y. The significance of these observations is doubtful since no account was taken of the insensible loss. There was probably no true water retention since there was no evidence of edema. The results of this study are presented in Table VII.

TABLE VII SUMMARY OF THE "WATER BALANCE"

DOG	PERIOD	NUMBER OF WEEKLY OBSERVATIONS	INTAKE (ML) 3 DAY			OUTPUT OF URINE (ML) 3 DAY (AVERAGE)	BALANCE (ML) 3 DAY (AVERAGE)

Y	Control	3	2,070	—	2,070	1,240	+ 830
Y	Exper	4	3,453	2,550	6,003	4,690	+1,308

*Blood Chemistry and Liver Function*—There was no change in total plasma protein concentration. The plasma nonprotein nitrogen remained within the normal range throughout the infusion period except in the case of Dog M which showed a slight increase. However, there is no basis to assume that such change was due to renal damage incident to those infusions since the findings observed during the control period were high. The rose bengal clearance test was reduced in three of the four dogs (Dogs B, C, and M) receiving complete parenteral alimentation. Serum phosphatase was somewhat elevated in all the animals of this group. The animal (Dog Y) which received no fat demonstrated the same changes. However, the serum phosphatase determinations made just before the animals were sacrificed showed lowered or normal levels in all five dogs. These results are shown in Table VIII. Neither sugar nor albumin was detected in the urine throughout.

*Histologic Study*\*—Gross examination revealed no abnormalities at the end of the four week infusion period in both groups of animals (with or without the fat). Microscopically, Dogs B, R, C, and M, the animals receiving complete parenteral alimentation showed a few stainable fat granules in some of the Kupffer cells. However, the parenchymal cells were fat free and normal. There was no fat observed in the liver of Dog Y. In the kidney sections of all five animals including the dog (Y) receiving no fat, there was positive fat stain in the cytoplasm of some of the distal convoluted tubules. The

\*Acknowledgment is made to Dr. James R. Dawson, Jr., Professor of Pathology, Vanderbilt University Medical School, for interpretation of the histologic sections.

glomeruli appeared normal and no fat was demonstrated. The sections of the lung of Dogs R, M, and Y showed normal structure and were fat free. There were three or four fat emboli observed in the lung section of Dog C, otherwise it was essentially normal. There was a very small ulcer which was in the acute stage seen in the section of the duodenum of Dog M, but no similar finding was seen in the sections of the other animals. Other sections revealed normal heart, pancreas, stomach, spleen, bone marrow, and adrenal and thyroid glands in all five experimental animals.

†Just before animals were sacrificed

#### DISCUSSION

The animals used in the previous experiment<sup>7</sup> were injected while fastened on their sides on a canvas frame. It is obvious that the urinary bladder became very much distended since the animals were not accustomed to void in

such a position Hematuria resulted simply by rupture of the blood capillaries of the urinary bladder due to mechanical stretching. This was proved to be true by autopsy findings. By using the swivel device in this study, the animals were permitted to move at will. There was not the slightest difficulty encountered in urination or defecation and hematuria has never been observed.

Although the results showed a statistically significant fall of red cell count and hematocrit, it is reasonable to believe that the fat emulsion infused was not responsible for the slight change. In the first place, the observed average decrease for red cell count of Dogs B, R, C, and M was only -0.74 after the fourth week of complete parenteral alimentation with the fat. Second, Dog Y, the animal which received no fat, also demonstrated the reduction of hematocrit (Tables V and VI). Such small changes would not be surprising in view of the change of diet and degree of hydration. Finally, histologic examinations showed essentially normal bone marrow in all the experimental animals which would further support the belief.

The reduction of rose bengal clearance and elevation of serum phosphatase observed during complete parenteral alimentation indicate the impairment of liver function. However, the changes were demonstrated in all five dogs including the one which received no fat. The serum phosphatase determinations made just before the animals were sacrificed gave values which were at the control level (Table VIII). In view of this fact it seems reasonable to state that the signs of liver impairment were not caused by the intravenous administration of fat but rather were due to the complete parenteral alimentation in general since Dog Y which received no fat, demonstrated the same result. It is quite likely that during the infusion period the liver was under a heavy burden and had to work extremely hard in order to carry out the necessary processes for the utilization of the nutrients intravenously introduced. Furthermore the histologic examination of the liver showed normal parenchymal cells which again rules out the possibility of severe liver damage. The presence of a few fat granules in some of the Kupffer cells of the liver is probably as one might expect. However, it might be suggested that in clinical use if a patient's liver function is severely impaired, parenteral alimentation of any kind be given only after careful consideration.

The stainable fat found in the renal tubules is probably not the result of intravenous administration of fat. There was more stainable fat demonstrated in the tubules of Dog Y the animal receiving no fat, than in those of the fat infused animals. Albumin was never detected in the urine, and surprisingly enough glycosuria was never observed during the complete parenteral alimentation although the infusion rate of glucose was approximately 1.4 Gm per kilogram of body weight per hour. Woodyatt and associates<sup>11</sup> reported that 0.85 Gm per kilogram per hour (in 10 to 50 per cent solution) was the maximum speed of intravenous infusion of glucose without production of glycosuria. Lockhart and Elman<sup>12</sup> recently found that in human subjects 0.5 Gm per kilogram per hour was the maximum speed of infusion with

out production of glycosuria. This may be interpreted in part, at least, as being due to the following factors: (1) The addition of protein hydrolysate to the glucose solution increases the rate of utilization of glucose by the tissues as suggested by Lockhart and Elman<sup>12</sup>. (2) The addition of vitamin and mineral mixtures as carried out in the present study may further enhance the glucose protein hydrolysate utilization. (3) The rate of glucose utilization may be faster in the dog than in man. Nevertheless, the absence of albuminuria and glycosuria demonstrates that there was no impairment of renal function which can be attributed to the complete parenteral alimentation.

The increase in urinary volume output during parenteral alimentation was simply due to the intravenous administration of a large quantity of fluid. The water intake by mouth of Dogs B, R, C, and M varied very little, with an average of 1,755 ml for the three-day interval scheme during the control period. Even during the experimental period, oral water intake of Dogs B and R was in this range. However, water intake by mouth of Dogs C and M was increased during the experimental period. The average water intake by mouth of Dog Y was 2,070 ml during the control period as compared with the average of 3,453 ml during the experimental period. The increase of water intake by mouth of Dogs C, M, and Y was probably due to the elevation of room temperature during the first part of the winter when the rooms were first heated. The water loss by channels other than urinary output, e.g., panting, was increased, leading to an increase of "water balance." However, it is not a true retention. The average "water balance" of Dogs B, R, C, and M during the control period was +818 milliliters. The average amounted to +1,447 ml during the experimental period for the same group of animals. The average increase of "water balance" for the three-day interval scheme was 629 ml which is only 209 ml per day. The average "water balance" of Dog Y, the animal receiving no fat, was also increased during the experimental period (+28 ml for three-day period) (Table VII). It is our belief that there was no disturbance in body fluid of different compartments during parenteral alimentation (with or without fat) in the present study.

The experiment of omitting fat from the diet for complete parenteral alimentation of Dog Y was planned in an attempt to obtain further evidence for the utilization of the intravenously administered fat. The animal (Dog Y) received inadequate caloric intake during the infusion period. It is assumed that if the infused fat is not utilized in the body then the results demonstrated by the two groups of animals (with or without the fat) should be similar. It is true that part of the intravenously administered protein hydrolysate is lost in the urine. Unfortunately, determination of amino nitrogen in the urine was not carried out in this study. However, it was probably not more than 10 per cent, since most investigators have shown it will not exceed this if the rate of infusion is not too rapid. The loss of amino nitrogen by means of the kidney might account for the difficulty in establishing nitrogen balance during parenteral alimentation. Nevertheless, the two groups of animals (with or without the fat) should appear similar as far as the nitrogen

loss is concerned. In view of these findings it is logical to believe that the injected fat is utilized in the body for energy. Dog Y lost 14 per cent of its initial body weight and appeared apathetic and emaciated while the other animals which received the fat were healthy, lively and in good spirits and maintained or increased their body weights (Fig. 3). The gain in body weight of the animals receiving fat was not due to the deposition of the injected fat as adipose tissue as has been demonstrated by McKibbin and associates<sup>13</sup>. Moreover the dry, coarse hair and the epilation of the hind legs of Dog Y were probably due to a deficiency of the essential fatty acids as demonstrated by Evans and Burr<sup>14, 15, 16</sup> Burr and co workers,<sup>17, 18, 19</sup> and by Evans and Lepkovsky<sup>20, 21</sup> on rats, and by Hansen and Wiese<sup>2</sup> on dogs since low caloric intake (53 calories per kilogram per day) is probably not the only factor responsible for the general picture. Mann and associates<sup>3</sup> showed additional evidence of utilization of the intravenously injected fat in growing puppies. More recently Geyer and co workers<sup>4</sup> and Lerner and co workers<sup>5</sup> were able to demonstrate the presence of  $C^{14}$  from the collected expired  $CO_2$  from rats after intravenous injection of  $C^{14}$  labeled triolein and tripalmitin fat emulsions. However further investigation should be carried out in this regard with adequate and inadequate caloric intake when fat is omitted in the parenteral basal ration to show the dispensableness of the fat.

The cause of the small ulcer observed in the duodenum section of Dog M is obscure. At any rate, there is no reason to suspect that it is related to complete parenteral alimentation. The presence of three or four fat emboli in the lung section of Dog C is certainly not significant insofar as the clinical picture is concerned since the animal was normal in all other respects. The failure to show any pathologic changes in other histologic sections indicates that this emulsion could be used clinically with considerable confidence.

#### SUMMARY AND CONCLUSIONS

Dogs have been maintained for as long as four weeks on a diet administered exclusively by vein. The diet furnished proportional amounts of carbohydrate, protein, fat, minerals, and vitamins. Thirty-four per cent of the caloric content of the diet was furnished by a special fat emulsion. The dogs remained healthy, lively, and in good spirits throughout and most of them gained weight. Extensive physiologic tests during the course of the experiments, and a complete histologic study following sacrifice, failed to reveal any significant abnormalities attributable to the procedure.

One dog was given the same treatment as the others except that the fat was omitted from the diet. It lost 14 per cent of its initial weight, appeared apathetic and emaciated and developed lesions suggestive of a fatty acid deficiency. The behavior of this dog gives considerable confidence to the belief that the injected fat in the other dogs was fully utilized and that its presence in the medium enhances the value.

It is concluded that this emulsion could be used clinically with considerable confidence, and that it would be very beneficial in cases where complete parenteral alimentation is necessary.

# THE NUTRITIVE VALUE OF INTRAVENOUSLY ADMINISTERED HYDROLYZED HUMAN SERUM ALBUMIN IN MAN

RICHARD D. ECKHARDT, M.D.,\* AND CHARLES S. DAVIDSON, M.D.  
BOSTON, MASS.

HUMAN serum albumin serves as a protein nutrient for human subjects when administered in the intact form by mouth or by vein<sup>1 2 3</sup>. The present study was undertaken to determine its nutrient value when administered intravenously in the hydrolyzed form as amino acids. The results indicate that the parenterally administered hydrolyzed albumin, supplemented with l-tryptophane, was nutritionally adequate for a slightly undernourished subject and was metabolized and excreted in a manner similar to that of other hydrolysates.

## MATERIALS AND METHODS

The subject selected for the study was a 43 year old man who was admitted to the hospital ten days previously for acute alcoholism. His general health in the past had been excellent, although during his intermittent alcoholic sprees he drank heavily and ate poorly and had recently lost 10 pounds in weight. The physical examination and laboratory findings, including tests of liver function were entirely within the limits of normal. The subject was asymptomatic throughout the twenty third day period of study while hospitalized on the Thorndike metabolic ward.

A 50 Gm protein diet was used in the first period and supplied 3,000 calories daily. It contained the foods ordinarily eaten in a well balanced, nutritious diet. The nitrogen content was calculated from standard food tables. In the second period a protein free diet was used which supplied 3,500 calories but only 0.4 Gm of nitrogen daily as determined by macro Kjeldahl analysis; the diet has been described previously.<sup>2</sup>

The hydrolyzed albumin solution was prepared by the complete acid hydrolysis of human serum albumin and was supplemented with l-tryptophane†. The composition of the solution and the quantity of amino acids infused are given in Table I. Previously reported values for the amino acid content of casein<sup>4</sup> and of human serum albumin<sup>5 6</sup> are listed for comparison. One liter of the 7 per cent solution was administered intravenously once daily, together with 100 cc of 50 per cent dextrose. The injection was made one hour after a 1,000 calorie breakfast in order to achieve maximum utilization of the infused amino acids by the simultaneous provision of adequate carbohydrate and protein.<sup>7</sup>

The daily urine and pooled stool nitrogen analyses were determined by the standard micro or macro Kjeldahl methods. The urinary alpha amino nitrogen was determined by the gasometric ninhydrin method described by Van Slyke, MacFadyen, and Hamilton.<sup>8</sup> The amino acid analyses of the urine and of the albumin hydrolysate solution were by the microbiologic method of Stokes and co-workers.<sup>4</sup>

\*From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard) Boston City Hospital and the Department of Medicine, Harvard Medical School.

The expenses of this investigation were defrayed in part by a grant from Merck & Co. Inc., Rahway, N. J. to Harvard University.

Received for publication May 20, 1949.

\*U. S. Public Health Service Postdoctorate Research Fellow.

†The human serum albumin was processed and supplied by the Medical Research Division, Sharp & Dohme Inc., Glenolden, Pa., from blood collected by the American National Red Cross from voluntary donors. The hydrolysate was specially prepared for this investigation by acid hydrolysis of the albumin which had been rejected for clinical use because of pyrogen content. The hydrolysis preparation and analysis of the pyrogen free 7 per cent solution were done under the direction of Dr. E. E. Howe, Merck & Co. Inc., Rahway, N. J. The authors express their thanks to the individuals and organizations concerned.

TABLE I AMINO ACID COMPOSITION OF THE HYDROLYZED HUMAN SERUM ALBUMIN SOLUTION

AMINO ACID	HYDROLYZED HUMAN SERUM ALBUMIN*		HUMAN SERUM ALBUMIN† (GM/100 GM)	CASEIN‡ (GM/100 GM)
	GM /INJECTION	GM /100 GM

\*Determinations by microbiologic assay. Prepared for intravenous administration as a 7 per cent solution and each 1000 c.c. infusion supplies (by analysis) 69 Gm. of amino acids, 11.1 Gm. of total nitrogen and 8.7 Gm. of alpha amino nitrogen.

†Values of Brand, Kassell and Saidel\* except isoleucine which is the value of Hegsted, Hay and Stare\*.

‡Microbiologic values of Stokes and co-workers\*.

## RESULTS

The solution of hydrolyzed human serum albumin was tolerated well clinically when administered intravenously over a period of approximately two and one-half hours. An attempt to administer the solution more rapidly was followed, on two occasions, by flushing and warmth of the face and upper neck together with mild nausea. Thrombosis of the infusion vein did not occur.

The nitrogen balance data for the subject are summarized in Table II. Nitrogen equilibrium was maintained during an initial five day control period while the subject received the basal 50 Gm. protein diet. Supplementation of this diet by the addition of 70 Gm. of hydrolyzed human serum albumin (1,000 c.c. of the 7 per cent solution) intravenously daily for five days resulted in a

TABLE II NITROGEN BALANCE DATA FOR SUBJECT GIVEN HYDROLYZED HUMAN SERUM ALBUMIN INTRAVENOUSLY

PERIOD OF STUDY (DAYS) AND CONDITION OF STUDY	NITROGEN INTAKE (GM/DAY)		NITROGEN OUTPUT (GM/DAY)		NITROGEN BALANCE (GM/DAY)
	ORAL	I V	URINE	STOOL	
1-6 Fore control	8.1	0.0	6.7	1.2	+0.2
6-11 Hyd. albumin, I V	8.1	11.1	11.8	1.2	+6.2
11-17 After control	8.1	0.0	6.4	1.2	+0.5
17-24 Hyd. albumin, I V	0.4	11.1	10.2	0.4	+0.9

sustained positive nitrogen balance averaging +6.2 Gm. daily. The nitrogen balance during a six-day after-control period was comparable with that observed initially, and equilibrium again was attained by the 50 Gm. of dietary protein. During the final seven days of study, the subject received the diet adequate in calories but essentially devoid of protein and 1 liter of the 7 per cent solution of hydrolyzed albumin (70 Gm. of amino acids) intravenously daily as the sole source of nitrogen. Nitrogen equilibrium and extreme constancy of the urinary

nitrogen excretion were observed. The nitrogen balance averaged +0.9 Gm daily. The subject's body weight remained constant throughout the twenty three day study period.

The excretion of alpha amino nitrogen and of the ten "essential" amino acids in the urine during each of these periods of study is tabulated in Table III. While receiving 50 Gm of dietary protein the subject excreted comparable quantities of amino acids during both the fore and after control periods. The urinary excretion of amino acids was considerably increased when hydrolyzed albumin (70 Gm of amino acids) was administered intravenously, whether as a supplement to the 50 Gm protein diet or as the sole source of nitrogen. While receiving the parenterally injected hydrolyzed albumin as supplemental protein, the subject showed a loss by excretion in the urine of from 0.2 to 14.2 per cent of the individual "essential" amino acids infused, of 2.7 per cent of the total of the ten "essential" amino acids injected and of 11.9 per cent of the alpha amino nitrogen administered. These losses were somewhat less when the hydrolyzed albumin was administered intravenously as the sole source of nitrogen\*. In this instance, the maximum loss of any individual "essential" amino acid infused was 8.4 per cent and averaged

\*Milligrams of amino acid or of alpha amino nitrogen in excess of that excreted during the preceding control period (see text footnote).

†Per cent of administered amino acid or of administered alpha amino nitrogen (Table I) excreted in urine.

The amino acid excretion values listed in the last two columns of Table III are in excess of the amount of alpha amino nitrogen and of individual amino acids excreted during the preceding 50 Gm protein diet period. Since the subject received the hydrolyzed albumin as the sole source of nitrogen during this final period these values should be in excess of the amount of amino acids excreted while he was receiving the diet devoid of protein. This was not determined. However, since the minimum endogenous amino acid excretion is increased only slightly by the ingestion of protein\* the error incurred in the calculation of these values is small particularly in view of the considerably increased excretion of amino acids following infusions of protein hydrolyzates.

17 per cent for the total of the ten "essential" amino acids administered, while only 5.7 per cent of the alpha amino nitrogen injected was excreted in the urine. In each instance, however, the subject excreted considerably greater percentages of administered histidine and threonine, and to a lesser extent lysine, than of the other "essential" amino acids in the infusion mixture.

During the periods while hydrolyzed albumin was administered intravenously the urinary excretion of total nitrogen, of alpha amino nitrogen, and of each of the ten "essential" amino acids promptly increased and remained constant throughout its administration. The day the hydrolysate infusions were discontinued, these values immediately returned to those of the preceding control period. Thus, the data presented in Tables II and III and averaged for each period of study are valid representations of the changes that occurred daily.

#### DISCUSSION

This study demonstrates that a complete acid hydrolysate of human serum albumin, supplemented with *L*-tryptophane, can maintain weight and nitrogen balance for short periods of time in man when administered intravenously (70 Gm of amino acids daily) as the sole source of food nitrogen. Furthermore, approximately half of that injected parenterally into the subject as a supplement to a 50 Gm protein diet was retained and presumably formed extra body tissue. The solution employed, therefore, contained all the essential amino acids required by man for maintenance of nitrogen balance and weight, and for tissue protein repletion when administered in adequate amounts by vein for short periods of time. In these regards, intravenously administered hydrolyzed human serum albumin was metabolized and utilized in a manner similar to hydrolysates prepared from other protein sources.

The values for the amino acid composition of hydrolyzed human serum albumin reported in this paper and determined by microbiologic assay agree quite closely with those previously reported (Table I).<sup>2,6</sup> The lysine content was higher than found before, while the phenylalanine and valine contents (7.8 and 6.8 Gm per 100 Gm of albumin respectively) have not been published previously.

The low isoleucine and tryptophane content of albumin, particularly when compared with casein (Table I), previously occasioned concern over the protein's nutritional adequacy, especially since albumin was found incapable of supporting growth when fed to young rats until extra quantities of these amino acids were provided.<sup>6</sup> However, no supplementation was required for maintenance of nitrogen balance in the adult dog.<sup>6</sup> Previous studies in this laboratory demonstrated that adequate quantities of orally ingested human serum albumin, not supplemented with isoleucine or tryptophane, maintained nitrogen balance and weight for short periods of time in a normal subject.<sup>2</sup> Furthermore, the provision of additional isoleucine and tryptophane failed to alter nitrogen excretion and balance whether albumin was given by mouth in amounts insufficient to maintain nitrogen equilibrium or by vein in amounts

adequate to achieve positive nitrogen balance. It also has been demonstrated that unsupplemented albumin serves as a protein nutrient when administered in the intact form intravenously.<sup>1, 2</sup> Finally the nutritional adequacy of albumin administered intravenously in the hydrolyzed form as amino acids supplemented with L-tryptophane was demonstrated in the present study. Since tryptophane is destroyed upon acid hydrolysis it was necessary to supplement the solution with this "essential" amino acid although considerably more was added (12 Gm per liter of 7 per cent solution) than is present in the native protein (0.19 Gm per 100 Gm of albumin). Since albumin containing only 0.19 per cent tryptophane is nutritionally adequate when administered in the intact form by mouth or by vein it would be unlikely that it is inadequate when administered intravenously in the hydrolyzed form as amino acids. Under these conditions however somewhat larger quantities of the hydrolysate might have to be provided since the quantitative requirement of hydrolyzed protein administered intravenously is probably greater than that of an equivalent quantity given orally.<sup>10, 11</sup>

The values for alpha amino nitrogen and for the ten "essential" amino acids excreted in the urine by the subject while receiving the 50 Gm protein diet (Table II) are in general agreement with those reported previously from this laboratory<sup>9, 12</sup> and by others employing microbiologic methods.<sup>13, 14, 15</sup> These values were considerably increased when hydrolyzed albumin was administered

TABLE IV COMPARISON OF AMINO ACID EXCRETION FOLLOWING INFUSIONS OF HYDROLYZED ALBUMIN AND HYDROLYZED CASEIN

Valine	4.7	3.1	11.6	10.2	37.1	42.1	3.4	5.9	0.8	1.4
Total	40.4	30.4	100.0	100.0	1.087	7.16	100.0	100.0	2.1	2.3

Averaged values following infusions of 500 cc. of a 10 per cent solution of hydrolyzed casein to two normal subjects in approximately one hour.<sup>12</sup>

intravenously. Since albumin and casein differ in regard to their amino acid composition (Table I), the amino acid excretion following infusions of hydrolyzed albumin was compared with that following infusions of a hydrolysate of casein previously reported from this laboratory.<sup>1</sup> These data are shown in Table IV. Despite differences in the amino acid composition of these two solutions quite similar percentages of each administered amino acid were excreted in the urine and the postinfusion pattern of the "essential" amino

acids was similar whether hydrolyzed albumin or hydrolyzed casein was injected. The individual amino acids, however, were not excreted in the same proportion as administered in either hydrolysate, so that considerably greater percentages of administered histidine and threonine, and to a lesser extent lysine, were excreted than of the other "essential" amino acids. Despite the difficulty in interpreting these observations, as discussed previously,<sup>12</sup> the similarity in the renal excretion of amino acids following infusions of hydrolyzed albumin and of hydrolyzed casein is apparent.

#### SUMMARY AND CONCLUSIONS

1 One liter of a 7 per cent solution of hydrolyzed human serum albumin, prepared by the complete acid hydrolysis of albumin and supplemented with *L*-tryptophane, was administered intravenously daily to a slightly undernourished subject for five days as a supplement to a 50 Gm protein diet, and for seven days as the sole source of food nitrogen.

2 Nitrogen equilibrium was maintained when hydrolyzed albumin (70 Gm of amino acids) was injected intravenously as the sole source of nitrogen, while a sustained positive nitrogen balance was achieved during its administration as supplemental protein. The subject's body weight remained constant throughout the study.

3 The excretion of alpha amino nitrogen and of the ten "essential" amino acids in the urine following the intravenous administration of the hydrolyzed albumin solution was similar to that previously observed following infusions of hydrolyzed casein.

4 It is concluded that parenterally administered hydrolyzed human serum albumin, supplemented with *L*-tryptophane, is nutritionally adequate for man and is metabolized and excreted in a manner similar to that of hydrolysates prepared from other protein sources.

The authors wish to thank Alice Ballou, Ellen Doyle, and Elaine Hushberg for technical assistance, and Kathleen Clinton for preparing and calculating the diets used.

# ABSORPTION OF UNEMULSIFIED AND EMULSIFIED VITAMIN A IN SPRUE

HERBERT J. FOX, M D  
DURHAM, N C

## INTRODUCTION

A CHIEF result of the sprue syndrome is the impaired absorptive power of the small intestine. Among the prominent features of the syndrome are deficiency of hematopoietic essentials, fat-soluble vitamins, minerals, and protein. Diminished absorption of ingested foods, especially fats and fat-soluble substances, is an important cause for the development of the many specific deficiencies. Even though therapy alleviates most of the symptoms, restores the weight, the blood picture, glucose absorption, and gastric acid secretion to reasonably normal levels, there still remains in a number of patients the problem of persistent steatorrhea. Much of the disability in sprue patients can be attributed to steatorrhea. With the steatorrhea, there is impaired absorption of vitamin A, vitamin K, and calcium.

Vitamin A deficiency does not always manifest itself by clinical evidence but may be demonstrated only with biochemical methods. The investigations reported here are concerned only with the aspect of vitamin A deficiency in sprue. A report of numerous other studies conducted on these patients will appear elsewhere.

Because previous investigators<sup>1</sup> had shown that vitamin A absorption was markedly augmented in children with steatorrhea when fed emulsified materials, it was decided to conduct similar studies on the comparable effect of feeding unemulsified and emulsified vitamin A preparations to adult patients with sprue.

## MATERIALS AND METHOD OF STUDY

The procedures for doing plasma vitamin A determinations were similar to those previously described.<sup>2,3</sup> The vitamin A levels herein reported are listed in micrograms. One microgram of vitamin A represents approximately 25 I U. For the unemulsified vitamin A material, oleum percomorphum was used. The vitamin A content of this fish liver oil is rated at 60,000 I U per gram and is largely in the form of esters. The emulsified vitamin A material used was a special preparation. The emulsion was composed of 15 per cent vitamin A acetate, 15 per cent Tween 20,\* and 70 per cent water. This emulsion contained 100,000 I U of vitamin A per gram. Determinations were made on plasma specimens taken fasting and at intervals of three, five, and seven hours after the feeding of a test dose of 200,000 µg of vitamin A material. The peak rise in vitamin A occurred during the three to five hour period and fell to lower levels at seven hours. Therefore, only the fasting and the three and the five hour levels are included in this report to show the maximum rise. The test dose of vitamin A material used in all these experiments was given to the patients after an overnight fasting period. Milk was used as a vehicle for the materials followed by feeding a normal breakfast.

From the Department of Medicine, Duke University.  
This material was presented in part before the Southern Society for Clinical Investigation, January 29, 1949, at New Orleans, La.  
Aided by a grant from Markle Foundation.  
Received for publication May 27, 1949.  
\*The Tweens (Atlas Powder Co., Wilmington, Del.) are very effective emulsifying agents and are nontoxic when fed to human beings.

Three groups of patients were used for obtaining vitamin A absorption curves. For the first group of absorption curves eight normal control patients were used. The next group of absorption curves was obtained from eight patients with sprue in relapse. Finally, a third group of observation curves was obtained on six patients who had had sprue but in whom there were no detectable clinical nor laboratory signs of activity and therefore were classified as having sprue in remission.

Tolerance curves on the patients were first obtained with unemulsified vitamin A ester in fish liver oil. Within a week of this original study another tolerance curve was obtained on the same patients but this time with the feeding of emulsified vitamin A acetate preparation. To each of the three groups of patients was administered the unemulsified vitamin A ester in fish liver oil. To the group of normal patients and to those with sprue in relapse was administered the vitamin A acetate emulsion composed of 15 per cent vitamin A acetate, 15 per cent Tween 20, and 70 per cent water. The test dose in terms of micrograms of vitamin A used in each preparation was the same.

## RESULTS

The vitamin A levels as determined by the procedures referred to are compared and summarized in Tables I and II.

In *normal adult patients* the feeding of unemulsified vitamin A ester in fish liver oil produced significant rises in plasma vitamin A. When the same group of normal patients was given emulsified vitamin A acetate in Tween a similar but higher peak level in plasma vitamin A was produced. The emulsified material accelerated absorption in only one instance producing a peak rise at three hours compared to a peak reached in five hours in the remainder of this group.

*Adult patients with active sprue* who were requiring maintenance dosage of folic acid or liver therapy and all of whom continued to show steatorrhea were fed unemulsified vitamin A ester in fish liver oil. Very poor absorption

resulted, as may be seen in Table I, the maximum rise of vitamin A being quite low in every patient. However, when preparations of emulsified vitamin A acetate in Tween were fed to this same group, a very marked increase in plasma vitamin A occurred of about the same degree as seen in normal controls. Only one patient, Case 8 in Table II, repeatedly proved an exception and showed very little rise in plasma vitamin A when given emulsified vitamin A acetate in Tween.

When the group of patients classified as having *sprue in remission* were fed unemulsified vitamin A ester in fish liver oil, the results as seen in Table I were, with one exception, fairly comparable to those obtained in the normal controls. After two members of this group were found to have normal absorption curves when fed the emulsified vitamin A material, it was decided not to expend the small supply of this preparation on the whole of the group.

#### DISCUSSION

Under normal physiologic conditions the absorption curves on adults demonstrate that the tested materials were well absorbed and that the peak levels of plasma vitamin A were somewhat higher following the use of emulsified preparations. Of chief interest were the striking differences in results obtained in patients with *sprue in relapse*. The marked improvement in vitamin A absorption in these patients, with one exception, was dependent upon the use of emulsified materials. Such emulsions, it has been determined,<sup>1</sup> contain only droplets varying in size from 0.5 to 10.0 microns. It has been postulated<sup>4</sup> that the degree of the dispersion of fat is perhaps mainly responsible for absorption. Finely dispersed particles result from a suitable emulsifying system. The emulsifying agent, Tween 20, apparently produced particles of appropriate size for enhanced absorption.

Fish liver oil contains vitamin A largely in the form of esters. Therefore, it is thought that the mechanism for its digestion is similar to that of other neutral fats and requires lipolysis. In patients with sprue there is no evidence of defective lipolysis. However, it is to be noted that fish liver oil is *unemulsified* material. Therefore, the hypothesis presented by one investigator that absorption is mainly dependent upon fine particle size seems to be further supported by the data herein reported.

The observations on patients with sprue in remission demonstrate that they absorbed the unemulsified material with one exception equally as well as normal controls. This would indicate a return to a normal physiologic status of the small intestinal tract. Further evidence of this was found in the normal clinical condition, normal radiologic pattern of the small intestines, and normal quantitative fecal fat.

It should be noted that we do not know the degree of absorption which might result from feeding vitamin A acetate alone. Would this form of vitamin A be as well absorbed without the addition of the emulsifying agent used in these experiments? Since it was impossible to obtain the necessary amounts of vitamin A in this pure form we cannot answer this question. However it has been reported that patients with steatorrhea who failed to absorb vitamin A esters in fish liver oil did show a marked increase in vitamin A absorption when polyoxyethylene sorbitan monooleate 'Tween 80' was added to the test dose of the same material.

The implications of these data would seem to be of great practical importance in the management of steatorrhea in sprue. These patients present a difficult problem in dietary fat control. It is probable that their poor absorption of vitamin A, as well as fats results from a defective emulsifying system in the small intestinal tract. Therefore the ideal diet should probably be one containing vitamin A and fats in emulsified form or else more practical the addition of an emulsifying agent to the diet.

#### SUMMARY

The feeding of emulsified vitamin A to normal adults resulted in a somewhat higher elevation of plasma vitamin A than did the feeding of unemulsified vitamin A material.

The patients with sprue in remission absorbed unemulsified vitamin A to a normal degree with only one exception.

Patients with active sprue showed very poor absorption when fed unemulsified vitamin A. When these same patients were fed emulsified material, the absorption of vitamin A was increased to approximately normal with one exception.

It is suggested from these results that patients with active sprue require the addition of an emulsifying agent to their dietary fat and fat soluble substances to promote absorption.

For the preparation and generous supply of emulsion of vitamin A acetate with Tween 20, we are greatly indebted to Dr. A. E. Osterberg of Abbott Research Laboratories, Durham, N. C. For performing the blood examinations we are indebted to Mrs. G. Stenhouse and Mrs. J. D. Moody.

## LABORATORY METHODS

### A NEW TABLET TEST FOR URINARY BILIRUBIN

MURRAY FRANKLIN, M D  
IOWA CITY, IOWA

THE need for a practical solution of the clinical problem of detecting small amounts of urinary bilirubin has received added emphasis with the increased incidence of liver disease during World War II<sup>1</sup>. Until recently we have had no simple sensitive and reliable bilirubin test which could be used routinely by the physician for the detection of bile in the urine and which could be employed in the armed forces and industry for mass examinations to detect latent liver disease or follow its course. The standard methods for the detection of bilirubin in the urine such as the foam, nitric acid, and iodine tests are relatively insensitive and are difficult to evaluate when pigments other than bilirubin are present in the urine<sup>2</sup>. The methylene blue test<sup>3,4</sup> although simple and useful as a screening or follow up test, is nonspecific and may give falsely positive results with urine containing yellow pigments such as riboflavin, penicillin or Atabrine. It is also less sensitive than other bile tests routinely employed<sup>5</sup>. Tests depending upon concentration of the bile pigment either by precipitation and adsorption of the pigment by barium chloride or calcium chloride or upon adsorption by talc are the most sensitive tests<sup>6</sup>. Such tests as the Godfried<sup>10</sup> diazo and Harrison<sup>11</sup> and Naumann<sup>12</sup> spot tests are relatively time consuming. Watson's<sup>7</sup> barium strip modification of the Harrison test has best met the requirements of sensitivity, simplicity, and applicability to mass and serial usage. With this test, higher concentrations of bilirubin give a definite green color. However, at low concentrations of bilirubin (below 0.1 mg per 100 cc) the color becomes blurred and indistinct and we have found the test often to be negative (Table I).

The object of this paper is to describe a simple yet sensitive test which is applicable to clinical work by the physician in everyday practice and to mass screening and serial testing. It is a tablet test, which can be prepared very simply and inexpensively. This test makes use of the principles of concentration of biliary pigment as in the Naumann and Harrison spot tests and subsequent oxidation with resultant color change of the bile pigment by Fouchet's reagent\*. Concentration of bilirubin pigment in the Naumann

\*Concentration of urinary bilirubin determined by Gibson's method  
†Watson's modification of Harrison's spot test

test is achieved by adsorption to a precipitated emulsion of talc. The Harrison spot test utilizes barium chloride as the adsorbing agent for bilirubin. The tablets used in this test concentrate bilirubin by utilizing the processes of filtration, adsorption by gypsum particles, and barium chloride adsorption. This test is thus a modification of both the Nummann and Harrison spot tests.

## MATERIALS

## PROCEDURE IN MAKING TABLET AND TEST

## PROCEDURE OF TEST

Fig 1

## DESCRIPTION OF METHOD

**A Preparation of Tablets (Fig 1 14)**—Three hundred fifty grams of ordinary commercial plaster of Paris (not dental plaster) are mixed in a container with 250 c.c. of a saturated solution of barium chloride. The resultant mix is then stirred and kneaded manually to remove any lumpy particles and to produce a homogeneous plaster mix which can be poured. This should be done in less than ninety seconds or the plaster will set in the container. It is then poured into a suitable rubber mold with approximately 250 indentations, each of which is 18 mm in diameter at the bottom, 19 mm at the top, and 5 mm deep. This is the size of the finished tablets. Before pouring the plaster, the rubber mat should be moistened by placing it under a running faucet or dipping it in water. The mat is inverted to get rid of excess water and the plaster is then poured onto the moistened mat. A squeegee (used to clean windows) is then drawn over the surface of the mat several times, distributing the wet plaster evenly in the indentations. The plaster is allowed to become firm and after

fifteen minutes the mat is inverted and the firm but still moist tablets will drop out. These are then dried in an oven and are ready for use at any time thereafter. The entire procedure of preparing the tablets until they are ready for drying should not take more than twenty minutes.

With the described proportions of plaster of Paris and barium chloride solution, the tablets should be of the proper consistency and should give optimal results. The proportion of 1 1/4 Gm. of plaster of Paris for every 1 c.c. of saturated barium chloride may have to be altered somewhat, depending upon the brand of plaster of Paris used. If the resultant tablets are too hard and do not absorb the urine quickly enough, the proportion of plaster of Paris to the saturated barium chloride may be decreased. Ordinary tap water instead of the saturated barium chloride solution may be used in the preparation of the tablet. However, tablets prepared in this manner do not absorb as much bilirubin, making the test less sensitive. The rubber mold we have used is an ordinary commercial door mat,\* 1 ft. by 2 ft., containing 500 indentations. The upper ridged surface is made smooth with sandpaper and the mat is cut in two, one half of this mat being used because it is easier to work with a smaller mold. An improved mat could be prepared with indentations of proper size, but with the bottom surface convex so that the prepared tablet would have a concave rather than a flat surface. The urine could then be dropped onto the concave surface of the indented tablet.

*B. Procedure (Fig. 1, A, B, C)*—Using an ordinary eye dropper or a pipette measuring 20 drops to the cubic centimeter, 10 drops of urine are dropped slowly upon the surface of the tablet so as not to cause any overflow. If bilirubin is present in the urine, a fine layer of yellow bile pigment will be adsorbed upon the surface of the tablet. The remainder of the urine will filter through. One or two drops of Fouchet's reagent are then dropped directly on the yellow area. A positive test is denoted by a blue green color, which varies in intensity with the amount of bilirubin present. The test is read in the same manner as the Harrison strip test trace to 4 plus. However, with urine containing low concentrations of bilirubin, the color change is much sharper with the tablet test. Normal urinary pigments give neither the yellowish discoloration on the tablet surface nor a positive test with the use of Fouchet's reagent. After addition of Fouchet's reagent, the green color should be read immediately, or its intensity will decrease. When no positive test is secured after addition of Fouchet's reagent, and it is still suspected that there might be a very faint trace of bile present, the use of 15 drops instead of 10 (the tablet will usually become flooded with more than 15 to 20 drops) may bring out faint traces of bile. This can be seen as a faint yellowish discoloration and will give a very faint but perceptible bluish green color after the addition of Fouchet's reagent. Occasionally in concentrated normal urines, as with the Watson modification of Harrison's strip test, a gray or lavender color develops after the addition of Fouchet's reagent. This is not due to bile pigment, but probably indicates dehydrogenation products of urobilinogen.<sup>13</sup>

#### DISCUSSION

This tablet test has been performed on more than 1,000 urine specimens. There have been no false positive results. In many instances it has been compared simultaneously with other urine tests, such as the foam nitric acid, iodine, methylene blue, and Watson's modification of the Harrison spot test (Table I). It is inexpensive to prepare, simple to perform, more sensitive and easier to read than any of the afore-mentioned tests. We have obtained a positive test with urines containing as little as 0.25 mg. bilirubin, although at these very low concentrations the test becomes difficult to read. We are attempting at present to correlate the degree of positivity of the test with bilirubin levels in the blood.

\*Rubber Maid Door Mat manufactured by the Wooster Rubber Company, Wooster, Ohio.

Ordinary urine pigments give no yellowish color on the tablet surface nor any bluish green color after Fouchet's reagent is added. Certain therapeutic agents, such as riboflavin, Atabrine, and Pyridium which discolor urine, may give a slight yellowish discoloration of the surface of the tablet. The first two, however, give no such discoloration with ordinary therapeutic doses. None of these drug pigments give a positive test after the addition of Fouchet's reagent. Urine from patients with hematuria will also discolor the surface of the tablet but no green color is produced after the addition of Fouchet's reagent. We have noted a purplish black pigment adsorbed onto the tablet surface from the urine of a patient with acute porphyria. This tablet when held under a Wood's ultraviolet lamp gave the red fluorescence of a porphyrin. When bile pigment is present with any of these extraneous pigments a positive test is still secured with Fouchet's reagent, although it is somewhat altered by the presence of these other pigments. The intensity of the yellowish color on the tablet surface or the green surface or the green color after the addition of Fouchet's reagent can be utilized to determine semi quantitatively the amount of bile pigment in the urine as Watson<sup>13</sup> has done with the Harrison strip test. The yellow color can be used provided the patient has not been given any Atabrine, riboflavin or Pyridium. With the therapeutic doses of Atabrine or riboflavin used routinely the urinary excretion of these drugs does not discolor the surface of the tablet to any noticeable degree. However, none of the drugs interfere with the green color obtained after the addition of Fouchet's reagent. A urine containing bile can be analyzed by a quantitative method such as the Gibson\* method or the Godfried<sup>10</sup> modification of the Hunter diazo method. Various dilutions can be made and the test run upon these different dilutions of the urine of known bilirubin pigment concentration. Either the initial yellow color or the green color after the addition of Fouchet's reagent can be used to determine the quantity of bilirubin. Color photographs or drawings can be made of these different intensities which can then serve as standards for a given batch of tablets.

The formula for plaster of Paris is  $\text{Ca SO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ . After addition of water the dry plaster sets to a coherent solid which is composed of interlacing crystals of gypsum ( $\text{Ca SO}_4 \cdot 2 \text{H}_2\text{O}$ ).<sup>14</sup> When urine containing bile is dropped upon the tablet surface the gypsum particles apparently adsorb the pigment as does talc in the Naumann test. There may be an added chemical adsorptive effect because of the presence of calcium in the gypsum molecule. Addition of barium chloride in the preparation of the tablet definitely increases the

---

Gibson's method for quantitative urinary bilirubin

Barium acetate 0.5 Gm. is introduced into a 15 ml. centrifuge tube and 10 ml. of urine (pH 5 to 6) are poured into it and the tube is thoroughly shaken. The tube is centrifuged and after fifteen minutes the supernatant liquid is poured off and the wall of the tube and the precipitate are washed gently with water and the tube is drained. One milliliter of Ehrlich's diazo reagent is added and the precipitate is thoroughly stirred with a glass rod. Two milliliters of water, 1 ml. of saturated ammonium sulfate solution (again stirring), 8 ml. of alcohol and 1 ml. of concentrated hydrochloric acid are then added. Let stand with occasional shaking and filter (Whatman No. 5 paper). Read in a Coleman Junior spectrophotometer in an 85 by 1 mm. cuvette, wave length 575 with a water reference. If too strong the filtrate may be diluted appropriately with a blank solution. The graph secured with the spectrophotometer on semilogarithmic paper is a straight line from 0 mg. per cent at 100 per cent transmission to 1 mg. per cent at 24 per cent transmission when 10 ml. of urine are precipitated.

bilirubin adsorption The addition of Fouchet's reagent oxidizes the bilirubin to green biliverdin This bluish-green color tends to fade and become less intense after several minutes, especially with urine containing very small amounts of bile The principle of using a plaster of Paris tablet as an adsorbing filter could be applied to other substances such as porphyrin and melanin We are at present investigating this possibility

#### SUMMARY

1 The preparation and use of an inexpensive, simple, sensitive table test for detection of urinary bilirubin are described This test is a modification of Naumann and Harrison spot tests for bilirubin

2 The test makes use of a plaster of Paris tablet, made with a solution of saturated barium chloride or tap water, upon the surface of which urine is dropped The addition of Fouchet's reagent to the bilirubin pigment which is adsorbed on the tablet surface gives a clear-cut easily readable, bluish-green color which is specific for bile The test can be used for mass and serial testing and can be made semiquantitative for the determination of urinary bilirubin

# TECHNIQUES TO OVERCOME THE LACK OF RARE RHESUS ANTISERA AND CELLS\*

I DUNSFORD, CHIEF TECHNICIAN  
SHEFFIELD ENGLAND

COMPARATIVELY few laboratories can rely on obtaining supplies of the rarer Rhesus antisera such as pure anti C (*anti rh'*) and pure anti E (*anti rh''*), nor are donors of the rarer blood cells Cde/cde or Cde/Cde (*rh'*) and cDE/cde or cDE/cDE (*rh''*) readily available. Most laboratories undertaking Rh typing will however have supplies of the mixed antisera C+D (*anti Rh<sub>0</sub>'*) and D + E (*anti Rh<sub>0</sub>''*) as well as complete and incomplete pure anti D (*anti Rh<sub>0</sub>*).

The preparation of anti C (*anti rh'*) and anti E (*anti rh''*) from mixed sera is often unsatisfactory. Dilution removes the anti C and anti E which are almost invariably of lower titer than the anti D (*anti Rh<sub>0</sub>*), and when an absorption technique is employed the titer of the anti C and anti E already low as a rule is still further reduced.

The lack of the rare cells Cde/cde or Cde/Cde (*rh'*) and cDE/cde or cDE/cDE (*rh''*) prevents the testing of sera for anti C or anti E in the presence of anti D, the sera having to be stored until these cells are available while the lack of pure anti C (*anti rh'*) or anti E (*anti rh''*) causes difficulties in genotyping.

Techniques are described below which overcome these difficulties. They have been used in this laboratory with satisfactory results having been controlled by the use of pure anti C (*anti rh'*) and anti E (*anti rh''*) and by fresh cells of the types Cde/cde and cDE/cDE (*r'r* and *r''r''*).

The principle on which they are based is the exclusion of the D antigen (*R<sup>0</sup>*) in Cde/cde (*R'<sub>1</sub>*) or cDE/cde (*R<sup>2</sup>r*) cells and the D (*R<sup>0</sup>*) antibody in mixed anti C + D (*anti Rh<sub>0</sub>'*) or anti D + E (*anti Rh<sub>0</sub>''*) from the field of action by means of a strong incomplete anti D (*anti Rh<sub>0</sub>*) serum using a modification of the blocking technique originally described by Wiener.<sup>1</sup>

DETECTION OF THE ANTIBODIES C AND E (*anti rh* AND *anti rh''*) IN THE PRESENCE OF ANTI D (*anti Rh<sub>0</sub>*) BY MEANS OF CELLS OF THE COMMON GENOTYPES CDE/CDE AND CDE/CDE (*R'<sub>1</sub>* AND *R<sup>2</sup>r*) —

"Prepare cells of the comparatively rare genotypes Cde/cde (*r'r*) and cDE/cde (*r''r*) from cells of the common genotypes CDE/cde (*R'<sub>1</sub>*) and cDE/cde (*R<sup>2</sup>r*) as follows

From the Office of the Regional Blood Transfusion Service Ministry of Health Northfield Road Sheffield 10 England

Received for publication Feb 4 1949

At the present time two systems of nomenclature of the anti Rh typing sera and cells are in wide use. One of the systems is based on the series of allelic genes proposed by Wiener the other on a series of closely linked pairs of genes proposed by Race and Fisher of England. A comparison of the individual anti crums has been made recently by the advisory board of the National Institute of Health. In this paper the Race Fisher nomenclature has been employed but for the convenience of the reader Wiener's nomenclature is also given in parentheses and italics.

1 Subject a saline suspension of the cells CDe/cde ( $R^1$ ) or cDE/cde ( $R^2r$ ) to the action of a strong incomplete (blocking) pure anti-D (*anti-Rh<sub>o</sub>*) serum for one and one-half to two hours at 37° C

2 Examine for absence of agglutination and confirm "coating" by means of Coombs reagent (antihuman globulin serum)

These "prepared" cells can now be used to detect the presence or absence of anti-C (*anti-rh'*) or anti-E (*anti-rh''*) in a serum known to contain anti D (*anti-Rh<sub>o</sub>*)

3 Divide the cell suspension into three portions—one test and two controls

Test one with the serum under examination, incubating for one and one-half to two hours at 37° C

Agglutination indicates the presence and no agglutination the absence of anti-C (*anti-rh'*) or anti-E (*anti-rh''*)

Test two with a saline agglutinating anti-D (*anti-Rh<sub>o</sub>*) serum having a titer comparable with that of the anti-D in the mixed serum, incubating for one and one-half to two hours at 37° C

Incubate the third at the same time as one and two

No agglutination should occur in two and three

DETECTION OF THE ANTIGENS C ( $r'$ ) AND E ( $r''$ ) IN THE PRESENCE OF D ( $R^0$ ) BY MEANS OF MIXED ANTI-C + D (*Anti-Rh<sub>o</sub>'*) AND ANTI-D + E (*Anti Rh<sub>o</sub>''*) SERA —

1 Subject a saline suspension of the cells under examination to the action of an incomplete (blocking) pure anti-D (*anti-Rh<sub>o</sub>*) serum for one and one half to two hours at 37° C

2 Examine for absence of agglutination and confirm "coating" by means of Coombs reagent

These "prepared" cells are now magglutinable by anti-D (*anti-Rh<sub>o</sub>*), and mixed anti-C + D (*anti-Rh<sub>o</sub>'*) or anti-D + E (*anti-Rh<sub>o</sub>''*) serum can be used to detect in them the antigen C ( $r'$ ) or E ( $r''$ )

3 Divide the cell suspension into three portions—one test and two controls

Test one with the mixed anti-C + D (*anti-Rh<sub>o</sub>'*) or anti-D + E (*anti Rh<sub>o</sub>''*) serum, incubating for one and one-half to two hours at 37° C

Agglutination indicates the presence and no agglutination the absence of the antigens C ( $r'$ ) or E ( $r''$ )

Test two with a saline agglutinating anti-D (*anti-Rh<sub>o</sub>*) serum having a titer comparable with that of the anti-D in the mixed serum, incubating one and one-half to two hours at 37° C

Incubate the third at the same time as one and two

No agglutination should occur in two and three

NOTE—Where cells of the genotype Cde/cde ( $r^1$ ) or cDE/cde ( $r^{11}$ ) are available, attention should be drawn to the fact that a proportion of them are CD<sup>e</sup>e/cde or cD<sup>e</sup>E/cde (Stratton)<sup>2</sup> A preliminary investigation in this laboratory shows that about 10 per cent of so-called Cde/cde ( $r^1$ ) cells are CD<sup>e</sup>e/cde. The technique outlined herein for the "preparation" of cells will

prevent errors through using a  $CD^u e/cde$  cells thought to be  $Cde/cde$  ( $r'$ ) or a  $cd^u E/cde$  cell thought to be  $cdE/cde$  ( $r''$ )

Wiener's nomenclature<sup>3, 4, 5</sup> is given in parentheses and italics for the convenience of those laboratories which still adhere to it, but difficulty is found in expressing the various allelomorphs of D, C, and c which are now known to exist, e.g., in this paper no equivalent in Wiener's nomenclature is suggested for the cells  $CD^u e$  and  $cd^u E$  thus may be left to the ingenuity of the reader

Thanks are due the Regional Transfusion Officer Lt Col R H Malone, for permission to publish this note and for his suggestions also to Dr R R Race of the M R C Blood Group Research Unit Lister Institute for his continued advice and encouragement, and especially to Mr F Gould of our Transport Department for his willing donations of  $cdE/cdE$  ( $r''r'$ ) cells wherever required

# A GALVANOTACTIC PROCEDURE FOR THE CONCENTRATION OF BALANTIDIUM COLI IN FECES

GEORG LUBINSKY, M.D.  
BAYREUTH, GERMANY

## INTRODUCTION

THE diagnosis of balantidiasis is seldom established by physicians because the disease is little known. Another important reason is that *Balantidium coli* are seldom found in fresh stool specimens. The common helminthological and parasitological methods of stool examination utilize only a small quantity of fresh material and often kill or injure the balantidia. By examining stool specimens diluted with physiologic saline, Stschensnowitsch in Azerbaijan<sup>1</sup> was able to increase materially the percentage of positive results. He found *B. coli* in 56 (51 per cent) of 1,100 cases. Before this study, only four cases of balantidiasis were discovered in the whole of Azerbaijan.

The employment of a procedure which would increase the recovery of parasites from stools would be of value in the diagnosis of balantidiasis. The idea of concentrating the parasites by employing the phenomenon of galvanotaxis used in the study of free living Infusoria and of parasitic Infusoria of frogs<sup>2, 3</sup> suggested itself. The apparatus, which utilizes a galvanic current and is described below, has been successfully used for concentrating Infusoria from the rectum of the frog and *b. coli* from the feces of swine.

## MATERIALS AND METHODS

**Apparatus**—As a source of current, a Kenotron rectifier with a potentiometer was used, but any standard rectifier is suitable. The apparatus produced a direct current of 132 volts. Preliminary investigations were set up in a chambered slide. These chambers were constructed with glass strips 2 mm thick and 5 mm wide and sealed with Canada balsam in such a way that three chambers of not quite equal size resulted (Fig. 1). These chambers were connected by means of channels 5 by 5 by 2 mm in size. The channels were initially filled with 2.5 per cent agar (pH 7.5) in Ringer's solution. The central chamber was filled with a balantidia containing fecal suspension in Ringer's solution and covered with a cover glass. The side chambers were half filled with Ringer's solution in which were immersed pipette like agar bridges connecting them with Petri dishes containing Ringer's solution. The Petri dishes were connected by means of agar bridges with other dishes containing saturated copper sulfate solution in which were immersed copper electrodes. The resistance between the electrodes was approximately 30,000 to 35,000 ohms. The diffusion of copper ions into the chamber may be practically eliminated by changing the Ringer's solution in the dishes at one half to one hour intervals.

Warming the chamber to 37 to 42° C facilitated the collection of balantidia at the cathode. Therefore, in the construction of a practical apparatus, a means of warming the chamber as well as increasing its volume had to be considered.

As concentration vessels, stool sample tubes 70 mm in length and 22 mm in diameter were chosen. These are immersed in a water bath in such a manner that they project a distance of about 1 cm over the cover plate, a rubber ring being placed about the tube

at this level. The anodic agar bridge was dipped a few millimeters into the suspension. The cathodic bridge is inserted into the upper dilated end of a special concentration tube, suspended in the stool sample tube by a glass hook (Figs 2 and 3). The lower end of the concentration tube is closed by a porcelain filter and the tube filled with Ringer's solution.

- 1 Copper electrodes
- 2  $\text{CuSO}_4$  solution
- 3 Agar bridges
- 4 Ringer's solution
- 5 Galvanotactic chamber

A short length of rubber tubing is placed about the end of the tube which does not reach the bottom of the stool sample tube. The balantidia collect inside the lumen of the rubber tube below the porcelain filter (Figs 2 and 3).

In filling the concentration tube and rubber tube with Ringer's solution, no air bubbles must be permitted to enter since these greatly increase electrical resistance. A cellophane cap may be used in place of the porcelain filter. If cellophane is used, one must be sure that no portion protrudes beyond the rubber tubing since balantidia would also collect there. Instead of the concentration tube described one may use a long cathodic agar bridge which is filled with agar except for about 5 mm at the lower end, this space being filled with Ringer's solution. Such an agar bridge may be used only once since the balantidia migrate into the capillary space between the wall of the tube and the agar. The concentration tube equipped with the porcelain filter need only be immersed in boiling water before reusing. The concentration process was carried on for a period of ten minutes at 39°C. The resistance when the porcelain filter was used was about 35,000 to 40,000 ohms, with cellophane 20,000 to 25,000 ohms. The current strength was 0.3 to 6.0 milliamperes.

Then the concentration tube was removed from the stool sample tube and the contents of the concentration space (below the porcelain plate) were pipetted out and examined microscopically.

**Staining Specimens**—For counting the *B. coli* a small drop of saturated potassium iodide-iodine solution was added. For nuclear staining a mixture of equal parts of a saturated aqueous solution of methyl green and 40 per cent formaldehyde (formalin) was employed.

In our material (cecal contents of swine) balantidia of the suis type with long sausage-shaped nuclei predominated. Balantidia with round or bean-shaped nuclei were seen only in about 15 per cent of swine. They formed less than 1 per cent of the whole balantidial population. The stool specimens were examined between two and six hours after the swine were killed.

The preliminary observations employing the apparatus shown in Fig 1 were done using *Infusoria* from the frog rectum and swine balantidia *Balantidium coloon* (frog) and also the swine balantidia collected at the cathode at room temperature, with a current strength of 0.3 to 1.0 Ma for three to five minutes, and remained there as long as the current was flowing. Under the same conditions *Opalina ranarum* and *Opalina dimidiata* collected at the anode where they soon were killed. Apparently it is possible to separate single species of ciliophoria from a mixed population in establishing the necessary current strength for the anadromous movement of different species.

The stool specimens taken from swine ceca were first investigated without concentrating and four cover glass preparations of sediment of a fecal suspension in a Ringer's solution (1:3) were examined at low magnification. Then the galvanotactic chamber (Fig 1) was filled with the same sediment and the inside surface of the agar cathode was examined at low magnification. Of twenty stool specimens investigated in this manner balantidia were found without concentration in eight specimens while with concentration they were found in twelve specimens. The percentage of positive results was increased therefore only from 45 to 60 per cent which was to be expected since the volume of the chamber (0.45 ml) is hardly greater (Fig 1) than the sediment observed under the four cover glasses.

*Optimal Position of the Electrodes*—Fifteen milliliters of a 1 to 3 dilution of stool suspension were placed in each of two sample tubes (Fig 2) and concentrated for ten minutes at 39° C using a current of 3 milliamperes. With one of the samples the long cathodic concentration tube described was used. With the second sample a long anodic agar bridge was employed with a short cathodic concentration tube which extended only 1 cm beneath the surface. In Table I are shown the numbers of balantidia 'captured' at different electrode positions.

TABLE I POSITION OF ELECTRODES IN RELATION TO RECOVERY OF *B. COLI*

EXPERIMENT	WITHOUT CONCENTRATION*	WITH CONCENTRATION	
		SHORT CATHODE	LONG CATHODE
1	0.25	0	0
2	3.75	92	174
3	1.75	23	98
4	0.75	1	45
5	0	0	24
6	0	2	17

The numbers in this column give the mean of four cover slip preparations. The material was taken from the sediment in the bottom of the stool sample tube before beginning concentration.

The best results were obtained when the cathode was near the bottom of the stool sample tube—a fact probably dependent on the positive geotaxis of balantidia.

*Optimal Temperature*—Each stool suspension was divided into six equal portions and concentrated at temperatures ranging from 25° to 50° C with a current strength of 3 Ma for ten minutes. The results are shown in Table II.

TABLE II TEMPERATURE OF FECES SUSPENSION IN RELATION TO RECOVERY OF B COLI

EXPERIMENT	WITHOUT CONCENTRATION*	WITH CONCENTRATION					
		25° C	30° C	35° C	40° C	45° C	50° C
1	3.5	2	14	73	126	83	0
2	2.5	2	9	8	100	15	0
3	0	0	2	4	4	0	0
4	0.75	8	31	115	135	14	0
5	1.0	0	5	17	52	43	0

\*The numbers in this column give the mean of four cover slip preparations. The material was taken from the sediment in the bottom of the stool sample tube before beginning concentration.

The optimal temperature is 40° C, as Table II shows. At 25°, the balantidia are not concentrated by this apparatus and between 45° to 50° the Infusoria died. A temperature of 39° C was thereafter chosen for our experiments, corresponding to the rectal temperature of swine.

*Duration of Concentration*—In order to determine the most practical time interval for concentrating the balantidia, experiments were done lasting eighty minutes at a temperature of 39° C, with a current strength of 1 milliampere. Every ten minutes the concentration tube was removed and the balantidia in the trap were counted. The results are given in Table III.

TABLE III TIME NECESSARY FOR MAXIMUM CONCENTRATION OF B COLI

EXPERIMENT	WITHOUT CONCENTRATION*	NUMBER OF BALANTIDIA RECOVERED AT							
		10 MINUTE INTERVALS WITH CONCENTRATION							
		1	2	3	4	5	6	7	8
1	0	18	15	4	1	—	—	—	—
2	4.0	1,732	168	85	53	38	27	51	22
3	3.0	938	105	54	29	11	6	5	6
4	0.5	35	14	11	5	2	—	—	—
5	0	3	—	—	—	—	—	—	—

\*The numbers in this column give the mean of four cover slip preparations. The material was taken from the sediment in the bottom of the stool sample tube before beginning concentration.

As is shown in Table III, about 50 to 80 per cent of balantidia were obtained in the first ten minutes. The number of balantidia diminished rapidly in later samples, although at the end of eighty minutes some still were present in two samples. Therefore, if no balantidia are obtained in the first ten minutes, further stool suspension should be investigated. Similar results were obtained when a current of 3 Ma was used.

*Optimal Current Strength and Its Relationship to the Age of the Stool Sample*—In determining the optimal amperage, four tubes were filled with stool suspension and currents of varying intensity (0.3, 1.0, 3.0, and 6.0 Ma) were passed for ten minutes at 39° C. The optimal current strength for concentrating balantidia from fresh stool samples was mostly between 1 and 3 milliamperes. In older stool samples, optimal current strength varies so that we were obliged to repeat our experiments until balantidia could no longer be found. They were found to persist in stool samples a maximum of ten days at room temperature. This is in contradiction to usually accepted ideas. Table IV shows the results.

TABLE IV OPTIMAL CURRENT STRENGTH AND AGE OF FECES SAMPLE IN RELATION TO RECOVERY OF BALANTIDIA

POOM TEMPERATURE 22 26 C											
AGE (DAY)	STOOL SAMPLE 87			STOOL SAMPLE 87			STOOL SAMPLE 88		STOOL SAMPLE 89		
	1	2	3	1	2	3	1	2	1	2	3

AGE (DAYS)	STOOL SAMPLE 90		STOOL SAMPLE 91		STOOL SAMPLE 92		STOOL SAMPLE 93		STOOL SAMPLE 94	
	1	2	1	2	1	2	1	2	1	2
Without concentration	0	0	0	0	0	0	25	0	0	0
03 Ma	0	0	0	0	0	0	15	0	0	0
10 Ma	0	0	0	0	0	0	150	0	2	0
30 Ma	1	0	1	0	0	0	97	0	1	0
60 Ma	0	0	0	0	2	0	62	0	2	0

AGE (DAYS)	STOOL SAMPLE 86									
	1	2	3	4	5	6	7	8	9	10
Without concentration*	405	325	40	10	025	10	175	10	0	0
03 Ma	2839	42	97	6	3	0	2	1	2	0
10 Ma	3639	389	86	50	24	6	1	6	0	0
30 Ma.	3803	490	84	125	107	23	41	11	2	0
60 Ma	2479	547	322	280	53	51	52	2	0	0

The numbers in this column give the mean of four cover slip preparations. The material was taken from the sediment in the bottom of the stool sample tube before beginning concentration.

It is apparent that balantidia remain viable up to ten days. In Fig 4 the percentage of positive findings after concentration are plotted against the age of the stool sample. All twenty five samples were positive on the first day. The disappearance of balantidia from the stool samples does not depend wholly on a change in pH. They may disappear even in neutral samples (pH 7.0 to 7.2). If numerous starch granules are present they may sometimes be found in acid stools (up to pH 5.6). When the concentrating procedure was used, balantidia could frequently be demonstrated one day later than without concentration.

The optimal current strengths tend to increase with the age of the stool sample. After several days, this amounts to 3 to 6 milliamperes. Such amperages are, however, also optimal for some fresh stool samples containing only few balantidia. The effect of pH on the optimal current strength must be further investigated.

We have examined one hundred stool samples from swine ceca at a temperature of 39° C, current strength 3 Ma for ten minutes. Without concentration 56 per cent were positive with concentration, 92 per cent were positive. The results of twenty of these experiments are shown in Table V.

Fig 4—The recovery of *B. coli* in relation to age of stool samples  
All twenty five samples were positive on the first day

TABLE V NUMBER OF *B. COLI* OBSERVED WITH AND WITHOUT CONCENTRATION IN TWENTY DIFFERENT SAMPLES OF FECES

NUMBER OF BALANTIDIA			NUMBER OF BALANTIDIA		
SAMPLE	WITHOUT CONCENTRATION*	WITH CONCENTRATION	SAMPLE	WITHOUT CONCENTRATION*	WITH CONCENTRATION
1	4.25	186	11	4.0	1,732
2	99.75	3,927	12	3.75	57
3	6.75	354	13	0.5	9
4	41.0	4,230	14	0	3
5	9.0	299	15	0	0
6	1.25	52	16	5.25	436
7	11.5	4,430	17	0	10
8	26.25	3,312	18	2.5	100
9	2.5	84	19	0	4
10	0	18	20	0.75	112

\*The numbers in this column give the mean of four cover slip preparations. The material was taken from the sediment in the bottom of the stool sample tube before beginning concentration.

It is seen that the number of balantidia after concentration is not directly proportional to the number obtained without concentration. For example, in Sample 13 the increase was eighteen fold, while in Sample 11, it was four hundred twenty fold. It is possible that these results might be improved by taking into consideration other factors, such as pH.

On examining fifty stool specimens from swine from another region, the positive results were increased from 34 per cent to 52 per cent by using the concentration procedure.

#### SUMMARY AND CONCLUSIONS

1. A galvanotactic method for concentrating *B. coli* from swine feces has been described.

2 By using this concentration procedure, the percentage of positive results has been substantially increased from 56 per cent to 92 per cent in one hundred samples and from 34 per cent to 52 per cent in fifty samples from swine from a different locality

3 It is suggested that this galvanotactic method also may be employed for concentrating *B. coli* and other protozoan parasites in the feces of man

This observation applies similarly to the globulin subfractions and is confirmed by the electrophoretic diagram before and after performance of the cadmium reaction (Fig 1). The fairly regular diminution of all peaks is easily recognizable.

In the myeloma Serum 3 (Table I) where three-fourths of the serum proteins consist of gamma globulin, the cadmium precipitate has a corresponding imbalance (Fig 2). Probably this would have been even more pronounced if it had not been necessary for technical reasons to keep the total protein content for the three electrophoreses constant. The relative increase of albumin content is thus also explained, however, calculation shows that the albumin in Serum 3 participated only 6.1 per cent in the diminution. In Sera 2 and 1, where the albumin contents were twice and three times that in Serum 3, the proportional figures of the diminution were 3 and 6.4 times as much albumin. Thus in the case of gamma myeloma (Serum 3) less albumin is precipitated than in the other sera. Moreover, in Serum 2, where the albumin and gamma globulin contents were nearly the same, the decrease in albumin amounted to 18.6 per cent, yet that in gamma globulin was 33.0 per cent. Hence it follows that the cadmium reagent precipitates more gamma globulin than albumin.

Alpha and beta globulin are precipitated to a smaller extent, although further investigations are necessary to decide which of these subfractions is predominantly included.

Summarizing, electrophoretic analysis of three pathologic sera with strongly positive cadmium reaction leads us to conclude that the cadmium reagent precipitates gamma globulin primarily, but that alpha and beta globulin and albumin are also included in the precipitate. In this respect the composition of the initial serum, which is relatively dependent on disease, is of decisive importance. In general, the higher the content of one subfraction as compared with the others, the more strongly is it affected by the reagent. Since it is first of all a question of an anion action (the  $\text{SO}_4$  ion having a strongly dehydrating action according to its position in the lyotropic group) all protein fractions are affected. Thus the cadmium reagent differs greatly from the thymol and cephalin-cholesterol reagent.

According to Recant, Chaigaff, and Hanger<sup>7</sup> (1945), increased lipoproteins lead to a positive thymol test, though they influence the cephalin test but little, they state that the latter reacts considerably to an increase of gamma globulin, whereas thymol shows little or no reaction. Cohen and Thompson<sup>16</sup> (1947) obtained similar results and found a strong thymol turbidity each time the lipid-carrying beta globulins were markedly increased. This correlation was supported also by electrophoresis after centrifugation of the precipitate, which forms after standing overnight. Since then, Kunkel and Hoagland<sup>8</sup> (1947) have shown by electrophoresis of three thymol-positive sera that this reagent combines chiefly with beta globulin, and to a lesser degree with gamma globulin. In this case also the relative quantity precipitated is in close relation to the protein composition of the initial serum. The complex composition of the precipitate shows that probably our grasp

of these reactions between reagent and protein subgroups is not yet complete. Verification of the precipitation optima by MacLagan and Bunn<sup>9</sup> (1947) on electrophoretically-isolated protein fractions suggested, however, a greater susceptibility of the cephalin-cholesterol reagent to gamma globulin. This was found to be increased about ten times with gamma globulin taken from a hepatitis serum. This is at variance with the findings of Kabat, Hanger, Moore, and Landow<sup>10</sup> (1943) who observed a similar precipitation with the cephalin test, and also with the colloidal gold test, even when the gamma globulin had been isolated from different patients. MacLagan<sup>18</sup> found no reaction between isolated alpha and beta globulins and the thymol reagent. He concludes that the latter reacts with gamma globulin. Further investigations are necessary to clear up this question, including the intense yet varying inhibitive action of albumin (Kunkel and Hoagland<sup>8</sup>) and the alterations in precipitative ability of the individual reagents in disease connected with their varying response in the course of the illness. It also has been proved that during convalescence the individual tests remain positive for varying lengths of time. (See Gray and Barron,<sup>11</sup> Martin,<sup>12</sup> Maizels<sup>13</sup>)

For clinical needs simultaneous application of several tests to the same case is to be recommended at present. As we have already shown (Wuhrmann, Wunderly, and Bubb<sup>14</sup>) the average response to the cephalin and thymol reaction agrees to a large extent in extensive series of tests on three different disease groups (hepatic disorders, infectious diseases without participation of the liver, pulmonary tuberculosis). This is true also when the cadmium test is included in such a comparison (Table II). On the other hand, parallel tests performed simultaneously often exhibit divergences, some times one, sometimes another test appearing more sensitive. These individual deviations are only equalized, as Table II shows, to a very considerable extent, when results are taken as a whole.

TABLE II

	HEPATIC DISORDERS	INFECTIOUS DISEASES (WITHOUT PARTICI- PATION OF THE LIVER)	PULMONARY TUBERCULOSIS
	NUMBER OF CASES EXAMINED		
	180	135	106
Positive result			
Cephalin test	126	84	55
Thymol test	131	82	60
Cadmium test	123	93	68

We have already drawn especial attention to the significant fact that under pathologic conditions a globulin increase (of one or more subfractions) together with a simultaneous albumin decrease is always observed in every case, and that among many thousands of investigations we never observed an albumin increase. The observation of this one-sidedly inverse regulation mechanism is thus of especial importance to the result of serum lability tests, since the positive result of these tests is dependent on an increase of one or

several globulin fractions, the albumin always appearing diminished at the same time. Precipitation of the albumin by the cadmium reagent never occurs in normal plasma under the test conditions described, in the case of disease occasioned alterations in the serum, where precipitation of the albumin may occur by means of the cadmium reagent the albumin is always quantitatively diminished. In exactly the same way, the quantitative decrease of the albumin always also appears to be connected with qualitative alterations as is observed in the increase of the globulin fractions connected therewith. It remains to be seen whether in disease the two fractions of albumin as they were shown by Luetscher<sup>17</sup> (1939) at pH 4, have different ratios from normal serum. An increase in one of them might easily lead to a different reactivity with the reagents of the lability tests. As a rule albumin does not split up into several underfractions at the pH range in which electrophoresis is usually carried out and we are therefore, not well informed on the changes in the albumin fraction. According to our experience also the lipid content of the serum (and thus the beta globulin complex) plays a particular part in the thymol turbidity test (Kunkel and Horgland<sup>8</sup> Hange<sup>1</sup>).

The view that an actual specificity exists in all these tests in respect to hepatic diseases or parenchymatous damage to the liver finally has been abandoned (Wuhrmann Wunderly and Bubb<sup>14</sup>). For the cadmium reaction we have emphasized from the beginning that clinical evaluation must make a strict distinction between afebrile disease (positive result especially in *hepatic* and *renal* diseases) and fever states in which the positive result is generally speaking an expression of the reaction of the reticuloendothelial system. Table II shows that this observation also applies to the cephalin cholesterol and thymol tests.

#### SUMMARY

1 The cadmium reaction a simple test utilizing a stable reagent and five minute reading is described. According to electrophoretic tests it is not dependent on one but on several protein fractions and especially on their relationship with one another. The positive cadmium reaction is due above all to an increase of the gamma globulin but an increased content of the alpha and to a lesser extent of the beta globulins contributes. Precipitation of the albumin is likewise observed in such sera.

2 The greater the increase in content of an individual globulin fraction the more will be precipitated by the cadmium reagent. The albumin fraction precipitates only if the globulin fractions exhibit morbid displacement.

3 Attention is drawn to the clinical importance of the cadmium reaction and its delimitation in respect to the cephalin cholesterol and thymol reactions.

# AN IMPROVED DEVICE FOR OBTAINING PLASMA ANAEROBICALLY

ALDO GABARDI AND HORACE W DAVENPORT  
SALT LAKE CITY, UTAH

THE method of centrifuging blood in the syringe in which it is drawn in order to obtain plasma anaerobically\* has proved useful in research and clinical laboratories. When the syringe is centrifuged the barrel is prevented from being forced over the plunger by means of a metal or plastic spacer held

Fig 1—The use of the syringe spacer to obtain plasma anaerobically

on the plunger by rubber bands. However, construction of the spacers as originally described requires the services of a moderately skilled mechanic. The improved spacer described here can be made by anyone.

From the Department of Physiology, University of Utah College of Medicine.  
Received for publication May 1, 1949.

1947 Davenport, H. W. A Simple Anaerobic Method of Obtaining Plasma. Science 100, 717

## DESCRIPTION

The spacer is made of a 1 cm wide strip of 20 gauge aluminum or other metal bent into the shape shown in Fig 1. The strip of metal can be shaped by bending it around two nails driven in a board. It is advisable to make spacers of graded sizes. The most useful sizes are those which when placed over a 5 ml syringe will permit it to hold 5, 4, or 3 ml of blood. Spacers for 2 ml syringes are particularly useful when blood is being drawn from small animals.

The entire plunger of the syringe is greased with a light-bodied stopcock lubricant. The plunger is pushed into the barrel and turned through several revolutions. A needle is placed on the syringe, and a few drops of heparin solution are drawn into it. If more than a small bubble of air remains in the syringe it is expelled. Blood is drawn into the syringe, and some is expelled for measurement of pH. The needle is removed, and a length of pressure tubing about 15 cm long is placed on the tip of the syringe. With the tip held upward the plunger is forced in to fill the lumen of the tube with blood. A glass plug, fire polished on one end and flattened into a knob on the other, is inserted into the lumen of the tubing.

The appropriate spacer is placed around the plunger and tightly wrapped with rubber bands. The plug is removed, and the plunger is pushed in until the spacer comes to rest against the barrel. While the spacer is held in this position the plug is replaced. The assembly is then centrifuged with the plunger down. When centrifugation is finished the syringe is held with tip up and the spacer is removed. The plug is withdrawn and plasma is forced into a blood gas pipette whose tip is inserted into the lumen of the tubing.

# ON THE DETERMINATION OF PROTEIN IN SERUM AND IN FRACTIONS OBTAINED FROM SERUM WITH A BIURET REAGENT PREPARED WITH SODIUM HYDROXIDE

ANDRE C KIBRICK, PH D  
NEW YORK, N Y

IN 1942 Kingsley proposed the use of a biuret reagent containing 11.7 and 17.3 per cent sodium hydroxide for the determination of total protein and albumin, respectively in serum.<sup>1</sup> Gornall and co workers have recently reported that the reagent prepared in this way may lead to serious error and they suggest the use of tartrate as a stabilizing agent.<sup>2</sup> Other workers have applied the biuret reaction in various ways.<sup>3, 4</sup> For the past two years we have employed the reagent of Kingsley with 11.7 per cent sodium hydroxide for the determination of total protein in serum and of the protein remaining in solution after the precipitation of globulin fractions with either sodium sulfate or methyl alcohol.<sup>5, 6</sup> Our experience with this reagent is quite satisfactory and we endeavor to show in this paper that it permits a convenient method for clinical laboratories.

## EXPERIMENTAL

The method of Kingsley was modified slightly in order to use the same reagent for serum and for filtrates obtained from serum. The reagent was prepared by adding 1200 ml of 1 per cent copper sulfate to 6000 ml of a solution containing 968.4 Gm of sodium hydroxide, using sodium hydroxide pellets of ACS grade from only one source\* and copper sulfate ACS fine crystals, from only one batch. In contrast to the experience of Gornall and co workers we have found the reagent prepared in this way to be stable in a stock bottle for several months and to be uniform on repeated preparation. Standard curves obtained from serial dilutions of serum or filtrates of serum of known protein content, determined by the Kjeldahl method and correction for nonprotein nitrogen have been identical. Although we have not succeeded in finding a convenient substance which gives the biuret reaction to substitute for serum in the standardization Hiller, Grief and Beckman have reported that chromium ammonium sulfate has essentially the same absorption curve as that of the biuret color.<sup>7</sup> Apparently this is not true of the color obtained with the reagent containing 11.7 per cent sodium hydroxide. Fig. 1 compares the curves obtained with an Evelyn colorimeter of chromium ammonium sulfate, cobaltous sulfate, and potassium permanganate. Although neither the chromium complex nor cobalt sulfate is similar to our biuret color, potassium permanganate is quite similar and may be used for standardization. Fig. 2 shows that the color of permanganate obeys Beer's law over a considerable range at 540 millimicrons.

The determination was made as follows. For total protein 0.15 ml of serum was added to 10 ml of the reagent in a colorimeter tube. About 2 ml of ether were added, and the mixture was thoroughly shaken and allowed to stand at room temperature for fifteen minutes. The color was then measured in an Evelyn colorimeter at 540 m $\mu$  using a blank solution containing 10 ml of reagent and 0.15 ml of 0.9 per cent sodium chloride. For albumin in the methyl alcohol filtrates obtained by the method of Pillemer and Hutchinson,<sup>8</sup> 1 ml of solution was added to 10 ml of reagent and the color was measured after fifteen minutes, using a blank solution containing all of the reagents. For filtrates

obtained from serum with various concentrations of sodium sulfate, 3 ml were added to 10 ml of the biuret reagent and the color also was measured after fifteen minutes, using a blank solution containing all of the reagents

Fig 1—Absorption curves  
*T* Serum *A* filtrate of serum in 21 per cent sodium sulfate *B*, 0.5 per cent chromic ammonium sulfate *C*, 0.39 per cent crystalline cobaltous sulfate *P*, 0.00088N potassium permanganate

The concentration of protein was calculated from the standard curves which are described by the following equations, in which *D* is the optical density at 540 millimicrons

Total protein in serum	$\frac{D}{0.088} \times 100 = \text{per cent}$
Methyl alcohol filtrates	$\frac{D \ 0.004}{0.1145} \times 100 = \text{per cent}$
Sodium sulfate filtrates	
21 per cent*	$\frac{D \ 0.01}{0.072} \times 100 = \text{per cent}$
26 per cent†	$\frac{D}{0.0694} \times 100 = \text{per cent}$
15, 16, and 19 per cent†	$\frac{D + 0.012}{0.073} \times 100 = \text{per cent}$

\*Concentration of the final mixture obtained by adding 0.5 ml of serum to 9.5 ml of sodium sulfate reagent

†Concentration of the final mixture obtained by adding 0.5 ml of serum to 10 ml of sodium sulfate reagent

The filtrate from the method of Pillemer and Hutchinson with methyl alcohol was added at refrigerator temperature and the standard curve was prepared by also adding samples of filtrate at this temperature. The sodium sulfate filtrates were added at incubator temperature but the determination in 21 per cent salt

Fig. 2.—Values of optical density for different concentrations of potassium permanganate

was also made at room temperature. Standard curves were prepared at both temperatures and were found to be essentially the same when the concentration of the reagents of sodium sulfate was adjusted either to 100m temperature or to 37° C.

Although the temperature of the room is not critical, the results may be affected significantly in warm weather. Table I shows the values of optical density in a series of identical samples which were determined in a water bath at 25° and 30° C. During the summer months it is our practice to keep the tubes in a water bath at 25° until measurement in the colorimeter.

A final remark may be made concerning the determination of protein by the biuret reaction. Our experience confirms that of Wokes and Still that the intensity of the biuret color may be markedly increased in aged samples of serum.<sup>9</sup> We occasionally have found an apparent concentration of as much as 10 and 11 per cent in samples which were stored in the refrigerator for about six weeks. We do not have an explanation for the change which takes place, but it is probably due to bacterial action. There was no increase in the apparent concentration of normal serum that was drawn and stored in the refrigerator for

TABLE I MEASUREMENT OF THE BIURET COLOR IN SERUM AT 25° AND 30° C

SAMPLE	OPTICAL DENSITY		APPARENT CONCENTRATION	
	25°	30°	25°	30°
	D		GM PER 100 ML	
1	0.653	0.683	7.42	7.76

6	629	663	7.15	7.54
7	615	634	7.00	7.21
8	611	638	6.95	7.26
9	602	620	6.85	7.05
10	699	716	7.95	8.14
11	611	634	6.95	7.21

six weeks under sterile conditions. However, an apparent change from 7.5 to 8.5 per cent protein took place in the same serum when the flasks were opened occasionally without sterile precautions.

#### SUMMARY

A biuret reagent prepared according to Kingsley with 11.7 per cent sodium hydroxide is shown to be stable and is recommended for the determination of protein in serum and in both methyl alcohol and sodium sulfate filtrates of serum. Absorption curves are presented for the biuret color obtained with serum and with a sodium sulfate filtrate of serum, and for chromic ammonium sulfate, cobalt sulfate, and potassium permanganate. The curve of the latter most closely resembles that of the biuret color, and this substance is recommended for the standardization of the reagent.

# STUDIES OF THE DIFFERENCES BETWEEN BIURET AND KJELDAHL DETERMINATIONS OF SERUM PROTEINS

## I EXPERIMENTAL PERITONITIS

GEORGE R. KINGSLEY, M.S.\* AND L. A. TERZIAN, Ph.D.†  
PHILADELPHIA, PA.

A PREVIOUS report on patients with liver disease<sup>1</sup> established definite differences in the results of determinations of serum proteins by biuret and Kjeldahl methods. A further comparison of these methods was made in experimental peritonitis in dogs to confirm previous findings in similar diseases in human individuals. As indicated previously it is not known whether the changes observed represent a gain or a loss of nitrogen or of peptide linkages. For convenience they are described in terms of net change of biuret reactivity.

### METHODS

All protein determinations in this investigation were made simultaneously by the macro Kjeldahl and biuret methods,<sup>2</sup> using the ether sodium sulfate method<sup>3</sup> for the separation of albumin and globulin. Fresh unhemolyzed serum from blood samples taken either by vein or cardiac puncture was used. Adult mongrel dogs weighing an average of 16 kilograms were used. Prior to operation, small doses of morphine and atropine were administered subcutaneously. Ether anesthesia and aseptic technique were employed. Spreading peritonitis was induced according to the procedure described by Bower, Burns, and Mengle.<sup>4</sup> The appendix and its mesentery together with all its blood vessels, were ligated and the appendix was traumatized. Sixty to 90 ml of castor oil varied according to the weight of the animal, were administered by a catheter immediately following operation. Water was withheld for forty eight hours to avoid persistent vomiting. Simple laparotomies were performed on control animals exposing the viscera without ligation of blood vessels or traumatization of the appendix following the same anesthetization as in the experimental animals. Plasma volume and blood volume were estimated according to the method outlined by Gibson and Evans.<sup>5</sup>

### EXPERIMENTAL

Induced spreading peritonitis in dogs apparently caused an average decrease of biuret reactivity of globulin of 0.66 Gm per cent (Table I) with a standard error of  $\pm 0.08$ . This value is highly significant. Nine out of ten animals showed a significant difference in serum globulin as determined by biuret and Kjeldahl methods. Apparently the change occurs soon after the development of peritonitis, since this difference was fairly uniform from the

Peritonitis	1	8	1	9	1	0

second to the tenth day following the operation. No significant change occurred in the albumin biuret reactivity or total N during the same period. Average differences between protein determined by biuret and Kjeldahl N methods in both albumin and globulin were within normal limits before peritonitis was induced, and similarly, average differences in the control (laparotomy) animals were not significant. In spite of a large loss of 8 to 31 per cent (18.9 per cent average) of total circulating plasma protein, an increase of 0.4 Gm per 100 ml was observed in total protein by the Kjeldahl determination, probably as a result of dehydration. However, the biuret determination indicated no change in total protein before and after peritonitis. The Kjeldahl determination indicated a decrease in A/G ratio from 1.66 to 1.09, while a smaller decrease from 1.67 to 1.39 in A/G ratio was shown by the biuret method.

#### DISCUSSION

It has been shown<sup>1</sup> that liver disease will cause changes in the normal relationships between total N and biuret N in serum proteins, especially globulin. The degree of loss of biuret N in globulin in experimentally induced peritonitis is similar to that observed in cirrhosis. A comparable change in experimental peritonitis after two to ten days may be due in part to the rapid loss of large amounts of circulating plasma protein which placed an additional burden on a liver already actively involved and further impaired by the toxemias of the disease. Since these dogs ate little during the acute phase of the infection, malnutrition may have been an additional factor.

#### SUMMARY

1. Induced spreading peritonitis in dogs produced differences in serum globulin determinations by the biuret as compared with total nitrogen methods. These differences were similar to those observed in cirrhosis.

2. No corresponding changes in the albumin fraction were observed.

# STUDIES OF THE DIFFERENCES BETWEEN BIURET AND KJELDAHL DETERMINATIONS OF SERUM PROTEINS

## II EFFECT OF OCCLUSION OF THE HEPATIC ARTERY AND LIGATION OF THE GASTRODUODENAL ARTERY ON SERUM PROTEINS

GEORGE R. KINGSLEY, M.S.,\* AND ALBERT A. BEHREND, M.D.  
PHILADELPHIA, PA.

A PREVIOUS report on patients with various diseases<sup>1</sup> and one on animals<sup>2</sup> established definite differences in the results of determinations of serum proteins by biuret and Kjeldahl methods. Further comparison of these methods was made following occlusion of the hepatic artery and ligation of the gastroduodenal artery in dogs to determine the effect of a disturbance of arterial circulation and nutrition of the liver upon the biuret and Kjeldahl N relationship in serum proteins and in addition to establish the relationship of this liver impairment to previous findings in liver disease.

### METHODS

All protein determinations were made simultaneously by the macro Kjeldahl and biuret methods.<sup>3,4</sup> The ether sodium sulfate method<sup>5</sup> was used for the separation of albumin and globulin. Only fresh unhemolyzed serum was used for all determinations.

Sodium Amytal intraperitoneally was used for anesthesia. A partial clamp was applied to the hepatic artery which was gradually tightened from one to eight minutes during the two or three weeks following the operation on three dogs. Cellophane was placed and held by two to three Michel skin clips around the hepatic artery to produce occlusion in fourteen other dogs. The gastroduodenal branch of the hepatic artery of all dogs was double ligated and divided at the time of operation. Ten or more weeks later the hepatic artery was ligated at the point of occlusion. Repeated determinations of serum proteins (biuret and total N), urea, nonprotein nitrogen, uric acid, hemoglobin, sugar, cholesterol, and cholesterol ester were made on the blood of the dogs for periods up to 120 days following the initial operation.

### RESULTS

In every dog in the periods studied (Table I) a loss of biuret reactivity occurred in the globulin fraction. The average loss of biuret N in the globulin fraction from the second to the one hundred and thirtieth day after the operation was 0.36 Gm per cent (Fig 1, Table I).

There was a gradual return to normal in the biuret N/Kjeldahl N ratio of the globulin following the operation from a loss of 0.40 Gm per cent biuret N to 0.08 Gm per cent on the thirty-fifth day. Losses occurred again until 0.58 Gm per cent globulin biuret N had been reached on the fifty-fifth day, after which a slow recovery occurred until the one hundred thirtieth day when a smaller loss of biuret N of 0.30 Gm per cent was reached. No average significant gain or loss in albumin biuret N occurred in the 130 days following the

operation (Table I) However, the albumin values represented diagrammatically in Fig 1 show an irregular loss of albumin biuret N in the first thirty five days following the operation from 0.1 Gm per cent to -0.20 per cent

Fig 1.—Diagrammatic representation of gain and loss of biuret linkages (Gm % N) of serum proteins in dogs after occlusion of the hepatic artery and ligation of the gastroduodenal artery (data from Table I)

TABLE I DIFFERENCES BETWEEN BIURET AND KJELDAHL DETERMINATIONS FOLLOWING OCCLUSION OF THE HEPATIC ARTERY AND LIGATION OF THE GASTRODUODENAL ARTERY

NUMBER OF DOGS	DAYS AFTER OPERATION	BIURET		DIFFERENCES BIURET MINUS KJELDAHL	
		ALB. (GM %)	GLOB (GM %)	ALB (GM %)	GLOB (GM %)
10	2	3.7	2.1	0.1	-0.4
7	3 10	3.3	2.2	0.1	-0.4
11	11 30	3.0	3.4	0.1	-0.3
10	31 50	2.6	3.2	-0.1	-0.1
8	51 70	3.0	2.9	0.2	-0.6

8	91 130	3.2	3.1	0.0	-0.3

Albumin biuret N increased from the thirty fifth day to the sixty fifth day when a gain of 0.30 Gm per cent was shown. The biuret N/Kjeldahl N ratio returned to normal on the seventy fifth to eighty fifth days. The greatest average loss of albumin biuret N occurred on the thirty fifth day. There was an apparent relationship between the simultaneous gain of albumin biuret N and loss of globulin biuret N, and loss of albumin biuret N and gain of globulin biuret N as shown in Fig 1. The highest globulin biuret N occurred at the

time of the greatest loss of albumin biuret N, and the reverse occurred when the greatest loss of globulin biuret N was reached at the approximate time of the greatest increase in albumin biuret N. A few animals, Dogs 405 and 427 (Fig 2) and Dogs 479 and 723 (Fig 3), showed marked reversal in their loss and gain of biuret N in albumin and globulin. A gain of globulin biuret N

Fig 2—Diagrammatic representation of gain and loss of biuret linkages (Gm % N) of serum proteins and hemoglobin in dogs after occlusion of the hepatic artery and ligation of the gastroduodenal artery (data from Table I)

was reflected in a simultaneous loss of albumin biuret N, and loss of globulin biuret N occurred when there was a gain of albumin biuret N. This direct relationship was continuous throughout all periods studied after the dogs were operated upon.

Hemoglobin levels had a direct quantitative relationship to the biuret changes in albumin and globulin, as shown in Dogs 405 and 427 (Fig 2). Loss of albumin biuret N accompanied loss of hemoglobin, and an increase in hemoglobin occurred with a gain in albumin biuret N. However, only these two dogs had abnormally low hemoglobin levels.

All dogs showed no significant change in whole blood urea N, nonprotein nitrogen, uric acid, glucose, and serum cholesterol and ester. Only a few dogs showed slightly lowered hemoglobin levels.

All dogs were examined at autopsy, and sections of the liver, spleen, and arteries were taken. Histologic findings are to be reported elsewhere. The hepatic artery was completely occluded except in three dogs in which occlusion was almost complete.

#### DISCUSSION

The most persistent change in the serum proteins of dogs following occlusion of the hepatic artery and ligation of the gastroduodenal artery is the loss of globulin biuret N. This is also the most typical change in the serum proteins of patients with liver disease.<sup>1</sup> This similarity would indicate that impairment in arterial circulation and nutrition of the liver produces structural changes within a relatively short time in the serum proteins which are observed in cirrhosis after much more time has elapsed. The large loss of globulin biuret

N immediately after the operation in the dogs (Fig 1) probably results from the ligation of the gastroduodenal artery. Apparently collateral circulation to replace that of the gastroduodenal artery is established in the first thirty five days following the operation since the globulin biuret N returned to almost normal. However, there is a gradual loss of albumin biuret N during this time. This inverse relationship of the biuret N of albumin and globulin is

Fig 3—Diagrammatic representation of gain and loss of biuret linkages (Gm % N) of serum proteins and changes of hemoglobin in dogs after occlusion of the hepatic artery and ligation of the gastroduodenal artery (data from Table I)

very clearly shown in individual Dogs 405 and 427 (Fig 2) and 479 and 723 (Fig 3). These changes observed in the thirty five days following the operation would primarily result from the malnutrition produced by the loss of gastroduodenal arterial circulation. The increasing loss of globulin biuret N accompanied by increase of albumin biuret N after the thirty eighth day following the operation (Fig 1) may have resulted from the gradual occlusion of the hepatic artery. This change increased until about the sixty fifth day when greater loss of globulin biuret N and gain of albumin biuret N were reached. The rate of occlusion of the hepatic artery was variable in the dogs. Some dogs examined showed complete occlusion of the hepatic artery after thirty five days. After the sixty fifth day the albumin and globulin biuret N again started to return to normal, probably as a result of establishment of collateral hepatic arterial circulation. Nearly every period studied in each dog showed a total net loss of biuret N. This is also true in induced peritonitis in dogs<sup>2</sup> in which the principle loss of biuret N occurs in the globulin. The tendency for the globulin fraction to be more labile to greater biuret N changes than albumin may be due to its larger molecular size which requires a more highly developed complex biologic process for its formation and maintenance. The biuret linkages in globulin may be less stable. The formation of globulin also may be secondary to that of albumin. However it is interesting that the approach to normal biuret N in albumin and globulin occurs at the same time (Figs 1, 2 and 3) and that their graph lines of a gain or loss of biuret N nearly always cross at 0.1 per cent biuret N. This would indicate that there is some definite relationship between

albumin and globulin in the mode of formation, origin, or exchange of their biuret N. There is also some indication that hemoglobin concentration has some relationship to gain and loss of biuret N in albumin and globulin (Dogs 405 and 427, Fig. 2). The greatest loss of albumin biuret N and the greatest gain of globulin biuret N is accompanied by the lowest hemoglobin levels. Since loss of albumin biuret N usually occurred only when the A/G ratio was 1 or less, it would appear that quantitatively albumin and globulin levels have some relationship to the maintenance of normal biuret N/Kjeldahl N ratio of serum proteins.

#### SUMMARY

1. Disturbance of the metabolism of the liver either by occlusion of the hepatic artery or ligation of the gastroduodenal artery in dogs is followed by a large loss of serum globulin biuret N and a smaller gain of serum albumin biuret N, resulting in a net loss of biuret N in the serum proteins.

2. No significant change in whole blood urea N, nonprotein nitrogen, ureic acid, glucose, and serum cholesterol and ester was observed in dogs following occlusion of the hepatic artery and ligation of the gastroduodenal artery. Low hemoglobins were observed in a few dogs.

# STUDIES OF THE DIFFERENCES BETWEEN BIURET AND KJELDAHL DETERMINATIONS OF SERUM PROTEINS

## III LIVER AND OTHER DISEASES

GEORGE R. KINGSLEY, M.S.,\* AND THOMAS E. MACHELLA, M.D.  
PHILADELPHIA, Pa.

**P**RELIMINARY reports on patients with chronic liver disease,<sup>1</sup> peritonitis in dogs,<sup>2</sup> and occlusion of the hepatic artery and ligation of the gastroduodenal artery in dogs<sup>3</sup> established definite differences in the results of determinations of serum proteins by biuret and total nitrogen (Kjeldahl) methods. Since good agreement between these methods exists in normal individuals,<sup>4</sup> further comparison was made in order to ascertain the significance and possible diagnostic value of such differences in various diseases. The changes observed indicate that either gains or losses of nitrogen or of biuret linkages have occurred. The data at present do not permit a distinction to be made.

### METHODS

All protein determinations in this investigation were made simultaneously by the macro Kjeldahl (using factor 6.25 to convert N to protein) and biuret methods.<sup>4, 5</sup> The ether sodium sulfate method<sup>6</sup> was used for the separation of albumin and globulin. Only fresh and unhemolyzed serum was employed. Urea and nonprotein nitrogen determinations were made to correct the Kjeldahl protein determinations for nonprotein nitrogen. The Kjeldahl digestion for total protein determination was carried out by gently boiling in a 300 ml. Kjeldahl flask 10 ml. of concentrated sulfuric acid, 4 Gm. of sodium sulfate and 0.5 Gm. of copper sulfate with 1 ml. of serum for one hour. Twelve milliliters of albumin sodium sulfate solution from the globulin precipitation equivalent to 0.8 ml. of serum were used for the albumin determination. The same amounts of reagents were used as in the total protein determination with the exception of the addition of only 1.5 Gm. of sodium sulfate. No increase in total nitrogen was observed when digestion was continued for two, four and six hours.

### RESULTS

The data obtained from the study of various types of liver disease have been classified (Table I) as Laennec's cirrhosis, Banti's syndrome, biliary or obstructive, and miscellaneous hepatomegalies. The data of this table confirmed previous observations<sup>7, 11</sup> with regard to decreased albumin and correspondingly decreased A/G ratio. Differences between the results of biuret and Kjeldahl determinations in the various types of liver disease were very similar. There was a consistent decrease of peptide linkages as measured by the biuret reaction (or increase in total nitrogen) of the globulin fraction in all types of liver diseases studied. The average loss of normal biuret reactivity of the globulin fractions of the eighty-four patients with liver disease studied was 16 per cent. The

\*T =  $\frac{\text{Average difference}}{\text{Standard error}}$  where P = 0.01

average difference of 0.47 grams per cent between protein determined by Kjeldahl and biuret methods in the globulin fraction was highly significant as the standard error of this difference was only  $\pm 0.10$

This difference between Kjeldahl and biuret determinations of the globulin fraction was reflected in a corresponding difference of Kjeldahl and biuret N in the total protein determinations which resulted in a significantly higher A/G ratio as determined by the biuret method. On the average, there was no significant increase in the biuret reactivity of the albumin, although there appeared to be a tendency for an increase in twenty four cases. In the group of eighty four cases of hepatic disease only three one of chronic cholangitis one of scurvy with hepatomegaly, and one of metastatic neoplasm, exhibited a significant increase in biuret linkages of the globulin fraction.

Toxic thyroid disease (Table I) was very similar to portal cirrhosis in the abnormal biuret reactivity/Kjeldahl N ratio of the globulin fraction. A decrease of 17 per cent in the biuret linkages of the globulin fraction occurred. However, as the number of cases in this group was small, the standard error of the differences of the Kjeldahl and biuret determinations of globulin and A/G ratio was not as highly significant as in the much larger group of liver diseases. The increase of biuret linkages of the albumin fraction even though small was much more significant than that found in portal cirrhosis. The total protein and A/G ratio as determined by the Kjeldahl method were fairly normal, the A/G ratio being the highest of any group studied. This demonstrates that in disease, serum proteins may be normal quantitatively by Kjeldahl determinations when they are actually abnormal in their biuret linkages. The finding of a small significant change in the albumin fraction in thyrotoxicosis together with a large loss of biuret linkages in the globulin fraction substantiates the evidence<sup>12, 13</sup> presented for the activity of the thyroid in the formation of serum globulin. However, secondary liver damage may follow thyroid hyperactivity.

A majority of the various types of anemias diseases of the blood (Table I) as individual cases showed an increase in biuret linkages in both protein fractions. This group on the average showed no significant increase in biuret linkages, probably because of the great range of individual values (globulin 1.4 to 5.4) and because of the different types of anemias in the small group. However, if the gain and loss of biuret linkages in serum albumin and globulin are added, a significant net gain in biuret linkages is observed, the average gain being 0.3 Gm per cent with a standard error of  $\pm 0.12$  per cent. This is the only group studied which showed an overall gain in biuret linkages. These data indicate that a disturbance of the blood cells may act as a stimulus for the temporary overproduction of biuret linkages in serum albumin and globulin.

Serial determinations of biuret linkages (Table I) were made in four cases of typhoid fever from the second and fourth to the eighth and twelfth week of the disease. Little change occurred in the albumin fractions except in one case complicated by hypertension. In all, the globulin fraction showed a loss of biuret linkages starting with the fourth week and returned to normal with clinical recovery. The loss of biuret linkages in globulin resembled that in

portal cirrhosis and may indicate at least temporary liver damage in typhoid. An indication also was given that the liver's ability to form normal proteins was noticeably impaired until after the third week of illness.

A large number of miscellaneous diseases, some of which showed significant changes in the distribution of biuret linkages in the protein fractions, are summarized in Table I. A case of malnutrition with transfusion reaction and another transfusion reaction showed a marked loss of biuret linkages in the albumin fraction. Diabetes, diabetic coma, and complicated diabetes showed wide variations in distribution of biuret N. Two cases of cystinuria showed a simultaneous loss of biuret N in the globulin and gain in the albumin fractions. A case of chronic ulcerative colitis resembled malnutrition in biuret N changes as did nutritional edema. A patient with myxedema showed a marked increase in biuret N in the globulin with no change in the albumin. This is in contrast to the decrease in biuret N in the serum globulin of thyrotoxicosis. A patient with dystonia quadriplegia showed an almost equal exchange of biuret N from globulin to albumin, a loss and gain of about 20 per cent. A case of schizophrenia showed an opposite transfer. However, this patient was suspected of having hepatic disease, although no definite diagnosis could be made. One patient with lymphogranuloma inguinale, who showed marked inversion of A/G ratio, exhibited changes in biuret N similar to those in portal cirrhosis. In one patient with lymphopathia venereum there was an increase in biuret linkages of the globulin fraction, while two others showed a decrease, all three of these patients had definite hyperglobulinemia. Patients suffering from cardiac decompensation, acute nephritis, myoma uteri, and bronchopneumonia showed no changes in the normal distribution of biuret N.

#### CASE REPORTS

A few interesting cases exhibiting reversal of biuret and Kjeldahl N differences coinciding with marked clinical changes were studied over a period of several weeks. A colored man, 30 years old (No. 1, Table II), with an apparently quiescent sickle cell anemia showed about 20 per cent gain in biuret linkages of the globulin fraction. There was also a 16 per cent loss of biuret linkages in the albumin fraction. About two weeks later, the distribution of biuret reactivity in the protein fractions had returned to normal. However, this condition was not stabilized. A marked reversal of biuret distribution occurred four weeks later resulting in a 26 per cent loss of biuret reactivity in the globulin fraction and a small increase of biuret N in the albumin fraction. During these six weeks the icterus index had increased from 7 to 450, urea N from 14 to 23 mg per 100 cc, while cholesterol ester decreased to 1 per cent of the total cholesterol. Although the total protein was elevated with a low A/G ratio, of 0.7 to 0.8, there was little significant quantitative change in the protein fractions throughout the six week period. This again shows that marked qualitative changes in the proteins may take place while no quantitative changes occur.

A 6 year old girl, five months after second degree burns (No. 2, Table II) exhibited changes in biuret reactivity of serum proteins similar to those observed in portal cirrhosis. Six to eight weeks later, coincident with malnutrition, fever, anemia, and urinary tract infection, a reversal of biuret nitrogen distribution had occurred with a loss in albumin and a gain in globulin biuret linkages. Eleven weeks later after a diet rich in amino acids, proteins and vitamins, the patient showed marked clinical improvement and the biuret distribution had returned to normal. However, seven weeks later the patient returned to the hospital with malnutrition, fever, and anemia and again exhibited abnormal biuret distribution typical of this clinical change.

A patient with multiple myeloma with pathologic fracture of the femur (No 3 Table II) and a large increase in globulin showed an increase in biuret linkages in the globulin fraction following the fracture. Three months later, a large decrease in biuret reactivity in the globulin occurred. Qualitatively and quantitatively the albumin remained fairly constant throughout the period of investigation. It is interesting to note that a quantitative globulin increase was accompanied by an increase in biuret reactivity in this case and a fall of total globulin to normal level was accompanied by a decrease in biuret reactivity.

No 4 (Table II) illustrates in biliary cirrhosis the constancy with which a large loss of biuret reactivity occurred in the globulin fraction over a period of several weeks with little change in albumin. Administration of bile salts for twenty days had no apparent effect on the proteins.

Simultaneous biuret and Kjeldahl determinations were carried out before several plasma transfusions in a patient presenting the symptoms of a nephrotic syndrome (No 5, Table II). Although the control for biuret linkages of albumin and globulin serum fractions before the first transfusion was within normal limits the biuret linkages of the albumin decreased and those of the globulin increased twenty three to thirty hours following transfusion. The net change as shown in total protein biuret reactivity was within normal limits in nearly every series of analysis. Two weeks following the last transfusion the biuret linkages of both serum albumin and globulin fractions had returned to normal.

#### DISCUSSION

Considerable evidence has been presented in the literature to show that qualitative as well as quantitative changes occur in serum proteins in various diseases. Analysis of the data presented in Table I has shown that very significant changes occur in the relationship between biuret linkages and total nitrogen of serum globulin during liver disease. A difference in the distribution of serum globulin fractions in normal and cirrhotic individuals has been shown by electrophoretic and immunologic means.<sup>14</sup> There is much evidence that fibrinogen production is wholly dependent upon liver function. The role of the liver in the production of albumin and globulin is not as well established. There is however clinical and experimental evidence that the organ is involved in the processes of albumin and globulin formation especially the former. Whipple and co-workers<sup>15, 16</sup> noted a lag in the regeneration of serum proteins of Eck fistula dogs following acute plasma depletion. Hepatectomy experiments in various animals have added little significant evidence relating to the origin and

mode of formation of plasma albumin and globulin since such a diastic procedure gives rise to profound systemic and circulatory disturbances. Hypoproteinemic dogs<sup>17</sup> exhibited a decreased deamination in impaired livers.

A relative loss of biuret linkages of serum globulin together with a concurrent gain of biuret linkages of albumin in toxic thyroid disease may indicate that the thyroid has some influence on formation, loss, or exchange of biuret linkages in serum proteins. Since no significant increase in biuret linkages of serum albumin occurred in liver disease, these alterations of serum albumin in thyroid disease cannot be explained as a result of secondary liver disease.

The tendency for overproduction of biuret linkages of both albumin and globulin in some anemias studied (Table I) may indicate a disturbance of a part of the normal function of blood cells in the formation of serum proteins. Hyperproteinemia observed in myeloid leucemia may indicate that serum globulin has its origin in bone marrow<sup>18</sup>. Since plasma proteins are within normal limits in aplastic anemia, more evidence is necessary to establish the proper function of marrow cells in protein formation<sup>19</sup>. However, the globulin albumin ratios for aplastic anemia are above normal<sup>20</sup>. In No. 1 (Table II), during sickle cell anemia, an enormous overproduction of biuret linkages equal to 1 gram per cent protein N in the globulin fraction occurred. In multiple myeloma, No. 3 (Table II), a large increase in biuret linkages in the serum globulin occurred in the early acute stage of the disease when there was probably an overstimulation of the red marrow. Two to three months later, a decrease of biuret linkages in serum globulin was observed. This probably was caused by the impaired activity of either the red marrow or liver. The production of a serum protein greatly altered in normal structure may be an important factor in the origin of the abnormal Bence Jones protein of multiple myeloma. Loss of biuret linkages of the globulin fraction in blood serum during chronic febrile disease similar to that observed in liver disease probably results from secondary liver damage caused by a fever of long duration. From a study<sup>20</sup> of the electrophoretic patterns of a series of normal and pathologic human sera, it was found that the serum  $\alpha$ -globulin albumin ratios were high in febrile patients, the average value being over twice the normal. This was particularly marked in pneumonia<sup>21, 22</sup>. Polarographic study<sup>23, 24</sup> of blood sera in experimental pneumonia (Type 1) in dogs has shown a decrease in wave heights in the denaturation curves which represented some change in serum (peptone fraction), probably a decrease in protein sulphydryl and disulfide groups, i.e. a decrease in cystine in peptide linkage. In acute infections, a protein has been found in the albumin fraction which gave a flocculation reaction with C polysaccharide of pneumococcus<sup>25</sup>. Electrophoresis has shown a decreasing albumin and increasing globulin in tuberculosis with the appearance of a new X component<sup>26</sup>.

The reversal of biuret and total nitrogen ratio in serum protein (Table II) over a comparatively short period of time in some diseases may indicate some relationship between albumin and globulin as to their interdependence, common origin, and mode of formation. It will be noted from the diagrammatic representation (Fig. 1) of the simultaneous gain and loss of biuret linkages in serum

albumin and globulin of Nos 1 2 and 3 presented in Table II that there is a definite relationship between albumin and globulin as to their relative gain or loss of biuret linkages. In No 2, especially, it is apparent that a gain or loss of biuret linkages in albumin is matched by an equal change in the opposite direction in the globulin. In all three cases an approach to normal in biuret

Fig 1—Diagrammatic representation of simultaneous gain and loss (grams per cent N) of biuret linkages in serum albumin and globulin (data from Table II)

linkages in both albumin and globulin occurs at the same time. In studies of protein metabolism by the isotope method<sup>27</sup> synthesis and degradation were found to be a balanced biochemical process which requires no distinction between exogenous and endogenous cellular metabolism. Labile protein reserves have been demonstrated<sup>28</sup> and may pass readily from cell to plasma and plasma to cell<sup>29</sup>. A depletion of these reserves lowered resistance to infection<sup>30</sup> and increased susceptibility to liver injury<sup>31, 32</sup>. These reserve protein stores have not been identified chemically<sup>33</sup>. The interchange of biuret linkages between albumin and globulin indicates the possibility of a normal exchange of biuret N between albumin and globulin, and/or they have a common origin in a labile protein reserve.

In most of the diseases studied it appears that the biuret linkages of the globulin are more labile and undergo wider variations than those of albumin. Liver typhoid, and thyroid diseases show a significant loss of biuret linkages in serum globulin. In these diseases the biuret exchange of a precursor type of albumin with globulin may be arrested. This also may be related to the greater molecular size of the globulin molecule.

It is interesting to note the changes in biuret linkages of serum proteins in a case of nephrotic syndrome (23 to 32 Gm protein loss per twenty four hours) (Table II) twenty three to thirty hours after a transfusion of 300 to

450 ml of plasma. Total biuret linkages remain little changed while equally large losses in the albumin and gain in the globulin biuret linkages occur over a period of about four weeks. A response of this kind would certainly indicate a lack of normal utilization of the transfused proteins. This patient exhibited biuret linkages within normal limits in both albumin and globulin before and several days after the last transfusion. The gaining of biuret linkages in globulin at the expense of albumin may be an indication that albumin acts as an intermediary labile protein or that the mechanism for the formation of albumin is repressed as might be expected where the A/G ratio is extremely low. It is also interesting to note that the A/G ratios by biuret determination remained abnormally low and unchanged after transfusion, while by Kjeldahl determination the A/G ratios were normal in four instances.

The possible diagnostic value of the determination of the ratio of biuret N to Kjeldahl N in serum proteins is obvious, since changes in ratio of biuret N to total N of serum proteins in various diseases show definite patterns and in some diseases Kjeldahl determinations indicate normal serum proteins when their biuret linkages are abnormal.

Lack of agreement between determinations by the Kjeldahl and biuret methods may result from (1) a change in nitrogen concentration, (2) a change in number or reactivity of biuret linkages, (3) a change in response to salting out with sodium sulfate, or (4) a combination of (1), (2), and (3). These changes may be related to alterations in number, kind, or structural arrangement of amino acids in the protein molecule, or altered content of sugars, lipids, etc., forming part of the protein molecule. Of the three possibilities, (1) seems more likely to be the cause of the lack of agreement of the two analytic methods since the biuret linkages are so numerous and fundamental in protein structure that rupture or replacement of these bonds by other types would probably result in greater physical changes in plasma or serum proteins than those observed in the conditions studied. However, both (1) and (2) may be simultaneously operative or each may predominate under certain conditions. Peters and Van Slyke<sup>34</sup> mention the altered chromogenic power of serum proteins in disease, in reference to the use of tyrosine as a standard in the Greenberg<sup>35</sup> serum protein method. The possibility that polypeptides, amino acids, or other biuret reacting compounds were causing the differences observed was investigated in several cases where unusual differences between the biuret and Kjeldahl methods were noted. The concentration of these compounds was never high enough in the plasma or serum to have any appreciable effect on the biuret reaction.

Incomplete digestion of some amino acids of proteins have been reported,<sup>36</sup> but errors of this kind could not have occurred, since great care was exercised in all of our Kjeldahl determinations. The Kjeldahl digestion technique used in this investigation agreed well with the method recommended in an exhaustive experimental survey of Kjeldahl methods.<sup>37</sup> Our Kjeldahl-biuret analyses are not in agreement with a report<sup>38</sup> of significant differences of protein determinations on normal human serum made by the Kjeldahl and Kingsley biuret methods. However, analyses for only four normal serums and one cirrhotic serum were reported.

## SUMMARY

1 In various diseases, differences were observed in serum albumin and globulin determinations by the biuret and total N methods. In Laennec's cirrhosis, Banti's syndrome biliary cirrhosis, hepatomegaly due to other causes, thyrotoxicosis, and typhoid fever, the principal change is loss of biuret linkages by the globulin.

2 In certain anemias an increase of biuret linkages in both albumin and globulin is the rule, although a rapid reciprocal change of biuret reactivity can take place in the protein fractions in some instances.

3 In general it may be said that primary hepatic disease or secondary liver damage resulting from impairment in circulation, malnutrition, fevers of long duration, severe infections, or tissue damage will cause changes in the normal relationship between total N and biuret reactivity of the serum proteins.

4 Theoretical implications derived from experimental clinical data as to the chemistry of certain phases of serum protein formation or degeneration as well as the actual chemical change responsible for abnormal biuret N and total N ratios have been presented.

# HEBERDEN'S NODES THE RELATIONSHIP OF THE MENOPAUSE TO DEGENERATIVE JOINT DISEASE OF THE FINGERS

ROBERT M. STECHER, M.D., EDMUND E. BEARD, M.D., AND A. H. HERSH, PH.D.  
CLEVELAND, OHIO

**H**EBERDEN'S nodes are enlargements of the terminal interphalangeal joints of the fingers due to degenerative joint disease. Individual fingers are at times affected, especially in men, as a result of direct injury which produces a true traumatic arthritis. The deformities affecting multiple fingers on both hands, however, arise spontaneously without history of injury. The present study is confined to the latter type which is called idiopathic Heberden's nodes. Age is perhaps the most important single factor determining the appearance of this condition<sup>1</sup>. Heredity is also important, as is shown by vertical involvement in families in succeeding generations and horizontal involvement in siblings<sup>2</sup>. Women are affected much more commonly than men and, since Heberden's nodes are rare before the age of 50, their occurrence is thought to be related to the climacteric. The present study was made to test this supposition and to consider the mechanism by which the change of life influences the development of this deformity.

## CLINICAL OBSERVATIONS

Observations were made on ninety-nine women with idiopathic Heberden's nodes who had passed the menopause and who gave a reliable history of the time of occurrence of the menopause and appearance of the nodes (Table I). The age of these women at the time of the onset of Heberden's nodes ranged from 33 to 65 years. The median age was 49.8 years, the average age was  $48.8 \pm 6.80$  years. The age distribution at the time of onset of Heberden's nodes is shown in Fig. 1.

The age at the time of the menopause in this series of ninety-nine women ranged between 28 years as the result of a pelvic operation and 56 years. The median age was 49.7 years, the average age was  $48.6 \pm 5.25$  years. The age distribution is shown in Fig. 2.

The history of the menopause in these ninety-nine women with Heberden's nodes was compared with that of a control series of ninety-six women (Fig. 3). The control series had been assembled and observed in a previous study under the same conditions and at the same time as the Heberden's nodes series. The control series included the sisters of forty-three women chosen from the wards of City Hospital simply because they did not have Heberden's nodes, a collection of families observed in connection with the studies on heredity of Heberden's nodes. In the control series the age at which the menopause occurred

The interval is given a plus sign (+) when the age at time of onset of the menopause was greater than the age at the onset of Heberden's nodes and a minus sign (-) when the reverse was the case

ranged from 35 to 59 years. The median age was 49.1 years, the average age was  $48.9 \pm 4.90$  years. The age distribution in the control series of women is shown in Fig. 3. Thus it is seen that the history of the menopause in ninety-nine women with Heberden's nodes paralleled closely that of ninety-six women who were used as controls. The history of the menopause in this group of ninety-nine women with Heberden's nodes was not considered to be remarkable.

The time relationship between the menopause and the onset of Heberden's nodes in each individual woman is shown in Fig. 4. The menopause preceded the onset of Heberden's nodes in forty-four instances and followed it in forty-five. Both events occurred in the same year in ten instances. The average difference in time between these two events regardless of which event occurred first was  $4.9 \pm 4.04$  years. If the time interval between these events

Fig 1—Age at the onset of Heberden's nodes in the ninety-nine women studied  
Fig 2—Age at the onset of the menopause in the ninety-nine women with Heberden's nodes  
Fig 3—Age at onset of the menopause in ninety-six women of the control series

Fig 4—Time relationship between the age at onset of Heberden's nodes and the onset of the menopause in individual cases. Zero represents the age at onset of Heberden's nodes. Figures to the left of zero indicate the years before onset of Heberden's nodes at which the menopause occurred. Figures to the right of zero indicate the years after onset of Heberden's nodes at which the menopause occurred.

was computed always in the same direction, applying a positive sign to the number of years difference when the menopause followed the onset of Heberden's nodes and a negative sign when the menopause preceded the onset of Heberden's nodes the average difference was  $-0.72 \pm 6.33$  years. The average difference practically disappeared and the two events seemed to be closely correlated in point of time. There was, however, a long time interval between these events in individual cases the menopause occurring from twenty years after the onset of Heberden's nodes to fifteen years before. This is indicated by the large value for the standard deviation.

Despite the wide dispersion, close association of the menopause with the onset of Heberden's nodes was observed in many cases. In ten instances both events occurred in the same year. In forty four instances, or nearly half of the series, they occurred within three years of each other. The time relationship of these two events, independent of the age at which they occurred, was then studied. As has been shown already the average age of onset of Heberden's nodes in these ninety nine women was  $48.8 \pm 6.8$  and the average age for the menopause was  $48.6 \pm 5.2$ . When the group was divided into two equal parts on the basis of age it was found that those women whose Heberden's nodes occurred early had an earlier onset of the menopause than those in whom the onset of the nodes was late. The average age of the menopause was 46.2 years in the fifty women having the earliest onset of Heberden's nodes at 33 to 49 years. The average age of the menopause was 50.5 years in the forty nine women having later onset of Heberden's nodes at 50 to 65 years.

The degree of correlation between ages of onset and the menopause was calculated from grouped data by the usual product moment method for the determination of the coefficient of correlation ( $r$ ). The value of  $r$  with its standard error is  $+0.46 \pm 0.08$ . By using the test recommended by Pearl<sup>3</sup> this coefficient of correlation can be regarded as arising by chance from an uncorrelated population about once in a million times. The result leaves no doubt that the data show a highly significant statistical association between the ages of onset of Heberden's nodes and the menopause.

While a correlation coefficient of  $+0.46$  is descriptive of the statistical association between the ages of onset of Heberden's nodes and the menopause it gives no reliable indication of the causal factors involved. On the basis of certain assumptions, it is possible speculatively to draw a further conclusion by analogy with the interpretation of better known cases. It happens that the coefficient of correlation between stature of father and son is  $+0.46$ . Assuming that the number of elements causing the variability is the same in both instances and that they are normally distributed the conclusion is drawn that about 46 per cent of the genes determining stature are common to parent and offspring of the same sex. It seems fair to make similar assumptions in the present instance. The data are consistent with this assumption although they do not prove it. A number of factors obviously are involved in causing the variability in ages of onset of Heberden's nodes and of the menopause. The average age and the median age are about the same for both variables, indicating an approximately normal distribution for the causal factors involved.

Consequently, if the assumptions are justifiable, the conclusion is drawn that, on the average, 46 per cent of the total set of factors determining age of onset are common to Heberden's nodes and the menopause

#### LITERATURE

Many observers have noted a close relationship between the menopause and Heberden's nodes. Heberden<sup>4</sup> himself made no mention of the menopause in his very short description of "digitorum nodi" and neither did Chareot<sup>5</sup>. Haygarth,<sup>6</sup> about the beginning of the nineteenth century, stated that nodosities of the joints are almost peculiar to women and generally begin about the period when the menses naturally cease. Duckworth,<sup>7</sup> who thought Heberden's nodes were related to gout, said, "these may arise from the second to the fifth decade, are almost common perhaps as a gouty manifestation in women about or after the menopause". Monroe<sup>8</sup> stated that women display Heberden's nodes first about the menopausal period. Aschner<sup>9</sup> said he had seen Heberden's nodes often combined with the usual form of polyarthritis of the menopause. Cecil and Archer<sup>10</sup> noted Heberden's nodes in 74 per cent of the women in their series with menopausal arthritis. The *Primer on Rheumatism*<sup>11</sup> stated that Heberden's nodes often develop at the time of the menopause.

Besides the foregoing casual comments concerning the association of Heberden's nodes with the menopause, several students have presented statistical data to support the idea that the development of Heberden's nodes is related to ovarian dysfunction. Of forty seven women studied by Pineles,<sup>12</sup> thirty one noted the appearance of Heberden's nodes within a year of the last menstrual period. Four other women observed that their nodes occurred after the last menstrual period but while they were still having climacteric symptoms such as dizziness, nervousness, palpitation, hot flushes, and fleeting pains in various parts of the body. Four women under 45, though still menstruating regularly were having typical symptoms of the climacteric when their nodes began. Five women under the age of 40 stated that their nodes began shortly after pelvic operations which had resulted in cessation of the menses and menopausal symptoms. Only three of the forty seven women developed Heberden's nodes independent of the menopause or menstrual dysfunction. Von Noorden<sup>13</sup> described Heberden's nodes and other manifestations of degenerative joint disease in women under 30. In all such instances he had noted abnormalities of the sexual phenomena such as amenorrhea, sterility, or atrophic genitalia. Albright and co workers<sup>14</sup> described a 37 year old woman with ovarian agenesis who had well developed Heberden's nodes.

The clinical data seem to indicate a strong correlation between the climacteric and the development of Heberden's nodes. Since these deformities represent a particular manifestation of degenerative joint disease, it seemed pertinent to search the literature for evidence of correlation between the climacteric and this much broader and more general disease entity. The menopause is thought by some authors to cause or influence the onset of rheumatoid arthritis, by others to favor the development of osteoarthritis, while a third group believe its influence is limited to the production of arthralgia.<sup>15</sup> Hall,<sup>16</sup> studying seventy one women who had been ovariectomized, found most of them suffering from symptoms of arthritis beginning a few weeks after operation and often suggesting true rheumatoid arthritis. Eighteen of his patients had symptoms of either true rheumatoid arthritis or osteoarthritis. He thought fifty three of his patients had only arthralgia because no true joint disease developed.

The concept of arthropathia ovaripriva was discussed by Menge.<sup>17</sup> He observed a series of women having joint disturbances arising soon after inactivation of the ovaries by radiation. Complaints most often concerned the knees but frequently included the shoulder and occasionally the fingers. Involvement was most often bilateral. Crepitus on joint motion was frequently noted. Pain in some patients was slight but occasionally was severe enough to interfere with function. Menge was definitely of the opinion that the syndrome was due to ovarian failure, the same as occurred in spontaneous menopause.

Arthritis of the menopause was described by Cecil and Archer<sup>10</sup> as "a chronic polyarthritis of obese middle aged women occurring at or just after the menopause and characterized by persistent stiffness and pain in the joints affected". Slight crepitation of the

knees was noted but limitation of motion or objective signs of joint disease were rare. Fisher<sup>18</sup> stated, "Disordered endocrine function plays an important part in many of the more chronic forms of arthritis occurring after the meridian of life. The type of arthritis that immediately springs to mind is the chronic osteoarthritis often seen in the knees of women, the onset of which corresponds with the menopause." The *Primer on Rheumatism*<sup>11</sup> stated that the menopause seems to be an exciting cause of hypertrophic arthritis. Jones<sup>19</sup> thought that osteoarthritis of the knees was most commonly met with in women at the menopause. Thomson and Gordon<sup>20</sup> thought climacteric arthritis was essentially the same as chronic synovitis which may eventually develop into typical osteoarthritis. Fox and Van Breemen<sup>1</sup> recognized menopausal arthritis as a generally accepted clinical entity. Radiographs show no change in bone and cartilage during the incipient stage which may be very long. Later the appearance resembles that of osteoarthritis. Steinbrocker<sup>2</sup> states that so called menopausal arthritis consists merely of arthralgia associated with vasospastic symptoms of ovarian hormonal deficiency and that the symptoms are not of articular origin. Rheumatic pain was found to occur as a symptom of the climacteric in 24 per cent of 1,197 women by the British Sub-committee of the Council of the Medical Women's Federation.<sup>23</sup>

#### DISCUSSION

The nature of the phenomena considered in this study is such that exact data are not always obtainable. The development of Heberden's nodes is a slow process and its beginning cannot be identified with certainty. The degree of development necessary for recognition depends upon the discernment of the patient as influenced by her temperament, her degree of introspection and her experience in having seen the deformity in her mother, sister, or intimate friends. Identification of the date of onset always seems more definite and apparently more exact the more recent it has been. It is almost equally convincing to hear that in one instance both events occurred about twenty years previously the fingers not enlarging until one year after the last menstrual period. An uncertainty is suggested by a statement that the last menstrual period was six years previously and that the fingers began to enlarge about twenty years ago. To discard such data because they seem to introduce a different and more significant error in the study by eliminating those cases in which onset and menopause were not closely associated in point of time. The mere fact that onset and menopause were separated by many years and that both events were remote casts doubt only upon the exact time relationship of the two events and not on the fundamental fact that their occurrence was separated by a wide lapse of time. In several instances patients were observed personally for years while these events were occurring. In Case 7 the patient continued to menstruate for six years after finger enlargement had first been noted. Her mother, Case 96, was seen before her fingers enlarged. A series of photographs of her hand made for another purpose showed the onset of nodes at about 62 years of age although her menopause occurred at 48 years. Cases were excluded only when the patients were definitely uncertain of the dates of the events under discussion.

Although the date of the last menstrual period was ascertained with reasonable certainty, the date of the onset or the duration of the climacteric was not easily identified. Removal of the uterus may stop menses without interfering with ovarian function. In Case 5 the uterus was removed when the

# THE STATE OF COMPONENT A (PROTHROMBIN) IN HUMAN BLOOD, EVIDENCE THAT IT IS PARTLY FREE AND PARTLY IN AN INACTIVE OR PRECURSOR FORM

ARMAND J. QUICK, M.D., PH.D., AND MARIO STEFANINI,\* M.D.  
MILWAUKEE, WIS.

THE simple concept expressed in the classical theory of Morawitz and of Fuld and Spiro that prothrombin is converted by thromboplastin (thrombokinase) and ionized calcium to thrombin has become untenable because of a series of recent findings. In 1943 Quick,<sup>1</sup> and the following year Owien,<sup>2</sup> discovered a new factor which is essential for the formation of thrombin. Recently many other investigators have contributed data to confirm and support these original observations, but as is to be expected in the development of a new subject numerous conflicting interpretations have been offered. No successful attempt has been made to correlate the pertinent contributions, particularly of Munro and Munro,<sup>3, 4, 5</sup> Fantl and Nance,<sup>6, 7, 8, 9</sup> Seegers, Ware and associates,<sup>10, 11</sup> and Alexander and co-workers.<sup>12, 20, 1</sup> Recently we have obtained experimental findings which appear to bridge the conflicting and seemingly hostile views on prothrombin conversion currently expressed.

In the study made in 1943<sup>1</sup> it was observed that when stored oxalated human plasma was mixed with an equal volume of dog plasma in which prothrombin had been reduced by Dicumarol or adsorbed with aluminum hydroxide the resulting mixture had a prothrombin time of 9 to 10 seconds, which was shorter than that of fresh plasma. Three years later,<sup>2</sup> it was found that human citrated plasma (1 vol. of 0.1M sodium citrate to 9 vol. of blood) often showed a reduction of the normal prothrombin time of 12 seconds to as low as 9 seconds after twenty-four hours of storage. No explanation for these findings could be offered until 1948<sup>23</sup> when it was recognized that two changes were concurrently taking place in stored plasma: namely a decrease in the labile factor and an increase in some other factor which augmented prothrombin activity. Due particularly to the development of an assay method for component A,<sup>4</sup> and also to the discovery of the effect of silicone-coated containers on prothrombin activity during storage, it has been possible to obtain data which offer not only an explanation for the increased prothrombin activity of aged plasma but also a new concept concerning the state of prothrombin in blood.

Since the terminology of the prothrombin factors has become increasingly more complex, it is essential that the principal terms employed in this study be defined. The labile factor is a constituent of both plasma and serum. It loses its activity when heated to 58° C and is diminished in stored plasma because of oxidation. Removal of ionized calcium increases the speed of inactivation. Little if any of the labile factor is adsorbed by the amount of tricalcium

phosphate which completely removes component A. It is not reduced either in Dicumarol poisoning or in vitamin K deficiency. Rabbit blood contains approximately fifty times as much labile factor as human plasma.<sup>23</sup>

Component A of prothrombin probably corresponds to the classical prothrombin. It is inactivated at 58° C, but does not diminish during storage. It is completely adsorbed by tricalcium phosphate and can be quantitatively recovered by elution with sodium citrate. Component A is diminished in Dicumarol poisoning and in avitaminosis K. Evidence has been presented to show that this component combines with the citrate ion, thereby losing activity and becoming no longer adsorbable by tricalcium phosphate.<sup>25</sup>

#### METHODS AND MATERIAL

The reagents and procedures employed were essentially the same as those described in a recent paper.<sup>24</sup> Silicone coated glassware was prepared by means of Dri Film 9987 (General Electric), using the technique described by Jaques and associates.<sup>26</sup> For high speed centrifugation, an angle centrifuge which had a maximum revolutions per minute of 4,000 was employed. For slow speed the revolutions per minute were 800 to 1,000 in an ordinary centrifuge.

The method of isolating component A by adsorption with tricalcium phosphate and elution with sodium citrate, which we recently described,<sup>24</sup> concentrates the active factor ten times. In its assay, therefore, 1 vol was diluted with 9 vol of calcium phosphate treated plasma. Rabbit plasma was used because it has an exceedingly high concentration of labile factor. The concentrate of component A is called eluate in this paper.

#### RESULTS

*The Effect of Varying the Concentration of the Labile Factor on the Prothrombin Time When Component A is Kept Constant*—In a recent paper<sup>24</sup> it was shown that component A can be completely removed from oxalated plasma by an amount of tricalcium phosphate which takes out no detectable quantity of the labile factor. It was further shown that component A can be almost quantitatively recovered by elution with sodium citrate, and that this eluate when added to calcium phosphate plasma restores prothrombin activity provided sufficient labile factor is present. Since rabbit plasma contains fifty times and dog plasma ten times more labile factor than fresh normal human plasma and stored human plasma contains only a very small amount, treatment of these plasmas with tricalcium phosphate will yield testing media containing a wide range of concentrations of the labile factor. Such a series of deprothrombinized plasmas were employed to test the eluates from dog and human plasma. In the experiment, recorded in Fig 1, 1 vol of eluate was mixed with 9 vol of deprothrombinized plasma. It will be observed that when the labile factor was low the prothrombin time was prolonged, and as the labile factor was increased, the prothrombin time decreased and reached a fixed minimal value. Dog eluate which contains a higher concentration of component A required more labile factor to attain a fixed minimal prothrombin time. If the labile factor were acting catalytically, its activity should continue as its concentration increases.

These results therefore suggest that the reaction of the labile factor and component A is stoichiometric. We have further found (unpublished data) that

when plasma deficient in labile factor clots, very little component A is consumed even when thromboplastin is in excess and the calcium concentration is optimal, but as the labile factor is progressively increased, the utilization of component A rises in proportion. Since these results support the view that the reaction between thromboplastin, component A, and labile factor is stoehio

Fig 1—The influence of the concentration of the labile factor on the prothrombin time. The concentration designated as 50 was obtained by treating fresh oxalated rabbit plasma with tricalcium phosphate. 10 was dog plasma, 5, a mixture of dog and stored human plasma, and 1 fresh human plasma. One volume of eluate was mixed with 5 volumes of the plasma treated with tricalcium phosphate.

metric, one should question the correctness of calling the latter an accelerator. It is interesting to note that when Ware, Guest, and Seegers<sup>11</sup> corrected the two stage method by adding an optimum amount of labile factor, they increased their yield of thrombin over 50 per cent. It can be postulated that at least three agents interact to form thrombin and that this reaction follows the law of mass action. The equation can be expressed as follows:

At present there is insufficient data to determine whether all three agents interact simultaneously or whether two react to form a product which enters into a reaction with the third to form thrombin

*Evidence That Component A in Circulating Blood Exists Partly Free or Active and Partly in an Inactive State*—As already stated, when oxalated human plasma is stored in glass its prothrombin activity is markedly increased. Due to the fact that the labile factor is diminished on storage, this augmentation in prothrombin potency is masked and becomes demonstrable only by the addition of the labile factor. Interestingly, this increase in prothrombin activity does not occur or is greatly delayed if the plasma is stored in a silicone coated container. It should be mentioned that Alexander and associates<sup>21</sup> observed that when blood clotted in silicone apparatus, the prothrombin activity of the serum was abnormally high, and the factor which they call serum prothrombin conversion accelerator was decreased.

The pertinent facts are brought out by the following experiment. Blood was obtained from a normal subject. A silicone-coated syringe chilled in an ice bath was employed. The blood was immediately oxalated, transferred to cold silicone-coated tubes, and centrifuged. Part of the plasma was put in Pyrex test tubes and the remainder in silicone-coated tubes. The amount of plasma in each tube was the same, and all were stored in an ordinary refrigerator. The results are summarized in Table I.

TABLE I THE EFFECT OF TWENTY FOUR HOUR STORAGE OF OXALATED HUMAN PLASMA IN GLASS AND SILICONE COATED CONTAINERS ON COMPONENT A OF PROTHROMBIN

Rabbit $\text{Ca}_3(\text{PO}_4)_2$ plasma (cc)	0 00	0 01	0 02	0 03	0 04	0 05	0 06	0 07	0 08	0 09

Stored plasma eluate in silicone						12 sec				
Stored plasma eluate in glass						7 sec				

\*The eluate transferred to glass and stored for twenty four hours gave a value of 7 seconds

It is clear that the prothrombin time of the fresh plasma (12 seconds) was normal and that it was not increased by the addition of calcium phosphate treated rabbit plasma which is rich in labile factor. An eluate prepared from this plasma when added to rabbit calcium phosphate plasma yielded a prothrombin time of 13 seconds, which approximated the expected result. After twenty-four hours, the plasma in silicone-coated tubes lost labile factor, for the prothrombin time increased to 17 seconds, but component A remained unchanged since on adding rabbit calcium phosphate plasma a normal prothrombin time of

12 seconds was obtained. The eluate of this plasma yielded a prothrombin time of 12 seconds. In marked contrast, the plasma stored in glass, which had a prothrombin time of 13 seconds, showed when mixed with rabbit calcium phosphate plasma, i.e., with excess labile factor a prothrombin time of 8 seconds. The eluate from this plasma yielded a prothrombin time of 7 seconds. Significantly, the eluate stored twenty four hours in glass likewise showed the same increase in prothrombin activity. Usually maximum increase in prothrombin activity of plasma stored in glass is attained in twenty four hours.

These results can best be explained by postulating that component A exists in a free form which is responsible for the prothrombin time of fresh plasma, and in an inactive state which becomes activated by storage. This activation requires a rough surface such as glass but neither calcium nor thrombin are essential. Preliminary studies indicate that this reaction is very likely also independent of platelets. Eventually the activation occurs also in silicone coated containers. No studies so far have been made to determine in what form inactive component A occurs i.e. whether it is combined or merely existing as an inactive precursor. Tricalcium phosphate adsorbs both forms which accounts for the fact that the eluate on storage increases in potency. The nature of the activation remains undetermined.

*The Concentration of Active and Inactive Component A in Hemophilic Blood*—In the development of the prothrombin consumption test,<sup>2</sup> it was frequently observed that the prothrombin time of serum was considerably shorter than the prothrombin time of plasma which in hemophiliacs as in healthy subjects is 12 seconds. The solution to this anomalous finding was obtained by a simple experiment. Blood was collected from a hemophilic subject whose Lee White coagulation time was 60 minutes. The usual silicone technique was employed. Part of the plasma was obtained by high centrifugation the remainder by slow centrifugation. The native plasma in aliquotes of 3 c.c. was transferred to glass and silicone coated test tubes. The prothrombin times were determined at regular intervals.

It will be observed from the results in Table II that the prothrombin time became progressively shorter during the course of an hour in the glass tubes but remained unchanged in the silicone tubes. At the end of forty five minutes, the prothrombin times of both the highly and slowly centrifuged plasmas were  $8\frac{1}{2}$  seconds. The eluate likewise which in the original plasma yielded a prothrombin time of 12 seconds decreased in one hour to 7 seconds for the two plasmas kept in glass test tubes. It is clear that hemophilic plasma contains a normal concentration of both free and inactive component A and that the activation of the latter occurs promptly in glass. The fact that the reaction occurs as fast in platelet poor as in platelet rich plasma makes it appear that the platelets play no direct part.

One of us (A. J. Q.)<sup>2</sup> has presented evidence showing that the hemophilic defect is a lack of thromboplastinogen, as a result of which the utilization of prothrombin is extremely small. Since hemophilic blood contains a normal concentration of both component A and the labile factor but only a trace of throm-

boplastin, nearly all of the prothrombin complex remains unconsumed after coagulation. Therefore almost all of component A remains even though hemophilic blood clots, and in addition the inactive A becomes converted to the free state with the result that total free or active component A greatly exceeds the amount initially present at the time the blood was drawn.

*The Effect of Removing Platelets on the Conversion of Inactive Component A*—It was early observed that the prothrombin consumption time in thrombocytopenia was, as in hemophilia, actually shorter than the prothrombin time of normal plasma.<sup>22</sup> The problem could now be studied more effectively. Blood was drawn in a chilled silicone syringe and transferred to silicone-coated test tubes immersed in ice. The tubes were centrifuged for thirty minutes at 4,000 r.p.m. in an angle centrifuge. Three cubic centimeters of the platelet-poor plasma were put in a silicone-coated test tube and an equal amount in a glass tube.

It will be observed from the results in Table III that the prothrombin time in the silicone tube remained unchanged during one hour, whereas it shortened to 8½ seconds in less than twenty minutes in the glass tube. An eluate prepared immediately from the native plasma gave a prothrombin time of 12 seconds, and a similar value was obtained from the plasma remaining one hour in a silicone-coated tube. The eluate from the plasma in the glass test tube yielded a prothrombin time of 8 seconds.

In seeking the reason for these abnormally short prothrombin times of platelet-poor plasma in a glass container, the most satisfactory explanation is found in Quick's theory that thromboplastinogen is activated by a platelet enzyme. Since the platelets have been removed almost completely, only a trace of the activating enzyme is available and therefore only a minute amount of

TABLE III. THE EFFECT OF GLASS AND SILICONE SURFACES ON THE PROTHROMBIN ACTIVITY (CHANGE IN CONCENTRATION OF FREE COMPONENT A) OF PLATELET POOR NORMAL NATIVE HUMAN PLASMA

thromboplastin is formed. As in hemophilia only a small fraction of the labile factor and component A is consumed in the reaction with thromboplastin, and since additional free component A is derived from inactive component A, the total amount of the latter is more than twice that of the original plasma.

TABLE IV. THE EFFECT OF SURFACE (GLASS AND SILICONE) ON THE PROTHROMBIN CONSUMPTION TIME WHEN THROMBIN\* IS ADDED TO PLATELET POOR NATIVE HUMAN PLASMA

TIME OF INCUBATION (MIN)	PROTHROMBIN CONSUMPTION TIME†	
	IN GLASS (SEC)	IN SILICONE (SEC)

30	8	11
75	8	11

\*To 1 c.c. of native plasma 0.01 c.c. of thrombin (Quick's full strength) was added.

†The prothrombin consumption test time was determined by the procedure previously described.\*

In order to determine whether thrombin is the agent responsible for the conversion of inactive component A to the active form native platelet poor plasma was placed in silicone and in glass test tubes and thrombin added to both. As seen from the results in Table IV there is no indication that thrombin caused any activation of inert component A in silicone. Whether it participated in the reaction occurring in glass is difficult to decide.

*The Effect of Dicumarol on the Concentration of Free and Inactive Component A*—Only preliminary studies have been made. The findings indicate that both free and the inactive component A are reduced. Further studies are in progress.

*The Relative Ratios of Free to Inactive Component A in Congenital Hypoprothrombinemias*—There are three known types of congenital hypoprothrombinemia.<sup>28, 29, 30</sup> In one the labile factor is diminished while in the other two this agent is normal but component A is diminished. In the first type according to Owien<sup>30</sup> who has reported the only case so far known in which the labile factor (Factor V) was apparently diminished from birth the conventional prothrombin is quantitatively normal.

In types II and III of congenital hypoprotrombinemia the labile factor is normal. Both types show a prolonged prothrombin time by the one stage method, but curiously when 1 vol of type II is added to an equal volume of type III, the resulting mixture has a prothrombin time which is nearly that of normal plasma.<sup>29</sup>

To explain these results, Quick<sup>28</sup> postulated that one type (II) lacked component A and that the second type (III) was deficient in a hypothetical component B, and that when the plasmas of the two types were mixed in equal volumes they mutually corrected each other. With the new evidence obtained in this study that only a part of the total component A is present in the active state, a better interpretation of these findings can be offered and means to differentiate types II and III can be formulated.

From the results in Table V, the basic difference between the two types of congenital hypoprotrombinemia becomes clearly evident. In type II there is a definite lack of both free and total component A, whereas in type III, the free is diminished but the total may be practically the same as that of normal plasma. When plasma of type II is mixed with type III, sufficient inactive component A of the latter plasma is converted to the active form to bring the prothrombin time nearly to normal.

TABLE V THE CONCENTRATION OF FREE AND TOTAL COMPONENT A IN THE TWO TYPES OF CONGENITAL HYPOPROTHROMBINEMIA IN WHICH THE LABILE FACTOR IS NORMAL

Apparently there is in plasma a regulating mechanism which determines the ratio of free to total component A. In normal human plasma, the ratio is such that a prothrombin time of 12 seconds is obtained with the one stage method. When all of component A is converted to the free state as occurs in storage, the prothrombin time becomes 7 to 8 seconds. Similar values are obtained when type III plasma is stored in glass even though the prothrombin time of the fresh plasma may be elevated significantly. Clearly, in this form of hypoprotrombinemia, the concentration of free component A is fixed at a level lower than normal. The fixation of the free prothrombin level appears definitely to be established by heredity. The affected members of the family who have

been studied in our laboratory<sup>8 29 31</sup> have a prothrombin time of 16 seconds. A second family has recently been studied in which the prothrombin time of the mother and her two children is 14 seconds. None of these subjects has a bleeding tendency. It is likely however that if the level of the free component A falls below a critical level a hemorrhagic diathesis will develop. The patient studied by Hagen and Watson<sup>32</sup> very probably has a type III hypoprothrombinemia, and she has a severe bleeding condition\*. In rabbits and dogs nearly all of component A is in the free state, according to our preliminary studies.

#### DISCUSSION

The findings reported in this paper promise to offer for the first time means to correlate and harmonize the significant contributions of Bordet,<sup>33 34</sup> Nolf<sup>35</sup> and the more recent investigators. It will be recalled that Bordet concluded that both cytozyme (thromboplastin) and serozyme (prothrombin) were mother substances of thrombin. He believed that the platelets liberated cytozyme when they came in contact with a rough surface. He further postulated that the serozyme in circulating blood was in an inactive state which he named proserozyme. For its activation, calcium and a rough surface were required. He concluded that tricalcium phosphate completely removed serozyme and assumed that the resulting 'phosphate plasma' contained only one remaining clotting factor, namely fibrinogen. Nolf<sup>35</sup> on the contrary, postulated that serozyme contained two factors, thrombozyme adsorbable by tricalcium phosphate and thrombogen which remained in the 'phosphate plasma'. Nolf unfortunately failed to recognize the importance of platelets and in his earlier work looked upon thrombin not as the cause of clotting but as a consequence of the reaction.

In agreement with Bordet, the present findings confirm the existence of a proserozyme but differ in that not all but only a part of the serozyme is in this inactive state. The activation of proserozyme i.e., the conversion of inactive component A, requires a rough surface like glass but apparently is not dependent upon calcium as Bordet assumed since the activation occurs in ovalated plasma. Bordet was not aware that phosphate plasma still contained a clotting factor other than fibrinogen. Undoubtedly the thrombogen of Nolf is identical with the labile factor.

In the development of this subject the establishment of the concept that the interaction of thromboplastin with the prothrombin complex is stoichiometric was of basic importance. Mertz Seegers and Smith<sup>36</sup> showed that the amount of thrombin obtained from a fixed amount of prothrombin increased proportionately to the quantity of thromboplastin added until the optimum was reached. Later Quick<sup>37</sup> showed that calcium likewise acted stoichiometrically in this reaction. With the discovery of the labile factor and the finding that it shortened the prothrombin time a new period of confusion set in. Quick postulated its action was stoichiometric whereas Owien<sup>38</sup> claimed that it functioned in forming a prothrombin converting enzyme. Fantl and Nance<sup>7</sup> who studied this factor concluded that it increased the speed of the conversion of prothrombin and they named it prothrombin accelerator. Munro and Munro

Dr. Paul S. Hagen kindly supplied us with blood from this patient and it was found that she lacked both free and total prothrombin.

believed that prothrombin on storage became partly inactivated by an alteration of a labile group in the molecule and could again be reactivated, but they apparently did not consider that the activating agent was the labile factor. Seegers and associates, who are now inclined to agree<sup>18</sup> that the agent which they named Ac-globulin is the same as the labile factor, assumed that it increased the conversion rate of prothrombin. Murphy and Seegers<sup>17</sup> attempted to explain the discrepancies in prothrombin values of different species obtained by the one- and two-stage methods on the variations of the concentration of Ac-globulin.

As already mentioned, we have presented experimental findings which show that increasing the concentration of labile factor manifold did not decrease the prothrombin time.<sup>24</sup> Assumedly, the prothrombin time should be a sensitive test of the speed of conversion of prothrombin. In our studies, we learned that consistent results were obtainable only if silicone glassware was used. Since Bordet's work had been forgotten, it was generally assumed that a rough surface influenced only platelet disintegration, with the result that conversion of inactive component A to the active state which occurred was not recognized and was misinterpreted as a conversion of prothrombin to thrombin. The serum prothrombin conversion accelerator of Alexander and co-workers<sup>20</sup> is very probably concerned with the activation of component A rather than with the conversion of prothrombin to thrombin.

Many of the findings on Ac-globulin by Seegers and his associates are difficult to interpret because much of their material was collected in slaughter houses and generally in large containers. Under such conditions, considerable changes could occur even before the blood was decalcified, especially since sodium oxalate is relatively slow in its action.<sup>24</sup> Fahey, Ware, and Seegers<sup>18</sup> observed no difference in the influence of silicone and glass surfaces on the stability of Ac-globulin, which agrees with our observations. They failed to note however that a glass surface has a basic influence in converting inactive component A to the active state, because the methods of study which they employed did not distinguish between free and total prothrombin (component A).

A rational explanation for the differences in prothrombin determination by the one- and two-stage methods can now be offered. By the one-stage procedure, the prothrombin activity of dog blood is almost five times as great as that of human blood, whereas by the two-stage method, the prothrombin of dog blood is only slightly higher than in human blood. As already stated, the prothrombin time of fresh human plasma is 12 seconds, but the time of stored blood with the labile factor restored may be 7 to 8 seconds. The prothrombin time of dog plasma is 6 seconds. Since it can be assumed that in stored blood all the component A becomes activated, one can see that the prothrombin activity of dog plasma and of human plasma with all of its prothrombin activated is of the same order of magnitude. In carrying out the two stage method, the conditions are such that all of the prothrombin (component A) is converted to the active form. Therefore the method measures only total component A. The one-stage method, on the contrary, measures only free or active component A. The fact that component A can be quantitatively adsorbed and eluted and then tested on a standardized deprothrombinized medium makes it possible to

check the results of the one stage method. By this means it has been found that dog plasma contains over four times as much free component A as human plasma.<sup>4</sup>

The establishment that component A, or the classical prothrombin, exists in human blood both in the free and in the precursor state creates a new problem. How and when does the inactive prothrombin become available in physiologic coagulation? From test tube experiments it is clear that a rough surface is required, but it is still uncertain whether such a surface is available intracorporally. It still remains to be determined whether the precursor component A functions directly in coagulation or whether it serves as a supply of free component A.

It is obvious that the terminology now in general use is cumbersome and in some instances inaccurate. We have adhered to the term labile factor since it is descriptive and noncommittal. We see no justification for calling it an accelerator. Eventually when its action is better defined, a more suitable name may be found. In regard to component A it appears fairly certain that it is or is closely related to the classical prothrombin, the serozyme of Bordet, and the thrombozyme of Nolf. If component A be named prothrombin, it becomes difficult to decide what its inactive or precursor compound should be called. One term which suggests itself is prothrombinogen. Since such a term in recent enzyme chemistry implies that in its activation cleavage occurs, it seems advisable to postpone action until such time when the mechanism has been elucidated. For the present the neutral terms component A and pre A seem best.

#### SUMMARY

1 From studies based on the prothrombin time of plasma and from data obtained with the adsorption and elution of component A, it is concluded that the formation of thrombin requires component A, the labile factor, thromboplastin and combined calcium. This reaction appears to follow the law of mass action. There is no evidence that any of the factors are accelerators.

2 In fresh human plasma component A (prothrombin) is present partly free and partly in an inactive or precursor state which corresponds to the proserozyme of Bordet. It requires a rough surface for its activation, but there is no evidence that calcium, thromboplastin or thrombin are essential for its conversion to the active state. In ovalated human plasma nearly all of component A is changed to the active form after twenty-four hours of storage if kept in contact with a rough surface such as glass.

3 In the coagulation of plasma in which there is a deficiency of available thromboplastin due either to a lack of thromboplastinogen as in hemophilia or to removal of platelets, the concentration of free component A is markedly increased because little of the original active form is consumed and additional active component A is produced from the inactive precursor.

4 Two types of congenital hypoprothrombinemia are known in which a deficiency of component A occurs. In one type a true deficiency of both free and total component A exists. In the second type, which is the more common and is hereditary, the concentration of total component A is normal but the

amount of free or active is below normal. This suggests that a mechanism, still completely unknown, regulates the ratio of active to total component A.

5 The present work confirms the early conclusions of Boidet that serozyme or prothrombin may exist in an inactive or precursor state, but, unlike Boidet's concept that all exists as proserozyme, the present findings show that a large fraction of the total component A is in an active form. It appears probable that in a number of recent studies the activation of component A has been misinterpreted as an acceleration of the conversion of prothrombin to thrombin.

6 Since the procedure of the two-stage method for determining prothrombin is such that all of the component A is converted to the active form, this method determines total prothrombin (component A) but does not distinguish between the free and inactive form. The one-stage method, on the contrary, determines the free or active component A and, to determine the total, all of component A must first be converted to the active state.

# FAILURE OF SENSITIZED SHEEP CELL AGGLUTINATION TO CLARIFY THE DIAGNOSIS OF RHEUMATIC DISEASE

JAMES E. MILLER, M D, ELSA R. LYNCH, M T, AND JOHN LANSBURY, M D  
PHILADELPHIA, PA

## INTRODUCTION

EARLY joint pain in a patient often presents a difficult diagnostic problem. For this reason, the report by Rose, Ragan, Pearce, and Lipman<sup>1</sup> of a test that was diagnostic for active rheumatoid arthritis was received with much enthusiasm. However, much more study is indicated before the reliability of this test is established and before it can be placed in the hand of the clinician as a proved aid to the diagnosis of active rheumatoid arthritis.

Rose and co-workers<sup>1</sup> found that the sera of patients with active rheumatoid arthritis agglutinated sheep cells sensitized with rabbit antiserum in a much higher titer than they agglutinated plain sheep cells. In their series, the sera of twenty-seven patients with active rheumatoid arthritis were tested. Four of the sera had differential titers of 16 and the remainder had differential titers exceeding this level. Also reported in this series were sixteen cases of inactive rheumatoid arthritis, five of which had differential titers exceeding 16, while the remainder had differential titers ranging from zero to 16. Included in their report were twenty-nine patients without evidence of arthritis. Two of these patients had a differential titer of 16, while the remaining twenty-seven had a titer of eight or less.

Cases of rheumatoid spondylitis, rheumatic fever, arthritis other than rheumatoid arthritis and rheumatic fever, infectious mononucleosis, and Still's disease were included in their study, all but two demonstrating differential agglutination titers below 16. They concluded that a sixteen fold difference or more occurs almost exclusively with the sera of patients with rheumatoid arthritis, and that the magnitude of the difference in titer usually reflects the clinical activity of the disease.

It is the purpose of this paper to present our results with this procedure, to correlate, if possible, the results of this test with the activity of the disease, and to determine how much promise it might hold for the clinician in the differential diagnosis of the arthritides.

## METHODS AND MATERIALS

In our initial series we used the method of Rose and associates<sup>1</sup> as follows. The serum of patients with active rheumatoid arthritis was diluted serially and added to 1 per cent suspension of normal sheep erythrocytes in one set of tubes, and in another set of tubes the same serum in the same dilutions was added to a similar amount of 1 per cent suspension of sensitized sheep erythrocytes. Rose and co-workers<sup>1</sup> report agglutination up to 1+ occurs with the sensitized sheep erythrocytes in a serum dilution that is sixteen times (or more) the

From the Departments of Medicine and Bacteriology and Immunology Temple University School of Medicine

Received for publication July 5 1949

dilution with the normal sheep erythrocytes. Sheep erythrocytes were sensitized by 2 units of rabbit antsheep cell serum prepared by the technique used for the Kolmer complement fixation test.<sup>2</sup> The normal sheep erythrocytes were prepared from fresh defibrinated blood by washing the cells three times in saline (0.85 per cent) centrifuging, and resuspending in saline to make a 1 per cent suspension by volume.

Dilutions of rabbit antsheep cell sera ranging from 1:1000 to 1:10000 were made in saline, 0.5 ml of each dilution was then mixed with 0.5 ml of a 2 per cent suspension of washed sheep cells and to each tube 0.1 ml of a 1:10 dilution of fresh guinea pig complement was added. The tubes were incubated in a water bath at 37° C for one hour and the highest dilution of the serum producing complete hemolysis was considered to contain 1 unit of hemolysin.

When doing the agglutination test the rabbit antsheep cell serum was diluted so as to contain 2 units of hemolysin and mixed with an equal volume of a 2 per cent suspension of sheep cells.

This method determines the unit of sensitizing antibody according to its hemolytic titer, but, as will be discussed later, we were unable to obtain differential titers exceeding +8 by this technique. Rose<sup>3</sup> later suggested the agglutinative titer of the serum rather than the hemolytic titer as a more reliable index. Therefore the greater number of our determinations were made with the agglutinative titer.

For the agglutinative titer, dilutions of rabbit antsheep cell serum from 1:100 up, in steps of 100 in a volume of 0.25 ml were set up, to each tube 0.25 ml of a 2 per cent suspension of sheep erythrocytes was added. The tubes were incubated at 37° C for one hour and then kept in the icebox overnight. After centrifugation in order to obtain more definite agglutination, readings were taken. The highest serum dilution giving visible agglutination was taken as the agglutinative titer. For example if the titer were 1:500, a dilution of 1:1000 was used.

Whether the hemolytic or agglutinative titer was used the remainder of the test was set up identically. Serum was obtained from freshly collected venous blood of patients and the complement was inactivated by heating at 56° C for thirty minutes. Dilutions of serum in duplicate (twelve tubes each) containing 0.25 ml saline were made. To each of one series was added 0.25 ml of 1 per cent suspension of normal sheep erythrocytes and to the other series 0.25 ml of the 1 per cent suspension of sensitized sheep erythrocytes. The final serum dilutions were therefore 1:4, 1:8, 1:16, 1:32, 1:64, 1:128, 1:256, 1:512, 1:1024, 1:2048, 1:4096, 1:8192. These were mixed well and placed in the icebox and read in twenty-four hours. In reading the results the highest dilution of serum showing a 1+ agglutination was recorded as the end point. The differential titer was the highest dilution of the serum agglutinating sensitized sheep erythrocytes to 1+ divided by the highest dilution of the serum agglutinating normal sheep cells to 1+. For example, if sensitized sheep cells were agglutinated to 1+ in a serum dilution of 1:128 and the normal sheep cells agglutinated to 1:16 then the differential titer would be 8. (This can be referred to as the "algebraic difference".)

In obtaining material for this study it was decided to include all cases of arthralgia and cases of the so called collagen diseases. But after examining twelve patients it was apparent that the differential titers being obtained were not high enough to be significant. At this time the technique was reviewed and the decision made to use the agglutinative titer. Thereafter cases of rheumatoid arthritis, osteoarthritis, rheumatoid spondylitis, psoriatic arthritis, rheumatic fever, lupus erythematosus disseminatus and controls were used, but the primary interest was in active rheumatoid arthritis so that the reproducibility of the test could be determined.

## RESULTS

Using the hemolytic titer agglutination tests were performed with the sera of twelve patients. The results are tabulated in Table I. The differential titer never exceeded an eightfold difference even though this includes four cases of active rheumatoid arthritis. There was no correlation between activity and the differential titer.

TABLE I DIFFERENTIAL SHEEP CELL AGGLUTINATION USING THE HEMOLYTIC TITER

PATIENT	DIAGNOSIS	SEX	AGE (YR)	SED RATE	WBC	NSC	SSC	DIFF TITER
E K.	Rheumatoid arthritis active, with scleroderma and calcinosis	F	64	23	8,800	1 4	1 8	2

NSC Normal sheep cells  
SSC Sensitized sheep cells

Using the agglutinative titer, agglutination tests were performed on the sera of forty-four patients and the results are summarized in Table II. The cases may be divided into the following groups: (1) active rheumatoid arthritis, (2) nonrheumatoid joint disease, (3) latent syphilis, and (4) controls.

The differential titers in the twenty-one cases of active rheumatoid arthritis ranged from 0.25, in which the normal sheep cells were agglutinated to 1.16 and the sensitized sheep cells to 1.4, to the highest differential of 6.4. These patients all had elevated sedimentation rates, joint pain, and objective evidence of joint disease. The magnitude of the difference in titer did not reflect the clinical activity of the disease nor was there any definite correlation between the differential titer and the erythrocyte sedimentation rate. It is interesting to note that one of the controls had a differential titer of 6.4. An average of the differential titers of the twenty-one cases of active rheumatoid arthritis is 21.56 which is above the sixteen-fold difference which has been designated by Rose and co-workers<sup>1</sup> as the upper limit of "normal." Table III summarizes these averages.

TABLE II DIFFERENTIAL AGGLUTINATION WITH AGGLUTINATIVE TITER—FORTY-FOUR PATIENTS

CLINICAL DIAGNOSIS	NUMBER OF CASES	DIFFERENTIAL AGGLUTINATION TITERS							
		0	2	4	8	16	32	64	128
Rheumatoid arthritis active	21	3		3	1	7	4	3	
Rheumatoid spondylitis	2				2				
Rheumatoid spondylitis with peripheral joint involvement	1				1				
Psoriatic arthritis	2	1				1			
Rheumatic fever—acute	3		1	2					
Lupus erythematosus disseminatus	1			1					1
Osteoarthritis	1								
Infectious arthritis	1		1						
Syphilis	5				1	3	1		
Controls	7	2		3	1			1	

TABLE III. AVERAGES OF DIFFERENTIAL TITERS—FORTY FOUR PATIENTS

CLINICAL DIAGNOSIS	NUMBER OF CASES	DIFFERENTIAL TITER AVERAGES						
		0	2	4	8	16	32	64
Rheumatoid arthritis active	21	21.56						
Rheumatoid spondylitis	2	8						
Rheumatoid spondylitis with peripheral joint involvement	1	8						
Psoriatic arthritis	2	8						
Rheumatic fever	3	(3.33)						
Lupus erythematosus disseminatus	1	4						
Osteoarthritis	1	64						
Infectious arthritis	1	3						
Syphilis	5	17.6						
Controls	7	12						

The cases of nonrheumatoid joint disease included psoriatic arthritis two patients, rheumatoid spondylitis three patients one of whom had peripheral joint involvement, osteoarthritis one patient, active rheumatic fever, three patients, infectious arthritis, subsiding after evacuation of an ischorectal abscess, one patient, and one patient with lupus erythematosus disseminatus. The patient with osteoarthritis had a differential titer of 64. One of the patients with psoriatic arthritis had a differential titer of 16. None of the others had differential titers exceeding 8. The average of the differential titers of this group was 10.9.

Another point of interest is the consistently high differential titer which was obtained with the sera of patients with latent syphilis but without subjective or objective evidence of joint disease. Five cases averaged a differential titer of 17.6 (see Table III) with differentials ranging from eightfold to thirty-two fold.

The seven control patients with no evidence of joint disease and with negative serologies included two cases of psychoneurosis, two normal individuals, one case of pericarditis, etiology undetermined, single cases of heart failure and hypertension. These controls had differential titers ranging from zero to 64 and the average of the differential titers was 12. This indicates that the dilution of the rabbit anti-sheep cell serum used in our studies was of the proper quality and that its agglutinative titer was satisfactory. Certainly, if reproducible results are to be obtained, such an adequate agglutinative titer is necessary.

It is apparent from the results obtained in this study that sensitized sheep cell agglutination is not specific enough to be of value as a diagnostic aid for active rheumatoid arthritis. Of the twenty-one cases of active rheumatoid arthritis, 66 per cent showed a differential titer of 16 or less. If the upper limit of "normal" were reduced to a differential of 8, 33 per cent of these cases were still "negative." It would not be feasible to lower this dividing line to 8 since

# EVALUATION OF AN IN VITRO HEPARIN TOLERANCE TEST FOR THROMBOEMBOLIC DISEASE

DAVID I KRAVCHICK, M D , AND LOUIS SHELMAN, M D  
NEW YORK, N Y

THE need for a laboratory test to predict thromboembolic disease has been recognized for some time. Waugh and Ruddick,<sup>1, 2</sup> working along these lines, measured the ability of whole blood to counteract the anticoagulant effects of heparin in vitro. The basis for this test was the physiologic antagonism between thromboplastin and heparin, the former substance was considered to be increased in the bloodstream in cases of accelerated coagulation. By using increasing amounts of heparin in a series of test tubes, they attempted a "controlled deceleration of the clotting process." In interpreting the Waugh-Ruddick test, any curve that falls below the accepted normal range would indicate accelerated coagulability. On the other hand, results above the normal range would point to delayed coagulability.

Silverman<sup>3</sup> modified the test in an attempt at increasing its accuracy and eliminating certain inherent mechanical difficulties. In our studies at The Bronx Hospital, the Silverman modification of the Waugh-Ruddick test was used.

## METHOD

Serial dilutions of heparin were prepared as follows:

A stock solution was made containing 0.6 cc of heparin (1,000 units per cubic centimeter) in 300 cc of normal saline. The actual dilutions were made from the stock solution.

	STOCK SOLUTIONS (cc)	NORMAL SALINE (cc)	HEPARIN (UNIT PER 0.1 cc)
1	0	50	0
2	5	45	1/50
3	10	40	2/50
4	15	35	3/50
5	20	30	4/50
6	25	25	5/50
7	30	20	6/50
8	35	15	7/50

Four and one half cubic centimeters of blood were drawn and added to a tube containing 0.5 cc of 0.1M sodium oxalate. This was centrifuged to separate the plasma, 0.1 cc of plasma was placed in each of eight tubes (100 by 13 mm). To each tube 0.1 cc of one of the correspondingly numbered heparin solutions was added. Then 0.2 cc of 0.01M calcium chloride was added to each tube to offset the oxalate previously used and the time was noted. All tubes were then immediately placed in a water bath at 37.5° C and the rack was gently tilted periodically until coagulation was noted. Invariably the numbered tubes clotted in the expectedly orderly sequence.

The following precautions were taken to insure accuracy and uniformity of the test:

- 1 Stock solutions were kept at a temperature of 4° C when not in use.
- 2 The Wassermann type of tubes were of uniform size and scrupulously clean.
- 3 Venepuncture was done carefully and a clean dry syringe and needle were used.

From the Department of Pathology, The Bronx Hospital, Joseph Felsen, M.D., Director.  
The authors are deeply indebted to Dr. William Wolarksy for the statistical analysis presented herein.

Received for publication May 26, 1949.

4 The test was always performed in a water bath of constant suitable temperature as suggested by Whittaker <sup>4</sup>

5 At periodic intervals the heparin solutions were checked for stability. Determinations were performed on the plasma of a normal individual using both old and freshly prepared solutions. At intervals of two to three weeks these results checked closely. Likewise, a new unopened vial of heparin (1,000 units per cubic centimeter) was checked against the old one and again a close correlation in results was noted.

6 The test was performed at about 10 A.M. in each instance.

Fig 1—This graph shows the range and mean clotting times for each tube in ninety control determinations.

#### RESULTS

Seventy four individuals were used as controls and ninety determinations were performed on this group. The controls varied in age from the third to the seventh decade and none showed clinical evidence of heart disease, thromboembolic phenomena, or blood dyscrasias. All were ambulatory. Our findings with this group are recorded in Fig 1. It will be noted that as the tubes contain increasing amounts of heparin the mean clotting time increases. The average increase in clotting time from tube to tube is 1.56 minutes with an actual range of difference from 1.04 minutes to 1.80 minutes. Attention is directed to the wide scatter of clotting times among normal individuals, especially in the tubes containing larger amounts of heparin. Two and three determinations were performed on some of the controls to note the variation in heparin tolerance not only among different individuals but also in the same person from day to day.

A few individuals showed a close correlation on repeated determinations, while most showed marked variations. Fig 2 illustrates the different types of results obtained in two controls.

After having established the normal range, the test was performed on twelve obstetric patients and seven candidates for prostatectomy. In the obstetric cases a determination was made ante partum and forty-eight hours post partum,

### COMPARATIVE DATA IN 2 CONTROLS

Fig 2—These curves illustrate the variation in results upon repeating the test in two controls on different days. In Control 2 the correlation is good while in Control 24 a marked difference in coagulability is noted. The solid line 1, in each control represents the first study; the interrupted line 2 is the repeat study.

and if an accelerated curve was then found a third test was performed seven days post partum. The same routine was followed in the prostatectomy cases. The initial determination in each case was included in our control series. Table I shows comparison of these groups and our controls, with a statistical analysis of the results. The difference between the standard deviations of the control group and the obstetric postoperative group is smaller than 3 sigma, in the case of each of the eight tubes. Thus, none of the tubes shows a significant statistical difference from the control to the obstetric-postoperative group.

TABLE I STATISTICAL ANALYSIS OF MEAN DIFFERENCES OF SERIAL CLOTTING TIMES BETWEEN CONTROL AND POSTOPERATIVE GROUPS

TUBE	CONTROLS (90)		POSTOPERATIVE PATIENTS (19)		ANALYSIS	
	MEAN CLOTTING TIME*	STANDARD DEVIATION	MEAN CLOTTING TIME	STANDARD DEVIATION	DIFFERENCES BETWEEN MEANS	TEST FOR SIGNIFICANCE (3σ)

8	15.80	8.76	11.44	6.18	4.36	5.64

\*All clotting times expressed in minutes

## DISCUSSION

In clinical application, preliminary studies by Waugh and Ruddick showed that an accelerated type of curve was obtained under the following circumstances

- 1 During uncomplicated bed rest
- 2 Following operative procedures
- 3 In the presence of acute infections
- 4 In the presence of hemorrhage

Prolongation of the curve was noted in patients undergoing radiation therapy

In performing his test on nine operative patients Silverman<sup>3</sup> noted a definite increase in coagulability following operation. This began within twenty-four hours after operation and lasted for approximately one week. Concomitant platelet counts were done and no increase was found until six or seven days after operation, so that thrombocytosis was not a significant factor in these results in the early postoperative period.

Further application of the principles of the Waugh-Ruddick test by Ogura and co-workers in twenty-seven cases of coronary thrombosis revealed an accelerated coagulation curve in 77.8 per cent of the cases. The onset and duration of this acceleration corresponded with the time range pointed out by Silverman as noted. A total of sixteen controls was used in this series, seven were normal individuals and nine were cardiac patients without thrombosis and at bed rest. Conventional tests for coagulation performed alongside this *in vitro* heparin tolerance test failed to detect any acceleration. The conclusion reached by these authors was that the accelerated coagulation did not cause the coronary thrombosis but was a result of myocardial destruction.

De Takats<sup>6</sup> made use of an *in vivo* heparin tolerance test as an aid in the diagnosis of thromboembolic disease. Ten milligrams of purified heparin were injected intravenously and coagulation times determined by the capillary tube method before the test and at ten minute intervals for forty minutes thereafter. He found a group of patients who were resistant to heparin. These were patients in the early postoperative period, patients who had suffered cardiovascular accidents, and patients with Buerger's disease.

The heparin tolerance curves in the post partum and postoperative states in our patients did not vary significantly from those obtained in the control series. While there may be a difference in the degree of coagulability of the blood of post partum and postoperative patients as compared with normal individuals, our results fail to demonstrate this. This may possibly be due to inherent inadequacy of the test.

## SUMMARY

An *in vitro* heparin tolerance test for the prediction of thromboembolic disease was studied in seventy-four controls, twelve obstetric patients and seven patients who had prostatectomies. The results were subjected to statistical analysis. In our hands this test failed to show a significant difference between the control and the post partum/postoperative groups. This differs from the

reports of previous investigators<sup>2 3</sup> In view of this discrepancy, further investigative work with this test and on other factors affecting blood coagulation seems indicated in order to clarify their place in the prediction of thromboembolic disease

## OBSERVATIONS ON THE COAGULATION DEFECT IN THROMBOCYTOPENIC PURPURA

T LYLE CARR, M D, AND WILLIS M FOWLER, M D  
IOWA CITY, IOWA

THE presence of an excess of heparin or of a heparin like substance in the blood of patients with idiopathic or secondary thrombocytopenic purpura and other hemorrhagic states has been postulated by Allen and co workers<sup>1</sup> This opinion was developed in part as the result of protamine heparin titrations and also by clinical observations on the effect of protamine and toluidine blue on abnormal bleeding These agents are capable of reacting with several endogenous compounds in the body some of which are heparin like while others appear to be unrelated to heparin<sup>2</sup> They were able to show that higher concentrations of protamine were necessary to cause coagulation of heparinized blood from patients with thrombocytopenic purpura than from normal persons They also noted temporary cessation of hemorrhagic phenomena in some patients following intravenous administration of protamine or toluidine blue in a dosage of 1 to 4 mg per kilogram of body weight Attention had been directed to this 'heparinoid state' by the hemorrhagic tendency which appeared in dogs following total body irradiation (roentgen ray)<sup>3,4</sup> Allen and co workers found in the blood of these hemorrhagic animals a circulating anticoagulant which reacted in many ways similarly to heparin and the bleeding tendency could be controlled temporarily by the intravenous injection of protamine sulfate or toluidine blue

Holmgren and Wilander in 1937 found that acidic heparin was removed completely from blood in vitro by adding the 'basic' dye toluidine blue This was apparently a precipitation phenomenon Blood to which heparin is added has a prolonged coagulation time but the addition of a solution of toluidine blue will cause heparinized blood to clot in a few minutes Chargoff and Olson<sup>5</sup> observed that the 'basic' amine, protamine, had an effect similar to that of toluidine blue but this action was apparently mediated through its effect on the electrical charge of heparin Jorpes injected a protamine intravenously in man without untoward reaction and from in vitro studies concluded that protamine would neutralize heparin in the proportion of six parts of protamine to ten parts of heparin Parkin and Kvale<sup>6</sup> concluded, from in vitro studies however that protamine neutralized heparin in a one to one ratio There are several factors involved in blood coagulation through which heparin may act, but the exact mode of its action is not known Heparin, when added in increasing amounts to normal blood, first shortens and then lengthens the whole blood

Received for publication May 31 1949

clotting time<sup>9, 10, 11</sup> The amount of heparin necessary to shorten the clotting time has been shown to vary from 0.0001 to 0.01 unit per cubic centimeter of blood. One-tenth unit of heparin per cubic centimeter of blood will prolong the clotting time. This prolongation may be due to an effect on thrombin, prothrombin, thrombokinase, or possibly on other systems<sup>12, 13, 14, 15</sup>

The mechanism by which protamine alters the coagulation process has not been determined and it too may act in one of several different ways<sup>15, 19</sup>. An antithromboplastic or an antiprothrombic action in the first phase of blood coagulation has been postulated<sup>14, 15, 16</sup>. It also has been suggested that it may have a fibrinoplastic activity in the second phase. In sufficient concentration protamines also have been shown to precipitate fibrinogen and thereby may prolong blood coagulation when given in excess. Utilizing protamine and heparin in an attempt to determine changes in the coagulability of blood, as is done in the protamine titration test, introduces many unknown factors.

#### METHODS

While utilizing small amounts of heparin for prolonging the coagulation of blood by the method of Waugh and Ruddick,<sup>20, 21</sup> it was noted that some patients who were actively bleeding had an augmented reaction to heparin. The Waugh-Ruddick test was originally devised as a modification of the blood coagulation test of Lee and White<sup>22</sup> to provide a controlled deceleration of the coagulation process. The technique is as follows<sup>20, 21</sup>:

Nine Wassermann tubes (100 by 13 mm), thoroughly cleaned and dried, are placed in a rack. Tube number one remains empty until the blood is added. Tube number two contains  $\frac{1}{2}$  c.c. of  $\frac{9}{10}$  per cent normal saline. Serial dilutions of heparin in  $\frac{1}{2}$  c.c. of saline are added to the remaining seven tubes so that tube three receives 0.1 unit of heparin in  $\frac{1}{2}$  c.c. saline, tube four receives 0.2 unit of heparin in saline, and so on until tube nine receives 0.7 unit of heparin. To each of the tubes is added 1 c.c. of blood drawn with a minimum of trauma, using a number eighteen needle and measured from the same 10 c.c. syringe in which it was drawn. The tubes are stoppered and tipped to approximately 85 degrees at two minute intervals until coagulation occurs. The time which elapses from the moment blood is first seen in the syringe until coagulation occurs is the end point in that particular tube.

The test has been used to study the increased speed of coagulation of the blood of patients with myocardial infarction and other thrombotic conditions.<sup>23</sup> It has not been used heretofore, to our knowledge, in a study of patients with hemorrhagic tendencies.

#### RESULTS

The test was performed on thirty normal subjects and the results, as presented in Fig. 1, are in agreement with those of Waugh and Ruddick. The time of coagulation in tubes 1 and 2, which contain no heparin, varied from 4 to 12 minutes. In tube 3, containing 0.1 unit of heparin, coagulation occurred in from 12 to 40 minutes. A gradual increase in the time required for coagulation was found as increasing amounts of heparin are encountered. Coagulation ultimately occurred in from 40 to 90 minutes. In no instance was the blood rendered incoagulable under these conditions. The two extremes in the time of

coagulation in normal subjects are shown by the solid lines in Fig 1, while individual readings on each of the thirty patients are represented by the dots

When the Waugh Ruddick test was tried on the blood of patients who were actively bleeding because of thrombocytopenic purpura it was noted that there was an increased sensitivity to heparin as indicated by an increased time for coagulation in the tubes containing this material. Consequently the test was performed on fifteen patients who had bleeding tendencies associated with pri

Fig 1—Showing the response to the Waugh Ruddick test in thirty normal individuals. The lines represent the two extremes.

mary or secondary thrombocytopenia. The patients and their diagnoses are listed in Table I, nine of them being classified as idiopathic thrombocytopenic purpura. The laboratory findings were typical in all cases: the clotting time was essentially normal, there was prolongation of the bleeding time, the thrombocytes were diminished, clot retractility was absent, and they presented clinical manifestations of hemorrhage. In three patients the thrombocytopenia was secondary to leucemia. It was secondary to a chemical agent in Case 13, and in Case 14 autopsy revealed a diffuse reticuloendotheliosis. Patient J. B., Case

15, had aplastic anemia. One of the nine patients with idiopathic thrombocytopenic purpura died of cerebral hemorrhage before splenectomy could be performed. Splenectomy was done in eight patients, seven of whom responded satisfactorily with a return of the platelet count and bleeding time to normal and cessation of the hemorrhagic tendency. The eighth patient responded temporarily but reverted to the previous hemorrhagic state.

The studies on these patients with thrombocytopenic purpura revealed an essentially normal coagulation time in the first two tubes, which do not contain heparin, but a markedly prolonged coagulation time in the remaining tubes containing serial dilutions of heparin. Fluctuations were noted in the speed of coagulation in individual patients from time to time when there was no significant change in the number of platelets, but when there were active clinical hemorrhagic tendencies the increased sensitivity to heparin was always present. The variations in the Waugh-Ruddick test more nearly paralleled the clinical manifestations of hemorrhage than did the platelet level.

Fifty-six determinations were done on these fifteen patients and the results are presented in Fig 2. The solid line is a typical Waugh-Ruddick curve in a normal subject, presented for comparison. Coagulation occurred in 20 minutes in the presence of 0.1 unit of heparin, in 32 minutes with 0.2 unit, in 46 minutes with 0.3 unit, and in 84 minutes with 0.7 unit of heparin in the last tube. The shaded area in the figure represents the extremes in the response in fifty-six determinations on fifteen patients while they were actively bleeding. In these patients coagulation required from 45 to 100 minutes in the presence of 0.1 unit of heparin although the coagulation time in the first two tubes, containing no heparin, had been essentially normal. In the fourth tube, containing 0.2 unit of heparin, coagulation occurred in 60 minutes in one patient, but in many instances the blood was incoagulable in this dilution of heparin and in all subsequent dilutions. The shortest coagulation time with 0.3 unit of heparin was 80

minutes, but in most instances the blood was incoagulable with this dilution of heparin. There was a progressive lengthening of the coagulation time as the concentration of heparin was increased, and even in those having the shortest coagulation time it was much longer than the normal and an incoagulable state was reached in all cases. In none of the normal subjects was the blood made incoagulable by these dilutions of heparin. All determinations fell between the extremes represented by the shaded area. Incoagulability of the blood was usually produced with 0.3 to 0.4 unit of heparin and it remained incoagulable

Fig. 1.—The heavy line shows the Waugh Ruddick curve in a normal person. The shaded area represents the extremes in the response obtained in thrombocytopenic patients while actively bleeding. Blood from these patients is rendered incoagulable by this small amount of heparin. Although the chart is stopped at 190 minutes all blood samples were observed for twelve or more hours and were still incoagulable.

in subsequent tubes. These results show that the coagulation time in such patients is normal in the absence of heparin but is markedly increased with even small amounts of heparin and the blood is easily rendered incoagulable.

In four patients with purpura simplex (nonthrombocytopenic purpura) the Waugh Ruddick test was normal.

Protamine sulfate and toluidine (1 to 4 mg per kilogram of body weight) were administered to seven patients and then blood was studied in serial dilutions of heparin. Samples of blood were drawn prior to the administration of

protamine or toluidine blue, ten minutes after the administration was completed, and daily thereafter for variable periods. In two patients there was no demonstrable effect. In a third subject the Waugh-Ruddick curve returned to normal following the injection of protamine sulfate, but since the results persisted for more than one week it seems probable that the material was given concomitantly with a spontaneous remission. In the remaining instances the administration of protamine sulfate or toluidine blue apparently shortened the coagulation time in the tubes containing 0.1 and 0.2 unit of heparin and occasionally in the tube

Fig 3—Typical Waugh-Ruddick curves on a thrombocytopenic patient before and after the administration of protamine sulfate. The blood did not clot and was observed for twelve hours although the chart is stopped at 190 minutes.

containing 0.3 unit of heparin but had no effect on the tubes containing a higher concentration. In these tubes the blood remained incoagulable. This suggests that the protamine in the blood stream was sufficient to neutralize 0.1 to 0.3 unit of heparin in tubes 3 and 4 but not larger amounts. Fig 3 shows a typical response in a patient before and after the administration of protamine. The partial flattening of the curve, apparently due to the presence of circulating protamine, was not noted in the twenty-four hour sample.

The Waugh-Ruddick test was done on five patients before and after splenectomy. In four of the cases the operation was followed by a complete clinical remission and a return of the platelet count and other laboratory findings to normal levels. In all of these patients the Waugh-Ruddick test also returned to normal. Fig 4 shows the results of this test in the four cases before and after

splenectomy In the fifth case the operation was followed by an immediate but moderate rise in the platelet count and a normal Waugh Ruddick test Two months later cutaneous hemorrhages had reappeared the platelet count had dropped to its previous low level and the Waugh Ruddick test was again even more prolonged than initially Fig 5 shows the Waugh Ruddick test before operation, one hour postoperatively and two months later in the patient responding only temporarily to splenectomy

#### DISCUSSION

These experiments show that the blood from patients with thrombocytopenic purpura exhibits an unusual sensitivity to heparin in that coagulation is extremely prolonged in its presence and the blood is rendered incoagulable when very small amounts of heparin are added The prolongation of the coagulation time is less marked with normal blood and it does not reach an incoagulable stage under these conditions This reaction is not like that produced by the intravenous injection of commercial heparin The coagulation time of the whole blood as determined by the Lee White and capillary tube methods is not significantly prolonged in thrombocytopenic patients as is true when an excessive amount of commercial heparin is given Toluidine blue and protamine sulfate when given to these patients intravenously does not neutralize the incoagulability of the blood in the Waugh Ruddick procedure as would be expected if excess heparin were the basis for these changes These substances appear only partially to neutralize the effect of the heparin used in the test Further evidence against the presence of an excess of heparin in the blood of these patients was suggested by the administration of commercial heparin to normal subjects The Waugh Ruddick curves in these individuals are not the same as curves obtained in thrombocytopenic patients \* When heparin is given intravenously to a normal person in small amounts (10 mg) the coagulation time is only slightly prolonged and the blood does not become incoagulable in the Waugh Ruddick test containing the higher concentrations of heparin When heparin is given in larger amounts (50 mg), the coagulation time is definitely prolonged but still the blood does not become incoagulable in the Waugh Ruddick test This reaction differs from that of the blood of thrombocytopenic patients in that their blood always becomes incoagulable when tested during a period of hemorrhage and the Waugh Ruddick curve is entirely different from that of blood heparinized *in vivo* These observations agree with the conclusion of Conley, Hartmann, and Morse<sup>25 26</sup> that the increased susceptibility of thrombocytopenic blood to heparin apparently is not due to an increased amount of circulating heparin like substance

The blood of patients with thrombocytopenic purpura is more sensitive to heparin *in vitro* than the blood of normal persons This sensitivity closely parallels the clinical manifestations of hemorrhage and follows the clinical state more closely than it does the platelet count The parallelism between the clinical manifestations of hemorrhage and heparin sensitivity is also closer than that between the clinical manifestations and the platelet count

## SUMMARY

1 The Waugh-Ruddick test has been used to study the coagulation defect in patients with thrombocytopenic purpura

2 The blood from such patients is unusually sensitive to small amounts of heparin *in vitro*

Fig 5—This shows the Waugh-Ruddick curve in a thrombocytopenic patient before splenectomy one hour postoperatively and two months later at which time bleeding had recurred

3 The increased sensitivity of the blood to heparin parallels closely the clinical manifestations of hemorrhage

4 The coagulation defect does not appear to be due to an excess of heparin in the circulating blood

II is an exception in that the solution supplied must be diluted before administration. Previous experience in this hospital<sup>9</sup> showed that the solution used was a satisfactory one if administered at a slow rate. All preparations did not have an equal nitrogen content. A number of different lots of each preparation were used to obtain the values listed in Table I. Two lots of Preparation V are listed, the first (Va) consisted of a batch which possessed the highest glutamic acid content of any of this type of mixture. In the second (Vb) a lower glutamic acid content was found and represents an amount closer to the average obtained for this preparation.

TABLE I GLUTAMIC ACID CONTENT OF AMINO ACID PREPARATIONS

PREPARATION	AMINO ACID CONTENT (GM PER CENT)	CONCENTRATION OF AMINO ACID SOLUTION INFUSED (GM PER CENT)	VOLUME INFUSED (ML)	GLUTAMIC ACID CONTENT OF INFUSED SOLUTION (GM)
Preparation II	15	7.5	400	5.05
Preparation I	10	10	500	4.09
Preparation VI	5	5	1,000	2.65
Preparation V				
a	10	10	500	1.16
b	10	10	500	0.25
Preparation III	8	8	500	0.0

A summary of the information obtained by infusing Preparation II is listed in Table II. This preparation contained the highest glutamic acid content (5.05 Gm per 400 cc) of those studied. It can be observed that high serum free glutamic acid levels were reached. Nausea and vomiting was the usual reaction if the glutamic acid content of the blood exceeded 15.9 mg per 100 milliliters. The fact that marked variations in individual tolerance occurs is evident in that one subject did not become nauseated even though he had a serum free glutamic acid level of 42.6 mg per 100 milliliters.

TABLE II THE RELATIONSHIP BETWEEN BLOOD GLUTAMIC ACID LEVEL AND THE PRODUCTION OF NAUSEA AND VOMITING  
(PREPARATION II, 5.05 GM GLUTAMIC ACID PER 400 CC OF 7.5% SOLUTION)

AMINO ACID PREPARATION	SERUM FREE GLUTAMIC ACID		RATE OF INFUSION (CC/MIN)	REACTION

	4.0	43.0	10.2	Nausea
	2.8	43.2	5.7	Vomited
	--	85.0	3.7	Vomited

In Table III are summarized the results obtained by infusing Preparation I (4.09 Gm glutamic acid per 500 cc). All subjects who had blood free glutamic acid levels above 16 mg per cent became ill. One subject vomited at a lower level (10.9 mg per 100 ml). In general, serum free glutamic acid values were not as high after the administration of this preparation as with the previous one.

TABLE III THE RELATIONSHIP BETWEEN BLOOD GLUTAMIC ACID LEVEL AND THE PRODUCTION OF NAUSEA AND VOMITING

(PREPARATION I 4.09 GM GLUTAMIC ACID PER 500 CC)

	8.0	28.7	5.5	Vomited

Preparation VI (Table IV), an enzymatic digest of bovine blood proteins had a lower free glutamic acid content (2.65 Gm per 1,000 cc) than the previous two preparations and this preparation could be administered at more rapid rates without increasing the toxic symptoms. One subject became nauseated at the rather low serum free glutamic acid level of 9.7 mg per 100 ml, and one subject did not become ill in spite of the high blood level of 22.6 mg per 100 milliliters.

	3.6	22.6	25.6	0

Table V summarizes the data obtained using the preparations containing none or small amounts (1.10 to 0.25 Gm) of glutamic acid. The serum free glutamic acid values obtained following the infusion of 500 ml of an amino acid mixture containing no glutamic acid is of particular interest. In spite of the exceedingly rapid rate of administration (50 and 62 ml per minute), the two subjects showed no toxic symptoms and no appreciable increase in the serum free glutamic acid content. With Preparations Va and Vb attempts were made to produce elevated blood levels by increasing the rate of infusion. It was possible to increase the rate of injection of Preparation Va to such an extent (62.5

ml per minute) that nausea occurred. At the same time the blood free glutamic acid level rose to 12 to 15 mg per 100 milliliters. With Preparation Vb, in only one case of the twelve studied was toxicity noted, but there were no rates of administration which were comparable with the faster infusions given with Preparation Va.

TABLE V THE RELATIONSHIP BETWEEN BLOOD GLUTAMIC ACID LEVEL AND THE PRODUCTION OF NAUSEA AND VOMITING

(PREPARATION VA, 1.10 GM GLUTAMIC ACID, PREPARATION VB, 0.25 GM, AND PREPARATION III, 0.0 GM)

	5.4	9.1	6.0	0
	5.0	5.9	50.0	0
	5.4	6.3	62.5	0

The data presented in Tables I to V are summarized in Fig. 1. There is good correlation between the serum free glutamic levels and the per cent of subjects who either became nauseated or vomited. Without regard to the preparation used, when the blood free glutamic acid concentration reached 12 to 15 mg per 100 ml, about one-half of the subjects became nauseated or vomited. Above these levels the incidence of ill effects was correspondingly greater.

The subjects of Group C received infusions consisting of Preparation Vb plus 5.05 Gm of glutamic acid per 400 ml of solution (Table VI). The glutamic acid content of the fortified preparation was thus made equal to an acid digest of casein (Preparation II). In this series there was a decidedly greater frequency of toxic symptoms as compared with this same mixture before glutamic acid was added (Table V). With Preparation Vb alone, the incidence of toxic symptoms was 8.3 per cent, with the addition of glutamic acid the incidence rose to 55 per cent. All of the subjects who experienced ill effects had serum free

glutamic acid levels equal to or above the 12 to 15 mg per 100 ml range. It is noteworthy that three of the subjects who had high serum glutamic acid values did not exhibit any gastrointestinal symptoms (Table VI).

*Studies Involving Only Glutamic Acid Solutions*—In the next series of studies an attempt was made to determine whether there was a free glutamic acid level of the serum at which the occurrence of nausea and vomiting could be expected (Table VII upper half). The first eight subjects received infusions of solutions containing 5.05 Gm of partially neutralized glutamic acid per 400 ml of solution; the next nine subjects received infusions of a solution containing 10.1 Gm of glutamic acid per 400 milliliters. The level of serum glutamic acid reached was dependent on the concentration of the solution infused and the rate of injection. With the lower concentration none of the eight subjects who received the amino acid exhibited ill effects. Only two of these subjects had

serum free glutamic acid levels exceeding 12 mg per 100 milliliters. Nine subjects received the stronger solution, five of whom became nauseated or vomited. It should be noted that with the stronger solution higher serum free glutamic acid levels were quickly obtained. Forty-five per cent of the subjects who had levels of glutamic acid above 12 mg per 100 ml became nauseated or vomited.

TABLE VII THE RELATIONSHIP BETWEEN SERUM FREE GLUTAMIC ACID LEVELS AND THE OCCURRENCE OF NAUSEA AND VOMITING AFTER GIVING GLUTAMIC SOLUTION INTRAVENOUSLY

AMINO ACID PREPARATION	SERUM FREE GLUTAMIC ACID		RATE OF INFUSION (CC/MIN)	REACTION
	BEFORE INFUSION (MG PER CENT)	AFTER INFUSION (MG PER CENT)		
Sterilized by Autoclaving				
Glutamic acid 5.05 Gm/400 cc	6.8	5.5	5.3	0
	3.3	6.4	11.0	0
	5.7	7.1	4.0	0

	4.8	24.0	8.0	Vomited
	6.7	29.7	6.6	Vomited
	2.7	30.9	10.0	Nausea
	2.9	60.0	10.0	Vomited

Since many of the commercial protein digests are sterilized by filtration rather than autoclaving and since heat promotes the conversion of glutamic acid to pyrrolidone carboxylic acid, it was decided to repeat these studies using only glutamic acid solutions which had been sterilized by filtration, employing both the lower and higher doses (Table VII, lower half). When the lower dose was administered, two of the six subjects tested became nauseated or vomited, with the higher doses all of the eight subjects tested became ill. One subject vomited but had a blood glutamic acid level of only 7.5 mg per 100 milliliters.

## DISCUSSION

Until the present investigation the quantitative relationship of glutamic acid to the production of anorexia, nausea, and vomiting following the intravenous administration of casein hydrolysates was based on indirect evidence. Previous studies in this hospital indicated that no significant ill effects attended the giving of amino acid preparations orally, however, a depression of appetite, nausea, or vomiting frequently occurred with or immediately after infusions of casein digests<sup>10</sup>. These ill effects could be reduced to a large extent by reducing the rate of infusion. It was next observed that mixtures of the ten essential amino acids could be given intravenously at very rapid rates without producing ill effects<sup>6, 9, 11</sup>. Both Eckhardt and Davidson<sup>12</sup> and Weinstein<sup>13</sup> have administered intravenously to patients amino acid preparations containing reduced amounts of glutamic and aspartic acids and they have reported few toxic symptoms even with rapid rates of infusion. In the case of the dog<sup>1, 3, 4</sup> (and later confirmed in man), it was noted that the addition of either glutamic or aspartic acid to parenterally administered amino acid mixtures reduced the tolerance of these mixtures. Additional evidence indicated that there was a marked correlation between the content of these two dicarboxylic amino acids in amino acid preparations and the tendency of the solutions to provoke nausea and emesis in man. On the other hand Elman<sup>14</sup> has reported the intravenous injections of an unneutralized glutamic acid solution (1 000 ml of solution contained 30 Gm) into three patients without the occurrence of any ill effects. No reference was made by this investigator to the rate of infusion, or to the glutamic acid level which resulted. His interpretation, apparently based upon that study, that intravenously injected glutamic acid is not related to the production of nausea and vomiting is at variance with our experience.

Hoffman and co-workers<sup>15</sup> reported that if the blood amino acid nitrogen following the administration of an acid hydrolysate of casein exceeds 10 mg per cent, nausea and vomiting may occur. This finding has been confirmed previously in this laboratory<sup>6</sup> for the same preparation; however, using preparations which were either free of or very low in glutamic acid it was possible to obtain markedly elevated blood amino acid nitrogen values without ill effects. At that time it was suggested that the blood glutamic acid probably was more closely related to the nausea and vomiting than the amino acid nitrogen content. Kade<sup>16</sup> has suggested that following the intravenous administration of preparations rich in glutamic acid the blood level of glutamic acid rises faster than the amino acid nitrogen content of the same blood. Friedberg and Greenberg<sup>1</sup> have reported that glutamic acid is slowly cleared from the blood of rats after intravenous administration.

In this study the determination of the free glutamic acid content of serum was accomplished by using a microbiologic procedure employing *Lactobacillus arabinosus* as the test organism. This method has been shown to give reliable values when protein hydrolysates were investigated<sup>7</sup>. Recently it was stated by Prescott and Waelsch<sup>18</sup> that the microbiologic method for glutamic acid is not applicable in the presence of glutamine. By their chemical method it was found

that free glutamic acid of serum or plasma varied from 0.6 to 1.7 mg per 100 ml, and the "apparent glutamine" content ranged from 8 to 12 mg per 100 milliliters. Harper,<sup>19</sup> using a modified type of microbiologic method, more recently found glutamic acid and glutamine values in plasma similar to those given by the chemical method. The major portion of the preinfusion values for serum free glutamic acid reported in the present study would tend to show that a portion of the serum glutamine is being included in the value, because they are above the 0.6 to 1.7 mg range. Since they are almost all below the 8 to 12 mg range, not all the glutamine is being determined as free glutamic acid.

There appears to be some quantitative difference in the tolerance of glutamic acid when administered alone and when mixed with other amino acids. When 5.05 Gm of glutamic acid were given intravenously as a solution containing only this amino acid, 14 per cent\* (two of the fourteen studied) of the subjects either became nauseated or vomited. When a similar amount of glutamic acid was given intravenously in a mixture of amino acids (Preparation II), 60 per cent\* (six of the ten tested) of the subjects showed ill effects. On the other hand, when the concentration of glutamic acid was increased to 10.1 Gm and only this partially neutralized amino acid was given intravenously, 76 per cent (thirteen of the seventeen patients) of the subjects became nauseated or vomited. Thus, the incidence of nausea and vomiting following the intravenous administration of glutamic acid incorporated in an amino acid mixture is greater than that when an equivalent amount of partially neutralized glutamic acid is given alone. Both aspartic acid<sup>2</sup> and phenylalanine<sup>20</sup> have been reported to increase the toxicity of intravenously administered amino acid. dl Methionine also has been listed as an amino acid which is poorly tolerated when given intravenously to the dog.<sup>21</sup> The amino acid preparations which are low in glutamic acid are also generally low in aspartic acid. Phenylalanine and methionine are probably not offenders in this manner, at least not without the dicarboxylic amino acids being present. Preparations III and V contained these acids and were well tolerated even at rapid rates. The possibility of other amino acids increasing the effect of glutamic acid in the production of nausea and vomiting following its intravenous administration should be further investigated.

In attempting to evaluate the data concerning the relative toxicity of the autoclaved as compared with the filtered solutions of glutamic acid, it was noted that 71 per cent\* (ten of the fourteen cases) of the subjects that received the latter preparation became nauseated or vomited, while only 30 per cent\* (five of the seventeen subjects) became ill after receiving the autoclaved material. Thus, the filtered material would appear to be slightly more toxic than the autoclaved. Oleott<sup>22</sup> reported that if glutamic acid were autoclaved at a temperature of 125° C and in an acid media, pH 3.3 for four hours, 92 per cent of the amino acid would be converted to pyrrolidone carboxylic acid. The possibility of this occurring during the relatively short period of autoclaving used in the present

\*Since the difference is greater than two times the standard error of the mean the differences are considered significant.

study might be an explanation for the apparent difference in emetic effect. The likelihood of the pyrrolidone carboxylic acid assuming like glutamic acid (e.g., supporting the growth of the *Lactobacillus arabinosus*) while having an emetic action different from glutamic acid was investigated, in this case a high serum glutamic acid level might be attained without nausea and vomiting. Lyman found that this microorganism cannot utilize pyrrolidone carboxylic acid.<sup>23</sup> In the present study\* it was found that pyrrolidone carboxylic acid neither stimulated nor inhibited the bacterial growth in that assay of glutamic acid when present in one third to four times the concentration of glutamic acid. If much glutamic acid were converted to pyrrolidone carboxylic acid during the short period of autoclaving then the concentration of free glutamic acid in the autoclaved material should decrease, since the pyrrolidone carboxylic acid does not support growth of the microorganism. This did not occur. Hence, it seems unlikely that pyrrolidone carboxylic acid could account for the apparent difference in toxicity of the filtered and autoclaved glutamic acid solutions.

#### SUMMARY AND CONCLUSIONS

The free glutamic acid content of five different types of amino acid preparations was estimated using microbiologic methods. They are, in decreasing order of glutamic acid content: an acid hydrolysate of casein fortified with tryptophane, an enzymatic hydrolysate of casein, an enzymatic digest of beef blood proteins, a mixture of amino acids produced by the recombination and fortification of fractions of a casein digest, and a mixture of the ten "essential" amino acids plus glycine. The occurrence of nausea and vomiting following the administration of the various preparations in a series of fifty-seven human subjects was found to parallel the free glutamic acid content of the mixture given.

Until the present investigation only indirect evidence was obtained concerning the quantitative relationship of glutamic acid and the production of nausea and vomiting following its intravenous administration. A direct relationship between the free glutamic acid of the serum and the occurrence of toxic effects following the administration of amino acid preparations was found in this investigation. When the serum free glutamic acid level reached 12 to 15 mg per 100 ml, nausea and vomiting occurred in more than half of the subjects.

Solutions containing only partially neutralized glutamic acid were administered intravenously to thirty-one individuals and estimates of the free glutamic acid content of the serum were made. A lower percentage of these patients became ill at elevated glutamic acid levels than in the group that received glutamic acid containing amino acid mixtures. This is interpreted as showing that the toxicity of glutamic acid may be potentiated by other amino acids.

A study of the effect of autoclaving and of sterilization by filtration upon the toxicity of glutamic acid solutions indicated that the filtered material was slightly more toxic. This difference could not be attributed to the presence of pyrrolidone carboxylic acid.

\*These data are not included in the present report.

# CARBONIC ANHYDRASE ACTIVITY IN SICKLE CELL ANEMIA, SICKLE CELL TRAIT, AND PERNICIOUS ANEMIA

ROSE G. SCHNEIDER, PH.D., WILLIAM C. LEVIN, M.D., AND  
MARY ELLEN HAGGARD, B.A.  
GALVESTON, TEXAS

CARBONIC anhydrase, an enzyme first described by Meldrum and Roughton<sup>1</sup> and Stodieck and O'Brien,<sup>2</sup> is present in the erythrocytes of homeothermic animals and in the gills of some poikilothermic ones.<sup>3</sup> It plays an important role in the transport and exchange of CO<sub>2</sub>. No studies have been reported previously on the presence of carbonic anhydrase in sickle cell anemia, although this enzyme has been implicated in the sickling phenomenon by Tomlinson and Jacob.<sup>4</sup> These authors found that washing erythrocytes from patients with sickle cell anemia or sickle anemia twenty times in normal saline almost always removes their ability to assume sickled forms in normal saline. They suggested that the multiple washings remove some substance, possibly carbonic anhydrase, the presence of which is necessary for the phenomenon of sickling. Additional evidence for this hypothesis was presented by the demonstration that certain carbonic anhydrase inhibitors such as zinc acetate and sodium cyanide in concentrations of 1/1000 when added to oxygenated blood prohibit sickle cell formation; however, other carbonic anhydrase inhibitors, namely sulfamylamide and ammonium thiocyanate, give inconsistent results.

In the present studies the relationship between carbonic anhydrase and the sickling phenomenon was investigated by the following means: (1) The carbonic anhydrase content of the blood of patients with sickle cell anemia and with sickle cell trait was compared with that of normal individuals. Three cases of pernicious anemia were included for comparison. (2) Erythrocytes from patients with the sickling tendency were washed repeatedly in normal saline, until sickling no longer occurred; the red blood cell suspension was then made up to its original volume with water and again tested for the presence of carbonic anhydrase. The saline washings also were tested for the presence of carbonic anhydrase. (3) The susceptible erythrocytes were washed repeatedly until sickling no longer occurred and a concentrated solution of human carbonic anhydrase was added to determine whether such addition restored the ability of the cells to sickle.

## METHODS

Carbonic anhydrase determinations were made by the colorimetric method of Philpot and Philpot<sup>5</sup> and enzyme units were estimated according to this method. Each determination was made in triplicate. Oxalated blood was used throughout. Appropriate dilutions

From the Department of Urology and Psychiatry, The Tissue Culture Laboratory, The Department of Internal Medicine and the Hematology Research Laboratory, The University of Texas Medical Branch.

Aided by a grant from the American Cancer Society, C11A administered by C. M. Pomeroy.

Received for publication June 1, 1949

were made of whole blood, except in those experiments in which washed cells were used. Concentrated carbonic anhydrase preparations were made by treating the washed and hemolyzed red blood cells with a mixture of alcohol and chloroform and centrifuging off the precipitate. The carbonic anhydrase activity of the supernatant fluid was about fifty times that of the whole blood.

Sickling of cells was estimated by examining sealed wet smears of blood after incubation at room temperature for twenty four hours. The erythrocytes were washed twenty times with normal saline according to the technique described by Tomlinson and Jacob.<sup>4</sup> In certain instances carbonic anhydrase was added to whole blood and to cells washed five, ten, fifteen and twenty times. The amount of sickling after such treatment was compared with that of untreated cells.

## RESULTS

In Table I is given the carbonic anhydrase content of the blood of individuals with sickle cell anemia and sickle cell trait as compared with normal individuals and three persons with pernicious anemia. In Table II these data are summarized in the form of ratios of carbonic anhydrase to red blood cell count and hemoglobin content. These ratios indicate that the carbonic anhydrase content of red blood cells with sickling capacity is as high as or

TABLE II RATIO OF BLOOD CARBONIC ANHYDRASE TO RED BLOOD CELLS AND HEMOGLOBIN OF NORMAL INDIVIDUALS AND THOSE WITH SICKLE CELL ANEMIA, SICKLE CELL TRAIT, AND PERNICIOUS ANEMIA

NUMBER OF PATIENTS	DIAGNOSIS	RATIO OF AVERAGE CARBONIC ANHYDRASE TO AVERAGE RBC COUNT	RATIO OF AVERAGE CARBONIC ANHYDRASE TO AVERAGE HEMOGLOBIN CONCENTRATION
9	Normal	1 228	1 74
6	Sickle cell anemia	1 254	1 87
7	Sickle cell trait	1 223	1 85
3	Pernicious anemia	1 549	1 138

slightly higher than that of normal red blood cells. In pernicious anemia, red blood cells contain much larger quantities of carbonic anhydrase, although only three cases of pernicious anemia were studied the difference appears striking.

Table III summarizes the data obtained by determining the carbonic anhydrase content of cells with the sickling capacity washed twenty times in isotonic saline until sickling no longer occurred. Ninety per cent of the carbonic anhydrase content of the original whole blood is present in these washed cells. The saline washings contain only a trace of carbonic anhydrase, one determination of the carbonic anhydrase activity of the plasma of these washed cells is noted. Part of the carbonic anhydrase lost by washing is apparently contained in the plasma where it doubtless appears because of hemolysis.

TABLE III CARBONIC ANHYDRASE CONTENT OF RED BLOOD CELLS AFTER WASHING UNTIL SICKLING CAPACITY IS REMOVED

PATIENT	DIAGNOSIS	CARBONIC ANHYDRASE WHOLE BLOOD (ENZYME UNITS/C MM)	CARBONIC ANHYDRASE WASHED CELLS (ENZYME UNITS/C MM)	CARBONIC ANHYDRASE SALINE WASHINGS	CARBONIC ANHYDRASE CONTENT OF PLASMA (ENZYME UNITS/C MM)

#### DISCUSSION

Our results indicate that the loss of sickling capacity of red blood cells from patients with sickle cell anemia or sickle cell trait is not associated with a significant loss of carbonic anhydrase. After the completion of these experiments there appeared in *Blood* an editorial by Vallee and Altschule<sup>6</sup> referring to a series of papers in press on carbonic anhydrase in anemia. In this editorial and in an abstract recently published by Vallee<sup>7</sup> a striking difference is drawn between the carbonic anhydrase content of red blood cells from patients with pernicious anemia and those from patients with secondary anemias and from normal individuals. Our findings indicate that blood from sickle cell anemia and sickle cell trait is similar to that of secondary anemia in this respect. In contrast, our three cases of pernicious anemia have twice the ratio of carbonic anhydrase to red blood cells and hemoglobin compared with the normal values.

## SUMMARY

1 The carbonic anhydrase content of red blood cells exhibiting the sickling phenomenon corresponds to that of normal red blood cells

2 Washing red blood cells of individuals with sickle cell anemia or sickle cell trait with isotonic saline until sickling no longer occurs results in no significant loss of carbonic anhydrase activity

3 Addition of carbonic anhydrase to washed cells from which the sickling capacity has been removed does not restore this capacity

4 Carbonic anhydrase, under conditions described, has no effect on the sickling phenomenon

5 Confirmatory evidence is presented that in pernicious anemia unit values of carbonic anhydrase in respect to red blood cell count and hemoglobin are about twice those of normal individuals

## CLINICAL STUDIES ON THIOMERIN, A NEW MERCURIAL DIURETIC

IRVING W WINIK, M D , AND RUTH B BENEDICT, M D  
WASHINGTON, D C

SEVERAL effective mercurial diuretics are available and are widely used at the present time. The introduction of a new diuretic can be justified only if it is less toxic or more effective, or if it is more convenient to use. This report concerns itself with the results of a study of a new mercurial diuretic whose toxicity and efficiency have been compared with those of several of the preparations in common usage. The new material is the disodium salt of N( $\gamma$ -carboxymethyl mercaptomercuri  $\beta$ -methoxy) propyl camphoramic acid (Thiomein) \*. It has the same organic-mercurial structure as Mercuzanthin, with the theophylline replaced by sodium mercaptoacetate. Thiomein is a white amorphous powder which is supplied in vials containing 1.4 Gm. of the compound. The introduction of 10 cc. of sterile water into the vial results in a solution containing the equivalent of 0.040 Gm. of mercury per cubic centimeter at a pH of about 7.5.

## METHODS

The method of study was similar to that employed by DeGraff.<sup>1</sup> Patients in congestive heart failure and with considerable edema were digitalized and kept at bed rest on a relatively salt poor diet (approximately 3 grams of sodium chloride daily). There was no limitation of fluid intake. Each patient's weight was recorded daily at the bedside until there was no further weight loss over the course of several days. At this point the diuretic was administered. Patients who were too ill to be weighed or whose weight might have been affected by variation in dietary intake, vomiting, decrease in hyperthyroid state, or by factors other than edema were not included in this study. Each patient's urine was examined for abnormalities before and after the administration of the diuretic. Injections of Thumerin were given subcutaneously, except in two instances when it was administered intravenously. The injections of Mercuzanthin and of Salyrgan-Theophylline were given intramuscularly.

## RESULTS

The diuretic effect of Thiomeirin in seventy trials on thirty-six patients is indicated in Fig 1. There was diuresis resulting in weight losses ranging from 2 to 17½ pounds. This range of weight loss was roughly proportional to the amount of edema present. In all the Thiomeirin trials (in which weight loss was studied) the average weight loss was 6 pounds and the median weight loss was 5 pounds, while somewhat less than 50 per cent of injections resulted in a weight loss between 3 and 4 pounds. The diuretic effect usually appeared within several hours after the injection and lasted for twenty-four hours or more. The duration of action varied. Usually it was over by the end of twenty-four hours, although in several patients it lasted for three days. Variation in duration of

\*Thiomerin has the following structural formula

$$\text{CH}_3\text{CH}(\text{CONHCH}_2\text{CH}(\text{OCH}_2\text{CH}_2\text{HgSCH}_2\text{COONa}))\text{CH}_3$$

action sometimes occurred in the same patient from one injection to the next. In no instance was there any evidence of any nephrotoxic effect. From these results it can be seen that Thiomerin is an effective diuretic.

The diuretic effect of Thiomerin was next compared with that of two widely used mercurial diuretics, Mercuzanthin and Salyrgan. Theophylline. Approximately the same amount of mercury (0.04 Gm.) is present in 1 cc. of all these preparations.

#### DIURETIC EFFECT OF THIOMERIN IN 70 TRIALS

FIG. 1

As shown in Fig. 2, nineteen comparisons of the diuretic activity of Thiomerin and Salyrgan Theophylline were made in thirteen patients. In seven instances (37 per cent) the diuretic effect was the same. In nine instances (47 per cent) Thiomerin produced a greater diuresis and in three instances (16 per cent) Salyrgan Theophyllin had a greater effect. The duration of diuretic action was also noted for the two drugs. In six instances the Thiomerin induced diuresis was more prolonged; in two instances a more sustained effect was induced by Salyrgan Theophylline. In Case 44 Thiomerin induced diuresis in two trials was more prolonged and greater than that obtained with Salyrgan Theophylline. This was true despite the fact that the Thiomerin was given intravenously on one occasion and subcutaneously on the next.

The relative diuretic action of Thiomerin and Mercuzanthin was observed in ten comparisons on eight patients. In five of these instances the diuresis obtained was the same; in three it was greater with Thiomerin and in two it was greater with Mercuzanthin. It also was noted that in three instances Thiomerin induced diuresis was slower and more prolonged.

*Toxicity*—Urinalyses before and after the administration of Thiomerin did not reveal evidence of renal toxicity. This was true in a patient with chronic glomerulonephritis as well as in the patients with heart disease of other etiology.

COMPARISONS OF DIURETIC EFFECT OF THIOMERIN,  
MERCUZANTHIN AND SALYRGAN-THEOPHYLLINE  
INDIVIDUAL CASES

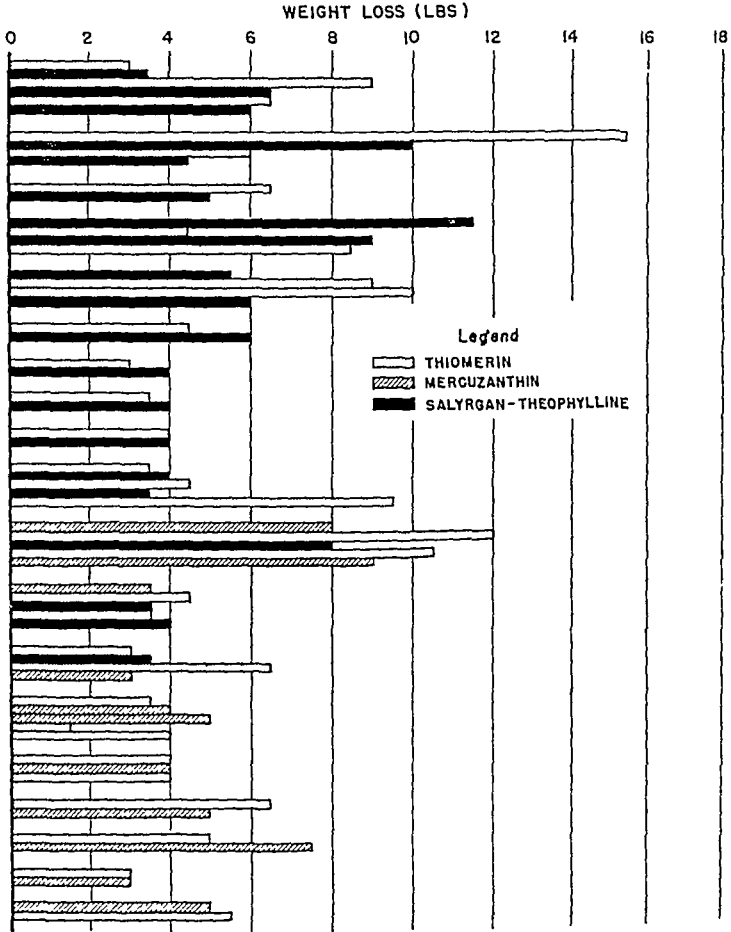

Fig. 2

Since Thiomerin is given subcutaneously, local effects were watched for. Immediate reactions were minimal. They consisted of slight burning or stinging at the site in 41 per cent of the injections. A small number of patients also had some aching or local soreness lasting a few minutes to a few days. Because a certain number of nodules or infiltrations were found to follow use of the drug, it was decided to study this long-term phenomenon more carefully in another group of patients. While the early product, no longer being manufactured, caused appreciable indurations in 12 per cent of injections, the drug as

it is now being prepared gave rise to such infiltrations only four times (3.3 per cent) in a total of 121 injections. These areas, which were similar after both products, were situated subcutaneously and could usually not be outlined clearly since they faded into the surrounding tissue. They were about  $\frac{1}{4}$  in to  $1\frac{1}{2}$  in in diameter, were up to  $\frac{1}{3}$  in in depth, were occasionally attached to the skin, and were only rarely tender. They cleared up gradually in a period of two to five months. Biopsies done on four of these infiltrations showed them to consist of areas of aseptic fat necrosis. In this last series of 121 injections there were also six instances (5 per cent) of local infiltrations so small that they would have been missed had they not been searched for carefully.

#### DISCUSSION

With the extensive use of mercurial diuretics, a number of reports have appeared which emphasize fatal or near fatal reactions from their intravenous use.<sup>3,4</sup> The possibility of such toxic reactions has been present regardless of the mercurial preparation employed. It is due to direct action on the heart with the production of disturbances in conduction and rhythm<sup>5</sup> and in working capacity.<sup>7</sup> A recent study in animals of the comparative toxicity of the commonly used mercurial diuretics and of Thiomerin has shown the latter to be 160 to 200 times less toxic to the heart.<sup>8</sup> No effect was seen by electrocardiogram in anesthetized cats after a dose of 4 c.c. of Thiomerin per kilogram, as compared with 0.1 c.c. per kilogram of other mercurial diuretics. If these results may be transposed to man this would compare a dose of 240 c.c. of Thiomerin to one of 6 c.c. of Mercuzanthin, Salyrgan, Theophylline, or Mercuhydrin. Thus the danger of sudden cardiac death would seem to be practically eliminated.

Our results confirm the findings of Boig and Craig<sup>9</sup> and Hermann and co-workers<sup>10,11</sup> as to the efficacy of Thiomerin as a diuretic for subcutaneous administration. The diuresis obtained by us following the subcutaneous injection of Thiomerin was comparable with that obtained with equivalent amounts of Mercuzanthin and Salyrgan Theophylline given intramuscularly. In some patients it was a more effective diuretic. The effect was more sustained in a number of instances. This may be related to the site of administration, although in one patient the intravenous injection of Thiomerin produced more sustained diuresis than did an intramuscular injection of Salyrgan Theophylline.

#### SUMMARY

- 1 The diuretic effectiveness of Thiomerin, a new mercurial compound which is reported to be less toxic to the heart when administered intravenously to cats, has been investigated in man.

- 2 Thiomerin was found to be an effective diuretic in seventy trials on thirty-six patients.

- 3 The diuresis obtained after the subcutaneous injection of 2 c.c. of Thiomerin was comparable with or greater than that noted after the intramuscular use of equivalent amounts of Mercuzanthin or Salyrgan Theophylline in twenty-nine comparative studies on twenty-one patients. In some patients the diuresis with Thiomerin was more sustained.

4 No systemic toxic effects were noted Kidney damage, as judged by urine examinations, did not occur

5 Local reactions following the subcutaneous use of Thiomerin were absent or insignificant 96.7 per cent of the time Three and three tenths per cent of injections were followed by annoying but seemingly harmless subcutaneous infiltrations of long duration

# LIMITATIONS AND MERITS OF A SINGLE SERUM SAMPLE ANALYSIS IN THE DIFFERENTIAL DIAGNOSIS OF JAUNDICE

F W HOFFBAUER, M D, LIEUTENANT E D RAMES MEDICAL CORPS, ARMY OF  
THE UNITED STATES \* AND J K MEINERT, B M  
MINNEAPOLIS, MINN

## INTRODUCTION

PREVIOUS experiences in the employment of multiple biochemical procedures to assay liver function and to assist in determining the cause of jaundice have been reported from this clinic<sup>1</sup>. The differential diagnosis of jaundice is a problem that can be solved only by the exercise of sound clinical judgment at the patient's bedside. Laboratory studies are at best only auxiliary aids to this problem. Until we possess specific biologic tests for the recognition of virus hepatitis the detection of this disorder depends chiefly upon inferences drawn from the history of the illness, the physical examination and the laboratory evidence of liver dysfunction. Since we lack a non-operative roentgenologic method of visualizing the extrahepatic biliary tract in the jaundiced patient the diagnosis of obstruction due to calculi, to tumors, or to stricture must similarly be based upon inferences from such data.

In 1945 Schwimmer, Klotz, Dieker and McGavack<sup>2</sup> described their extensive experience with a fasting blood sample in the differential diagnosis of jaundice. They pointed out the many practical advantages of this procedure. The single specimen group of tests employed by these investigators included the icteric index, the van den Bergh reaction, the cephalin cholesterol flocculation test, the serum alkaline phosphatase value, the total and esterified serum cholesterol, and the total serum proteins together with the albumin and globulin fraction. The application of these tests to a wide variety of hepatic disorders by Schwimmer and associates revealed that the composite test yielded results that were as delicate as accurate and as informative as those derived from the more elaborate tests of liver function.

Shay and Siplet<sup>4</sup> stated that a 'minimum yet adequate liver function study' may be made in jaundice with the following tests: (1) quantitative van den Bergh, (2) serum cholesterol partition, (3) serum alkaline phosphatase, (4) thymol turbidity and (5) cephalin cholesterol flocculation. They illustrated the merits of these tests when applied serially to individual cases. More recently Popper and Steigmann<sup>5</sup> have evaluated the merits of these tests as well as others in current usage in 285 patients. The initial series of liver function tests was taken into consideration in that study.

From the Department of Medicine, University of Minnesota Hospital.

Received for publication June 13, 1949.

Present address: Lowry Air Force Base, Denver, Colo.

The present study was made to test the accuracy with which a group of tests performed on a *single* fasting serum sample can assist in the differential diagnosis in a jaundiced patient. It is not our contention that the analysis of a single specimen of serum from a jaundiced patient should be entirely adequate. Serial observations are certainly indicated and were, in fact, carried out in the majority of our patients. These often included tests other than those to be discussed in this paper.

#### MATERIALS AND METHODS

In the selection of cases for the present study only instances of regurgitation jaundice have been chosen for analysis. Instances of retention jaundice usually have other distinguishing features and seldom present the diagnostic problems that regurgitation jaundice does. One hundred forty seven patients observed at the University of Minnesota Hospital were included. The following criteria were employed in the selection.

1 *Presence of jaundice* The study has been limited to instances in which the prompt direct reacting component (1 min. value) of the serum bilirubin was greater than 0.4 mg per 100 cc and the total bilirubin greater than 2.0 mg per 100 cubic centimeters.

2 *Available data* Evaluation has been limited to instances in which the following determinations were made on a *single* sample of serum secured in the fasting state: bilirubin, total and esterified cholesterol, alkaline phosphatase, thymol turbidity, and cephalin cholesterol flocculation.

3 *Proof of diagnosis* Evaluation has been limited to patients in whom the diagnosis was established by operation, necropsy, or biopsy except in the cases of virus hepatitis where a clinical diagnosis was accepted despite lack of biopsy data. A critical appraisal of the available clinical material was made and the selection was restricted to instances in which the course of the illness was believed to establish the diagnosis beyond reasonable doubt.

Of the 147 patients, seventy seven had extrahepatic biliary obstruction and seventy suffered from parenchymal liver disease. The former group included:

- 1 Twenty eight cases of carcinoma obstructing the bile ducts
- 2 Thirty nine cases of common duct calculus
- 3 Ten cases of stricture of the bile ducts

In each instance the diagnosis was verified by operation or by necropsy. The group of cases of parenchymal jaundice included:

- 1 Twenty six cases of cirrhosis
- 2 Thirty one cases of virus hepatitis
- 3 Thirteen cases of liver disease due to miscellaneous causes

The methods employed are listed in Table I. In three cases (see Table VI) and in one case (Table VII) the thymol turbidity was performed according to the colorimetric adaptation of Ducci.<sup>12</sup> The upper limit however is the same as by the MacLagan method.<sup>13</sup>

TABLE I. BIOCHEMICAL PROCEDURES EMPLOYED

PROCEDURE	METHOD	NORMAL VALUE
1 Serum bilirubin	Malloy and Evelyn <sup>6</sup> as modified by Ducci and Watson <sup>7</sup>	1* (prompt direct) 0.2 mg / 100 cc (total, direct plus indirect) 1.0 mg / 100 cc
2 Cephalin cholesterol flocculation	Hanger <sup>8</sup>	1 reading greater than 17 at 24 hr may be considered abnormal
3 Thymol turbidity	MacLagan <sup>9</sup>	0 - 4 units
4 Serum cholesterol (total)	Schoenheimer and Sperry <sup>10</sup>	180 - 220 mg per 100 cc
5 Serum cholesterol (esterified fraction)	Schoenheimer and Sperry <sup>10</sup>	50 - 65% of total
6 Alkaline phosphatase	Bodansky <sup>11</sup>	1 - 4 units per 100 cc

## RESULTS

The values presented in Table II indicate the anticipated results if one were to assume that these procedures would always yield results of differential diagnostic value. The values given are admittedly arbitrary. It is well known that certain cases of diffuse liver disease exhibit functional changes that are very similar to those produced by mechanical obstruction of the extrahepatic bile ducts. Such instances may be considered examples of cholangiolar dysfunction. However, the majority of cases of hepatitis and cirrhosis might be expected to exhibit hepatocellular dysfunction and to conform therefore to anticipated results insofar as these tests are concerned.

The actual values obtained in the different types of jaundice are given in Tables III to VIII. The cases have been arranged in order of the increasing duration of jaundice insofar as the duration could be ascertained from the history. The numbers in italics in these tables indicate instances in which the actual results fail to conform with those listed in Table II as anticipated results. These data have been tabulated in Table IX.

TABLE II ANTICIPATED RESULTS IN BIOCHEMICAL TESTS EMPLOYED IN PRESENT STUDY

TYPE OF LIVER DISEASE	CEPHALIN CHOLESTEROL (24 HR READING)	THYMOL TURBIDITY (MACLAGAN)	TOTAL SERUM CHOLESTEROL	CHOLESTEROL ESTER (PERCENTAGE)	ALKALINE PHOSPHATASE (BODANSKY)
Extrahepatic obstruction	1+ or below	0 - 4 units	Above 225 mg per 100 c c	Above 50%	Above 10 units
Parenchymal liver disease	Above 1+	Above 4 units	Below 225 mg per 100 c c.	Below 50%	Below 10 units

*Bilirubin*—In Tables III through VIII, the relationship of the one minute serum bilirubin to the total has been computed as percentage. The data for the serum bilirubin are presented in graphic form in Fig 1 where the cases are arranged in order of increasing duration of jaundice. No consistent pattern of behavior is discernable.

*Serum Cholesterol*—An analysis of Table IX reveals that the total serum cholesterol was below 225 mg per 100 c c in twenty instances in the seventy seven cases of extrahepatic biliary obstruction. Furthermore, the cholesterol esters constituted less than 50 per cent of the total in thirty four cases in this group. The cholesterol ester fraction was below 50 per cent in twenty one of the twenty eight cases in the carcinoma group.

The cholesterol levels failed to correspond with the anticipated results in twenty two of the seventy cases of parenchymal liver disease. The thirty one cases of hepatitis included in these seventy cases represent a more homogeneous group. Even so eleven of these thirty one patients had cholesterol levels greater than 225 mg per 100 c c at the time the multiple tests were performed. Nine of these eleven patients had ester fractions which comprised more than 50 per cent of the total cholesterol.

# Quantitative Serum Bilirubin

Fig 1

The cholesterol data are arranged in Fig 2 in the order of the duration of jaundice

*Serum Alkaline Phosphatase*—The results of the individual tests appear in Tables III through VIII. The instances in which the anticipated values were not obtained are listed in Table IX. It may be seen that the results were quite similar to those obtained with the cholesterol determination. The data are presented graphically in Fig 3 in the order of the duration of jaundice.

TABLE IX NUMBER OF INSTANCES IN WHICH ACTUAL RESULTS FAILED TO CONFORM WITH ANTICIPATED RESULTS

## Serum Cholesterol

Fig

## Alkaline Phosphatase

Fig 3

*Cephalin-Cholesterol Flocculation Test*—For the purpose of this analysis only the reading obtained at twenty-four hours has been considered although both values are presented in Tables III through VIII. The data for the twenty-four hour reading have been arranged according to the duration of

### Cephalin Cholesterol Flocculation at 24 hours

Fig 4

jaundice in Fig 4. Among the seventy-seven cases of extrahepatic biliary obstruction there were four instances in which abnormal, and therefore presumably misleading, results were obtained.

The two patients in the carcinomatous obstructive group (Cases 2 and 5, Table III) both exhibited positive Hanger tests early in the course of their jaundice. In Case 2, the patient, an 83-year-old woman, had jaundice due to a carcinoma of the gall bladder. Subsequent cephalin cholesterol flocculation tests also were positive repeatedly. The patient of Case 5, a 56-year old man, proved to have a carcinoma of the pancreas with hepatic metastases. Serial determinations were not possible in this instance.

There were two proven instances of common duct stone obstruction in which the Hanger test was positive (Cases 38 and 50, Table IV). Jaundice associated with chills and fever had been present for seven days in Case 38, one week later the cephalin cholesterol was only a trace at 24 hours, and though

jaundice had diminished, the other tests remained essentially unchanged. The presence of a positive test in Case 59 was not surprising since the patient had been jaundiced for six months.

There were twenty four cases among the seventy examples of parenchymal liver disease in which the Hanger test was negative. This should occasion no surprise since the group is a heterogeneous one, and save for the thirty one cases of hepatitis, uniform results would be unlikely.

### Thymol Turbidity Reaction

Fig 5

**Thymol Turbidity**—The data relating to the thymol turbidity test obtained from Tables III through VIII, are arranged graphically in Fig 5 according to duration of jaundice. Inspection of Table IX and Fig 5 reveals that the test gave positive results (values greater than 4 units) in four cases of carcinoma and one each in the patients with calculus or stricture.

Among the cases of cancerous jaundice with abnormal thymol turbidity tests three patients (Cases 2, 17 and 26) had values just slightly above the level of 4 units which is taken as the dividing line. Case 12 revealed a value of 9 units. Only one patient in the group of calculus jaundice had a value above 4 units. This was Case 52 with 5 units. Similarly one patient (Case 75 Table V) with a long standing stricture of the bile duct revealed a thymol test of 6 units.

The seventy cases of parenchymal liver disease included twenty four instances in which the thymol turbidity test was not elevated (Table IX).

**Multiple Tests**—The principal purpose of this study was to determine the merit of multiple laboratory tests that can be performed on a single sample of serum. It is therefore necessary to analyze briefly how often certain combinations of these procedures gave misleading information. It is evident that the

quantitative van den Bergh reaction (Fig 1) failed to give information of differential diagnostic value in this series of cases of regurgitation jaundice. The serum bilirubin will not, therefore, be considered further in relation to any combination.

The ester fraction of the serum cholesterol, when expressed as per cent of the total, failed to conform to the anticipated results in thirty-four cases in the extrahepatic obstructive group. In thirty-two cases in the parenchymal jaundice group the value of the cholesterol ester fraction was greater than 50 per cent and may, therefore, be considered unexpected. Because there appeared to be so much overlapping of values irrespective of what percentage level was chosen, this particular determination also will be eliminated from the present discussion of multiple tests.

Four procedures—the total cholesterol, the alkaline phosphatase, the cephalin-cholesterol flocculation, and the thymol turbidity—remain then for comparison. This comparison can best be made by examining the cases according to the established diagnoses.

*A Carcinoma* Results opposite to those anticipated were encountered in two cases, two of the four tests proved to be misleading. Case 2, in which both the cephalin-cholesterol and the thymol test were positive, has been discussed previously. The results were consistent on repeated examinations during the forty-five days that the patient survived. This was the only case in the group of seventy-seven surgical patients in which both the cephalin cholesterol and the thymol turbidity were simultaneously positive and thereby misleading.

Case 5 also has been discussed previously. In that instance the cephalin cholesterol flocculation value at 24 hours was 2 plus and the total cholesterol was only 198 mg per 100 cubic centimeters. Only one set of determinations was made in this patient.

*B Common Duct Stone* In one patient (Case 59) in this group, three of the four tests under discussion were misleading. This elderly man had been jaundiced for six months. The total cholesterol was only 138 mg per 100 cc, the cephalin-cholesterol reading was 2 plus, and the alkaline phosphatase value was 9 Bodansky units. Obstruction to bile outflow was presumably high grade since the total serum bilirubin at this time was 9.9 mg per 100 cubic centimeters. The fecal urobilinogen was not determined, but the presence of increased urobilinogen in the urine indicated incomplete obstruction.

In six cases in this group, two of the four tests failed to conform to the expected results. In each of these six instances (Cases 30, 32, 34, 40, 43, and 66) the total cholesterol ranged from 100 to 164 mg per 100 cc and the alkaline phosphatase was not elevated above 10 Bodansky units. The negative flocculation and turbidity tests in these instances were thus most helpful from the differential diagnostic standpoint.

*C Stricture* In no instance in these ten cases was more than one of the four tests incorrect in any one patient.

*D Cirrhosis* The results listed in Table IX indicate that the individual tests were frequently misleading in the twenty six cases of cirrhosis. In Case

98 all four of the procedures under discussion yielded results that were misleading as judged by the arbitrary standards. This patient did have a cirrhosis as proved by the surgical biopsy specimen. The patency of the bile duct was established by cholangiography at the time of surgery. The patient was believed to represent an example of cholangiolitic cirrhosis<sup>14</sup>. Further evidence of the regurgitation of bile was the elevated blood bile acid patient, 38, control 0.7 mg per 100 cc as determined by the method of Josephson<sup>15</sup>.

Four cases (Cases 93, 95, 97 and 99) gave results that were misleading with three of the four tests. These results were particularly disturbing in Cases 95 and 99 because both the thymol turbidity and the cephalin cholesterol tests gave normal values and the phosphatase levels were high. Both patients were middle aged women with jaundice of long standing and cirrhosis of unknown etiology. The patency of the bile ducts was established in each instance by subsequent exploratory operation. The cirrhotic process was not due to biliary stricture or ascending cholangitis so far as could be determined. In the remaining two instances (Cases 93 and 97) the thymol turbidity alone behaved in the expected fashion. Necropsy performed in Case 93 revealed a finely nodular 2625 gram liver that was classified as a portal cirrhosis of the Laennec type by the pathologist. The bile ducts were patent, the gall bladder had been previously removed surgically. In Case 97 the patient had had jaundice and pruritus of six years. A biopsy diagnosis of cirrhosis had been made previously and the patency of the bile duct established by operation. Although the cholesterol and phosphatase values were not remarkably elevated the blood bile salt level was (patient 4.1 control 0.7 mg per 100 cc). Clinically this patient also was believed to represent an instance of cholangiolitic cirrhosis.

In ten cases in the cirrhotic group two of the four tests proved to be misleading. In two of these Cases 79 and 82 this was especially serious in that both the thymol turbidity and the cephalin cholesterol tests gave negative results. Thus biochemically they closely resembled the previously mentioned six cases of common duct stone that failed to show the expected elevations of cholesterol and phosphatase. The other eight cases were characterized mainly by misleading elevations of the cholesterol or phosphatase (Table VI).

*E Hepatitis* The figures listed in Table IX show considerable deviation from the anticipated results in the thirty one cases of hepatitis. The results are slightly superior to those obtained in cirrhosis however possibly because this is a more homogeneous group. The criticism may be made that we have employed certain biochemical tests to establish a diagnosis of hepatitis and then have proceeded to use this diagnosis to demonstrate the value of the tests. This weakness in such a study is appreciated but in the absence of any specific biologic tests for virus hepatitis all such diagnoses in the absence of a biopsy must be based on clinical features and course.

In two cases in this group the results of these four tests were quite misleading in that three of the four procedures gave results more in keeping with the arbitrary standards listed for extrahepatic obstruction. Case 108 (Table VII) failed at any time to show a positive result by either the Hangei or the

Maclagan tests and the initial cholesterol level was 230, serial observations showed a rise to 398 mg per 100 cc and an eventual decline to 225. Yet, the clinical course appeared to leave little doubt that the jaundice was due to hepatitis. Complete recovery ensued after a three-week illness, subsequent examination by cholecystography revealed a normally functioning gall bladder. Case 129 (Table VII) was very similar in regard to these tests. The patient was followed by serial tests at intervals of one week. The tests performed during the fifth and sixth weeks revealed total serum bilirubin levels of 2.6 and 1.5 mg per 100 cc respectively. On these two occasions only, the cephalin-cholesterol test was 2 plus and the thymol test 6 units. Subsequent values were again normal and complete clinical recovery ensued.

In six of the cases of hepatitis, two of the four procedures gave misleading results. In three of these (Cases 112, 116, and 124) the cholesterol and the phosphatase were elevated rather than normal or decreased as might be expected in hepatitis, the abnormal turbidity and flocculation tests were therefore of considerable diagnostic value in these two instances. Cases 131 and 134 failed to demonstrate cephalin-cholesterol values greater than 1 plus at 24 hours and the total cholesterol values were higher than might be anticipated in hepatitis. The thymol turbidity value was only 2 units and the alkaline phosphatase level was 11 Bodansky units in Case 104.

*F Miscellaneous Hepatic Disease* This small group of thirteen patients has been included in this study chiefly because they had sufficient elevation of the serum bilirubin to conform with the criteria previously listed and because the tests under consideration were performed simultaneously. In general, the clinical nature of their illnesses was such that tests of liver function were not employed particularly for differential diagnosis. If judged arbitrarily, however, the results of the tests were misleading in most instances. The serum cholesterol showed to best advantage in this group. The low value in Case 147 was particularly striking. At necropsy, this 27-year-old woman was found to have a markedly fatty liver as a complication of severe and intractable ulcerative colitis of three months' duration.

#### DISCUSSION

The purpose of this study was to evaluate the merits of what has been termed a "minimal yet adequate" program of liver function studies in the differential diagnosis of jaundice.<sup>4</sup> For this analysis, the program has been minimal since only the initial single set of determinations obtained in each patient has been evaluated. The limitations and merits of the individual tests have been so frequently and thoroughly discussed in current literature that no attempt will be made to review that aspect here. The group of tests employed in this study can be performed on a single sample of serum and technically represent procedures that are well within the range of a modern hospital laboratory. The merits of these procedures in differential diagnosis have been subjected to critical testing on the basis of rather arbitrary standards.

The quantitative van den Bergh reaction when used as a means of determining the bilirubin content of the serum has much to recommend it. The very real clinical value of the test in differentiating retention and regurgitation jaundice has been mentioned. Malloy and Evelyn<sup>16</sup> indicated that the quantitative van den Bergh did yield results that would permit the differentiation of the various forms of regurgitation jaundice—a view shared by Meakins.<sup>17</sup> Ducci<sup>18</sup> indicated on the basis of his extensive experience in 1,770 cases, that the percentage of the prompt direct reacting bilirubin bore some relationship to the type of jaundice. In hepatocellular jaundice he observed the value to be "over 50 per cent," in incomplete obstructive posthepatic jaundice, "generally over 60 per cent," and in complete obstructive posthepatic jaundice, "generally over 70 per cent." In the present small series of cases the relationship of the degree of biliary obstruction to the behavior of the serum bilirubin has not been studied. It is apparent from Fig. 1 that the levels of the one minute and the total bilirubin and the percentage relationship were too variable to have diagnostic significance.

The serum cholesterol levels and particularly the level of the cholesterol ester in the jaundiced patient have long been employed to good advantage. We have been repeatedly impressed with the merit of serial determinations of the total and esterified cholesterol in evaluating the severity of liver damage. The occurrence of low values for the total serum cholesterol in jaundice usually indicates severe hepatocellular dysfunction. This is particularly true when there is an associated sharp reduction in the concentration of the esterified fraction.<sup>18, 21</sup> The results obtained in the twenty-eight cases of jaundice due to cancer indicate that the cholesterol ester fraction did not increase to the same degree as did the free form. In four of the cases (Table III) the total cholesterol was greater than 225 mg per 100 cc and the ester fraction comprised more than 50 per cent. In nineteen of the cases, though the total cholesterol exceeded 225 mg per 100 cc, the ester fraction was below 50 per cent. In nine of these nineteen cases the absolute value for the ester was below 100 mg per 100 cubic centimeters.

In the instances of calculus jaundice (Table IV) twenty of the thirty-nine patients exhibited total cholesterol values greater than 225 mg per 100 cc and esterified fractions greater than 50 per cent. Seven of these had total cholesterol values greater than 225 mg per 100 cc with less than 50 per cent esterified. However in only two of these cases was the absolute value for the ester below 100 mg per 100 cubic centimeters.

On the basis of this limited number of cases it might be suggested that this difference of behavior of the serum cholesterol ester in cancerous and calculus jaundice has some diagnostic significance. It should be noted that Epstein and Greenspan<sup>19</sup> found elevated cholesterol ester levels as well as elevated total cholesterol levels in 75 per cent of their fifty-two cases of jaundice due to cancer, a finding at variance with earlier reports.<sup>21</sup> Reduced serum cholesterol ester percentages in jaundice due to cancer have been recorded by others.<sup>2</sup> This

and other aspects of the serum cholesterol behavior in jaundice do not warrant undue emphasis, however. Snell<sup>24</sup> has indicated the difficulties encountered in attempting such correlations.

The variations of the serum alkaline phosphatase activity in jaundice have been utilized for diagnostic purposes since 1933.<sup>25, 26</sup> Gutman and associates<sup>27</sup> reported that the majority (approximately 90 per cent) of cases of extrahepatic biliary obstruction had levels of alkaline phosphatase activity greater than 10 Bodansky units. In many cases of diffuse liver damage, the alkaline phosphatase failed to exceed 10 Bodansky units. The diagnostic merits of combining the phosphatase determination with the cephalin-cholesterol flocculation test<sup>28</sup> or with the thymol turbidity test<sup>29</sup> have been described. The results of the present study are in agreement with the observations<sup>27</sup> that there is better correlation of elevated alkaline phosphatase in jaundice due to cancer than in that due to calculus obstruction (Table IX). The fact that certain cases of diffuse liver damage have phosphatase values greater than 10 Bodansky units is also well recognized.<sup>27</sup> The results shown in Table IX and in Fig. 3 bear this out.

The present study indicates that the cephalin-cholesterol and thymol turbidity tests, when considered together, were seldom misleading in the surgical cases. In only one instance in the seventy-seven cases of extrahepatic obstruction (Case 2) were both tests simultaneously positive on this single examination. The opposite aspect, that is the failure of the tests to exhibit positive reactions in the presence of parenchymal liver disorders, is more common. The two instances in the hepatitis group in which both tests were negative (Cases 108 and 129) have received comment. There were five such instances in the cholelithic group and seven in the miscellaneous group.

It seems apparent from recent observations that the zinc turbidity test of Kunkel<sup>30</sup> yields fewer false positive reactions in cases of extrahepatic biliary obstruction than does the thymol turbidity. As Popper and associates<sup>31</sup> have observed, the zinc turbidity test will likely prove to be of additional aid in the laboratory diagnosis of jaundice.

In summary, it may be stated that certain characteristic biochemical responses do occur fairly uniformly as the result of hepatic disease and bile duct obstruction. Most cases of extrahepatic bile duct obstruction exhibit elevated cholesterol and alkaline phosphatase levels and have normal responses to the thymol turbidity and the cephalin-cholesterol flocculation tests. Many cases of jaundice due to diffuse liver disease exhibit biochemical changes of an opposite nature, consequently such tests have differential diagnostic value. Certain cases of parenchymal liver disease exhibit changes that closely parallel those seen in extrahepatic obstruction, i.e. elevated cholesterol and phosphatase values and normal responses to flocculation and turbidity reactions. This constitutes a limitation of the use of so called tests of liver function in differential diagnosis that must be accepted. It is a reflection of a basic pathologic phenomenon—the diffuse liver damage existing in hepatitis and cirrhosis mix-

manifest itself with varying emphasis on hepatocellular or cholangiolar functional impairment. Hepatocellular functional impairment may be regarded as the classical type and the resultant biochemical changes are quite characteristic and readily recognizable. When cholangiolar functional impairment predominates in cases of hepatitis and cirrhosis, the results of the tests under discussion may prove misleading insofar as differential diagnosis is concerned.

#### CONCLUSIONS

1 The results of five biochemical procedures (bilirubin, cholesterol, phosphatase, cephalin cholesterol flocculation and thymol turbidity) applicable to a single sample of serum have been analyzed as to their respective merit in the differential diagnosis of jaundice.

2 The results in seventy seven patients with jaundice due to extrahepatic biliary obstruction have been contrasted with those obtained in seventy patients with jaundice due to parenchymal liver disease.

3 The results of these tests in jaundice due to extrahepatic obstruction were fairly uniform, nevertheless deviation from the anticipated results in two or more of the tests occurred in ten instances.

4 The results of these tests in jaundice due to parenchymal liver disease were variable. They were adequate from a diagnostic standpoint in the cases where hepatocellular dysfunction predominated. In a significant number of cases, cholangiolar dysfunction apparently predominated and the results of the tests resembled those seen in extrahepatic biliary obstruction.

# EFFECT OF EPINEPHRINE ON VITAMIN A AND GLUCOSE BLOOD LEVELS IN NORMAL AND CIRRHOTIC SUBJECTS

ROBERT W. HILLMAN, M.D.  
NEW YORK, N. Y.

THE role of the liver in the regulation of the blood plasma vitamin A level is poorly understood. Although accorded diagnostic significance in hepatic disorders, the plasma concentration does not necessarily reflect the vitamin A concentration in liver tissue.<sup>1,9</sup> On diets restricted in vitamin A the blood content ordinarily is maintained within the normal range virtually to the point of full tissue depletion. Moreover, although 95 per cent of the body's vitamin A is stored in the liver,<sup>10</sup> the recent work of Sexton and co-workers<sup>11</sup> suggests that this organ may not be, as was hitherto generally believed, the principal site of conversion from the carotene precursor.

Hepatic diseases, however, are often associated with lowered blood vitamin A levels.<sup>12-16</sup> This occurs in cirrhosis in which the vitamin A content of the liver is greatly reduced.<sup>15, 17</sup> The low plasma levels in cirrhosis might reflect an inability to mobilize the vitamin because of decreased body stores.

Young and Wald<sup>18</sup> noted an increase in the blood vitamin A level of rabbits following epinephrine injection. Observations made in this laboratory indicated that the same phenomenon often occurs in normal human subjects.\* This phenomenon was utilized in the present investigation to study the mobilization of vitamin A in patients with cirrhosis. The blood glucose response to epinephrine, which is thought to be a measure of hepatic glycogenolysis<sup>10, 19</sup> and may be otherwise related to vitamin A metabolism,<sup>5, 6, 10, 20, 21, 22</sup> was determined simultaneously.

## MATERIAL AND METHODS

Studies were made in twelve patients with cirrhosis of the liver and twenty-two control subjects, in two of whom the procedure was repeated. Two of the twelve cirrhotic subjects had complicating diabetes mellitus and one (with previous jaundice but no clinical diabetes) was discovered at autopsy to have hemochromatosis. The control group—recruited from non-cirrhotic patients, staff members and medical students—included ten persons with completely normal liver function studies and twelve without clinical evidence of hepatic disease but with one or more often transitory, abnormal function tests. One of each of these groups was diabetic.

The patients with cirrhosis were on a standard high protein, high calorie diet.<sup>23</sup> Except for appropriate diabetic regimens in two cases there was no regulation of food intake among the control subjects.

The test was performed in the fasting state and consisted of the intramuscular injection of epinephrine (0.6 cc. of a 1:1,000 solution). Samples of venous blood† were taken before and at one-half, one and two hour intervals after the injection. Plasma vitamin A (and carotene) levels were determined by the method of Kimble<sup>24</sup> employing the Carr-Price reaction. Blood sugar concentrations were measured by a modified Benedict procedure.<sup>2</sup>

From the Research Service, First (Columbia) Division, Goldwater Memorial Hospital.  
Received for publication June 1, 1949.

The reciprocal phenomenon, i.e. a decrease in the plasma vitamin A level likewise has been observed following injection of an epinephrine antagonist, insulin and, on occasion, following the injection of glucose alone.

†Simultaneous determinations have shown essentially parallel changes in arterial and venous blood plasma vitamin A levels.

## RESULTS

Results are shown in Table I

Following administration of epinephrine, the maximum variation in the direction of initial change is recorded in terms of percentage of the preinjection level of each constituent measured. In the case of vitamin A an increase of 5 per cent or more is arbitrarily regarded as significant, i.e. a positive test. A

TABLE I. BLOOD VITAMIN A, CAROTENE, AND SUGAR LEVELS FOLLOWING THE INTRAMUSCULAR INJECTION OF EPINEPHRINE IN PATIENTS WITH CIRRHOSIS OF THE LIVER (WITH MEAN VALUES FOR THE CIRRHOSIS AND CONTROL GROUPS)

PATIENT	BLOOD SUBSTANCE	BLOOD LEVEL SPECIMEN				PER CENT INITIAL CHANGE
		FASTING	½ HR	1 HR	2 HR

	Sugar					+17 (+ 4 to +156)

(C) Patient receiving carotene

(D) Patient with diabetes mellitus

blood sugar elevation of 30 per cent above the fasting figure is regarded as normal—virtually the same value as that generally accepted for the response to epinephrine<sup>10 13</sup>

In five of twelve (42 per cent) determinations in the cirrhotic group and in ten of twenty four (42 per cent) in the control group there was a significant increase in plasma vitamin A after injection of epinephrine. Among the twelve patients with cirrhosis only one showed a significant increase in both plasma vitamin A and blood sugar levels. The vitamin A level alone rose in four others, while a normal blood sugar elevation occurred in four without a positive vitamin A change. Three individuals showed no significant positive shift in either constituent.

Of the control subjects eight yielded a rise in both blood vitamin A and sugar levels, two an elevation in the vitamin A alone, eleven, in the sugar alone, and three, in neither substance.

Six patients with cirrhosis and seven of the control group showed decreased vitamin A levels after injection of epinephrine.

Blood plasma carotene levels measured as a necessary part of the Kimble procedure, showed no consistent changes in either group and served as a check on possible errors due to faulty sampling or variations in blood volume.

There was no apparent correlation between the initial blood concentration and the magnitude of the individual response. However, the most pronounced reductions in vitamin A levels were exhibited among individuals with low fasting levels.

Of the two control subjects in whom the test was performed twice one exhibited a rise in vitamin A and blood sugar on both occasions and the other showed a vitamin A rise in one and a blood sugar increase in both instances.

#### DISCUSSION

The plasma vitamin A response to the injection of epinephrine is apparently a variable one. While approximately 42 per cent of individuals exhibit an arbitrarily significant increase in plasma vitamin A concentration, the majority show a trend in that direction and only a few undergo a decrease of comparable magnitude. Since an elevation of plasma vitamin A level occurs with virtually the same frequency among patients with cirrhosis as among normal controls the response to injected epinephrine in the dose employed cannot be used as a test of hepatic function. Moreover the frequent failure of control subjects to demonstrate the so called normal mobilization of blood sugar following injection of epinephrine<sup>10 13</sup> casts doubt on the validity of this test as well. This finding is at variance with the opinion recently expressed by Kinsell and associates.<sup>24</sup>

Probably most significant is the demonstration that blood plasma vitamin A levels evidently are not a reliable index of body stores since individuals with abnormally low levels may show an increase in the concentration of this substance in response to injections of epinephrine.

## SUMMARY

Plasma vitamin A and blood sugar responses to injection of epinephrine were determined in twelve patients with cirrhosis of the liver and in twenty two control subjects

A significant increase in plasma vitamin A concentration was observed in 42 per cent of each group. There was no apparent correlation between initial levels and the magnitude of the vitamin A responses. Low fasting concentrations did not preclude a significant increase in plasma vitamin A. There was no correlation between the responses of blood vitamin A and blood sugar to epinephrine administration.

The plasma vitamin A response to epinephrine injection does not appear to be a valid test of hepatic function.

# INTESTINAL PARASITISM IN AMERICAN TROOPS IN GERMANY

## RELATION TO TRANSMISSION OF VIRAL HEPATITIS

PAUL L BURLINGAME, PH D,\* AND HORACE T GARDNER, MD †

WITH THE TECHNICAL ASSISTANCE OF GUENTHER RESEMANN,  
CORPORAL JACK CRANMER, AND ELEONORE VOLLMER

THE epidemiology of the sporadic, endemic hepatitis now occurring in Germany among American Occupation Troops is not clear, and it is impossible, in the absence of precise laboratory methods, to distinguish clinically homologous serum jaundice (SH) ‡ from infectious hepatitis (IH). As the manner of spread of the two infectious agents is different, with consequent difference in methods of prevention and control, it is important to determine which agent is the predominant one in Germany.

It has been shown definitely that the oral-intestinal route may be used to infect human volunteers with the agent of infectious hepatitis (virus IH), by Voegt,<sup>2</sup> by MacCallum and Bradley,<sup>3</sup> and by Havens and co-workers.<sup>4</sup> Whether there are other routes whereby the disease could spread naturally is not known. On the other hand, the virus SH of "homologous serum hepatitis" has not been transmitted by the oral route—with two possible exceptions<sup>6, 7</sup> which American workers<sup>8, 9, 10, 11</sup> have been unable to confirm. It was thought that at least a partial idea of the amount of fecal contamination in the food of soldiers with hepatitis might be gained by surveying the amount of intestinal parasitism present among them and by comparing the findings with those of soldiers in other Army hospitals who did *not* have hepatitis, with presumably healthy soldiers, and with the indigenous German personnel employed in Army messes.

Although as an oblique study of one facet of the epidemiological problem involved, no significant information was acquired, the findings of widespread intestinal parasitism in American troops in Germany seems worth reporting to call attention to the high incidence of parasitism in all groups studied.

## MATERIALS AND METHODS

At the Hepatitis Research Center, 220 patients with hepatitis were examined. The patients were in all stages of the disease, from the acute period to convalescence. The diagnosis of hepatitis had been established by the history, the appearance of icterus, and liver function tests. Patients with carbon tetrachloride poisoning with icterus were excluded from the series, as were patients in whom the diagnosis was doubtful or in whom the icterus had been determined to result from cholelithiasis.

From the Hepatitis Research Center 120th Station Hospital and the 4th Medical Laboratory European Command United States Army.

This study was conducted in cooperation with the Commission on Virus and Rickettsial Diseases of the Army Epidemiological Board Office of The Surgeon General United States Army Washington D C with the approval and interest of Maj Gen D A Noyes The Chief Surgeon EUCOM and Lt Col Carl V Lind MC Commanding Officer of the 4th Medical Laboratory to whom appreciation is expressed.

A preliminary report of some of this work has appeared in the Medical Bulletin EUCOM.<sup>12</sup>

Received for publication June 14 1949

\*4th Medical Laboratory United States Army EUCOM APO 403

†Now at the Section of Preventive Medicine Yale University School of Medicine New Haven Conn

‡The terms SH and IH have been suggested by Neefe<sup>1</sup> to designate homologous serum jaundice and infectious hepatitis respectively

As a comparable hospital population, the EUCOM Orthopedic Center (to which, as to the Hepatitis Center, patients are sent from all parts of Germany and Austria) was selected, and 116 orthopedic patients without hepatitis were examined. In addition, a survey of 138 patients on all services in the 279th Station Hospital in Berlin (excluding those with hepatitis awaiting shipment to the Hepatitis Center) was made. This hospital was selected because it receives patients chiefly from the Berlin area where the rate of hepatitis is somewhat higher than in the remainder of Germany and is, furthermore, not in a highly endemic area for any particular parasite while the Orthopedic Center was at Stuttgart where there is a high incidence of ascariasis among the indigenous population. The incidence of intestinal protozoa is quite uniform throughout the American Zone of Occupation. In addition, 190 presumably healthy soldiers from the hospital in Berlin were examined. At the same time parasitological examinations on the stools of 213 indigenous personnel\* employed in the hospitals were made, results of which have been combined with the findings on previous surveys (July, 1947, to April 1948) of 1492 indigenous mess personnel from various Army installations all over Germany. Altogether a total of 644† military‡ and 1705 indigenous personnel are herewith reported. The composition of the groups examined and the findings are given in Table I.

TABLE I INCIDENCE OF PARASITISM IN AMERICAN AND INDIGENOUS PERSONNEL IN THE AMERICAN ZONE OF OCCUPATION GERMANY

GROUPS SURVEYED	1	2	3	4	TOTALS OF GROUPS 1, 2 3 4	5
DATE OF SURVEY	NOV 1947	APR 1948	JAN 1948	APR 1948		JUL 1946 APR 1948
NUMBER OF PERSONS	212	111	134	187	644	1705
Endamoeba histolytica	35 (16%)	12 (11%)	13 (10%)	14 (7%)	74† (11%)	25%

Persons harboring parasites	128 (60%)	71 (64%)	70 (52%)	93 (44%)	302 (50%)	78%

- Group 1 120th Station Hospital Army Hepatitis Center Bayreuth
- Group 2 387th Station Hospital Army Orthopedic Center Stuttgart
- Group 3 Patients 79th Station Hospital Berlin
- Group 4 Detachment personnel 29th Station Hospital Berlin
- Group 5 Indigenous personnel employed in Army messes

†Large races only 20 large and small races together 3 small races only 31 Cysts only 44 cysts and trophozoites 1 trophozoites only 9

‡Parasitized individuals harbored from one to five species

Combined in Table I with 1492 indigenous personnel surveyed between July 1946 and November 1947. By indigenous personnel here is meant Germans employed in Army in stations

†Twenty persons included in a preliminary report<sup>1</sup> are here omitted because they either gave a foreign home address or gave no home address

‡Including twenty five United States civilians and dependents

Three techniques were employed on each stool (1) iron hematoxylin stained smears, (2) zinc sulfate centrifugal concentration, and (3) thick fecal smears, fixed and dehydrated in 95 per cent and 100 per cent alcohol and cleared in xylol. One zinc sulfate concentration, two hematoxylin smears, and two transparent thick smears were examined for each stool. Each person was given a saline purge and requested to submit a warm, soft, unformed stool sample, with a completed questionnaire. One stool sample from each person was examined. The same procedure was followed in all surveys previously conducted on indigenous food handlers in Army messes.

### RESULTS

A tabular presentation of the survey is shown in Table I. The possible effect of disproportionate numbers of persons with previous residence in "southeastern states" of the United States and with tropical service in the various groups and the groups in which trophic forms of protozoa might exist are indicated in Table II. While only 50 per cent of the stools obtained at the Hepatitis Center were actually unformed, a large percentage of the formed stools were soft and were promptly delivered to the laboratory. The material obtained at both Bayreuth and Stuttgart was quite comparable with that obtained from indigenous personnel for several previous surveys.

TABLE II INCIDENCE OF PARASITISM IN RELATION TO THE PERCENTAGE OF PERSONS FROM SOUTHEASTERN STATES AND WITH TROPICAL SERVICE EXAMINED, AND THE NATURE OF THE STOOL SAMPLE EXAMINED

	INCIDENCE (%)	INFESTATIONS 1,000	PER CENT FROM SE STATES	PER CENT WITH TROP ICAL SERVICE	PER CENT UNFORMED STOOLS
Stuttgart	64	1,252	45	23	80
Bayreuth	60	1,028	41	16	50
Berlin, patients	52	798	37	18	35
Berlin, detachment personnel	44	743	34	13	24
Mean	55	935	38.8	16.8	45

Table III shows the incidence of parasitism among persons from southeastern states as compared with that of persons from all other states combined. Thirty-two† (13 per cent) of 250 persons who gave a permanent address in a southeastern state harbored hookworm. Fifteen persons (6 per cent of 250) harbored no other parasites.

One hundred and eight (16.8 per cent of 644) persons had served in the tropics. Sixty per cent harbored intestinal parasites. Sixteen (21.6 per cent) of 74 persons who harbored *Endamoeba histolytica* had been in the tropics.

TABLE III INCIDENCE FOR PERSONS FROM SOUTHEASTERN STATES AS COMPARED WITH PERSONS FROM OTHER STATES

	SOUTHEASTERN STATES (%)	OTHER STATES (%)
Stuttgart	66	62
Bayreuth	69	54
Berlin, patients plus detachment personnel	63	39
Mean incidence	65	47

\*Alabama, Arkansas, Florida, Georgia, Kentucky, Louisiana, Maryland, Mississippi, North Carolina, Oklahoma, South Carolina, Tennessee, Texas, Virginia, West Virginia. District of Columbia, Arkansas, Oklahoma, and Texas are included because of the presence of hookworm in certain areas.

†One person from California (with tropical service) and one person from the state of Washington (with no tropical service) also harbored hookworm.

The incidence for persons (all groups combined\*) who had been in Germany one year or less was 50 per cent from not less than one year to two years, 55 per cent, and for more than two years, 48 per cent. In a group of 224 persons who were from states other than southeastern and who had not been in the tropics, incidences were, for these respective periods, 51 per cent, 47 per cent, and 55 per cent.

Fifteen (43 per cent) of 35 colored soldiers harbored parasites.

Seven women patients, 6 of whom harbored parasites, are included in the Berlin survey.

Of 633 persons who stated their age, 36.2 per cent were from 17 to 20 years of age, 30.6 per cent, from 21 to 25, 16.8 per cent from 26 to 30, and 16.4 per cent were over 30 years of age. In the hepatitis group alone the percentages in these respective age groups were 40 per cent, 25.7 per cent, 20.6 per cent, and 14.3 per cent, and the percentages harboring intestinal parasites in these age groups were 62 per cent, 69 per cent, 57 per cent, and 53 per cent. For all surveys combined the percentages harboring parasites in the four age groups were 53 per cent, 62 per cent, 52 per cent, and 43 per cent.

Sixty-five persons (10.1 per cent) of 644 stated they had had, at the time of the stool examination or within the recent past, one or more episodes of diarrhea. Thirty-nine of these 65 were in the group with hepatitis. Thirty-four (52 per cent) of the 65 harbored intestinal parasites. The percentage of persons with a history of diarrhea was for each group as follows: hepatitis patients, 18.4 per cent, orthopedic patients, 3.6 per cent, Berlin patients (all services), 5.8 per cent, Berlin detachment, 6.4 per cent. Of those harboring *E. histolytica*, 31.4 per cent gave a history of diarrhea. For other organisms the percentages were: *Giardia lamblia*, 17.6 per cent, *Chilomastix mesnili*, 25 per cent, *Dientamoeba fragilis*, 4.4 per cent, hookworm, 8.8 per cent.

The patients and detachment personnel at Berlin may be considered as representative residents of that particular area. The patients at the Hepatitis and Orthopedic Centers are drawn from all parts of the American Zone of Occupation.

#### DISCUSSION

As an oblique approach to the problem of the transmission of "infectious hepatitis" in Germany—one aspect of which may be the contamination of food and water with fecal material—surveys for intestinal parasites have been made on 644 healthy and hospitalized American personnel. The incidence of parasitism in the group with hepatitis was 60 per cent and in a group of orthopedic patients in another hospital the incidence was 6.4 per cent. A third group of hospitalized persons (all services) had an incidence of 52 per cent, and the incidence in a group of hospital detachment personnel was 4.4 per cent. An average of 55 per cent harbored from one to five species of parasites.

The variations in incidence found are probably attributable more to such variable factors as former residence in the southeastern part of the United

\*Persons with hookworm only. In this instance were regarded as showing negative results since the acquisition of hookworm in Germany is highly unlikely.

States, tropical service, and, perhaps mainly, the character of the stool sample examined than to any considerable difference in the amount of fecal contamination of food and water to which any one group had been exposed

There may be a real difference in the incidences for persons from south eastern states and from other parts of the country, partly attributable to hookworm infestations. However, in the group that contained the highest percentage of persons from southeastern states, and which submitted the most suitable material for stool examinations, no difference is to be noted

The average incidence for 1,705 indigenous personnel was 78 per cent, with parasitized individuals harboring from one to seven species. If the incidence of parasitism among Americans has been affected by environmental conditions in Germany or by contact with indigenous personnel, it is not apparent in the present study. No appreciable increase or decrease in incidence with continued residence in Germany was found

#### SUMMARY

1 A survey of intestinal parasitism among American Occupation Forces in Germany and indigenous German personnel is presented and compared with the incidence of intestinal parasitism in patients suffering from acute and chronic hepatitis. No significant difference between patients with hepatitis and other groups was noted

2 The average incidence of intestinal parasitism among hepatitis patients was 60 per cent, while the average in other hospitalized patients was 55.3 per cent. The average in apparently healthy American soldiers was 44.0 per cent, while in indigenous personnel it was 78 per cent. An analysis of the individual parasites in each group is presented

3 A discussion of the significance of these findings in relation to other factors is presented

# PRIMARY HISTOPLASMOSIS WITH RECOVERY OF HISTOPLASMA CAPSULATUM FROM THE BLOOD AND BRONCHIAL SECRETIONS

RALPH H KUNSTADTER, M D , FRANCES C WHITCOMB, M S , AND  
ALBERT MILZER, M D , PH D  
CHICAGO, ILL

**D**URING the course of studies on the significance of skin sensitivity to fungus antigens of children with acute respiratory infections and pneumonia,<sup>1</sup> we had the opportunity to observe the clinical course and carry out bacteriologic and serologic studies in a case of primary pulmonary histoplasmosis in a 12 year-old colored boy. We believe that this case is of particular significance because it adds further support to increasing reports concerning the benign nature of histoplasmosis and completes the missing picture comprising the initial infection and progress through the phase of healing. The infection was followed from the onset to complete recovery with beginning calcification. As far as we know, this is the first case of proved active primary pulmonary histoplasmosis to be reported in a child who was born and reared in the Chicago area.

## CASE REPORT

J G , a 12 year old colored boy who has been observed in the outpatient cardiac clinic for the past four years following an attack of rheumatic fever with carditis, was admitted to Sarah Morris Hospital on Sept 4, 1948, with a tentative diagnosis of recurrent acute rheumatic fever. This patient was born and reared in Chicago and never left Illinois. He developed rheumatic fever and carditis at the age of 9 years. He made a good recovery but was left with mitral insufficiency and some cardiac enlargement. During the past three years he attended a summer camp for cardiac patients and has been in good health. During the years preceding the attack of rheumatic fever he had measles and mumps. The family history was noncontributory except that a sister, 12 years old, died in April, 1944, of rheumatic heart disease. Also a brother, 18 years old, died in March, 1948, with a clinical diagnosis of pulmonary tuberculosis, but no autopsy was done.

Five days before admission, the patient had returned from a summer camp for cardiac patients located near Chicago. On the day of his return he complained of a head cold and headache. He had a slight nonproductive cough and a fever. The day before admission to the hospital he complained of pain in his left elbow, unaccompanied by swelling.

Physical examination revealed a well developed and well nourished colored boy of 12 years who did not appear acutely ill. The temperature was 102.6° F, respiratory rate, 28 per minute, and the pulse rate, 82. The positive findings were moderate nasal congestion, slightly enlarged anterior cervical lymph nodes, slight cardiac enlargement to the left, a loud blowing systolic murmur at the apex which was transmitted to the axilla, and an early diastolic murmur at the apex and base. The lungs were clear, the liver and spleen were not enlarged, and the extremities appeared normal. The laboratory findings are summarized in Table I.

An x ray of the chest on September 7 revealed clear lung fields and slight cardiac enlargement (Fig 1). Skin tests done on September 7 with histoplasmin\* and tuberculin gave positive reactions with 7 mm and 13 mm indurations respectively, while skin tests

From the Sarah Morris Hospital for Children and the Department of Bacteriology and Virology, Medical Research Institute, Michael Reese Hospital.

Aided by a grant from the Committee on Scientific Research of the American Medical Association. Supported in part by the Michael Reese Research Foundation.

Received for publication June 15 1949.

\*Fungus antigens were used in dilutions of 1:10000. PPD was used in dilution of 0.0001 milligram.

TABLE I SUMMARY OF LABORATORY DATA

DATE	9/4/48	9/7/48	9/14/48	11/17/48	12/7/48
Red cell count	3.6 mil	—	4.0 mil	3.9 mil	3.9 mil
Hemoglobin	11.2 Gm	—	11.2 Gm	11.9 Gm	12.6 Gm
White cell count	5,900	—	5,200	6,500	6,000
Differential count (%)					
Neutrophils	14	—	50	52	69
Lymphocytes	70	—	38	30	23
Eosinophils	3	—	1	2	0
Basophils	1	—	0	1	0
Monocytes	7	—	11	15	8

Weltmann reaction	—	5	—	5	—
Blood cultures	Negative	—	—	II capsula tum iso lated	—

with blastomycin, coccidioidin, and torulin were negative. On symptomatic treatment the patient's temperature became normal after forty-eight hours and he made an uneventful recovery. There were no significant changes in the cardiac findings. The patient was discharged from the hospital on Sept 15, 1948, eleven days after admission.

**Second Admission.**—The patient was readmitted to the hospital on Nov 17, 1948, with a history of malaise and fever for one day. The temperature was 104° F, pulse rate, 104, and respiratory rate per minute 22. The blood pressure was 130 mm of mercury systolic and 62 mm diastolic. Pertinent findings were injected pharynx, moderate injection of both eardrums, and cardiac findings indicative of mitral stenosis and regurgitation and aortic regurgitation. The pertinent laboratory data are shown in Table I.

The patient was given penicillin and salicylates. His temperature dropped from 104° F on the day of admission to a maximum of 101° F on the following day. Subsequently, a low grade fever up to 100.2° F persisted for an additional eight days, the total duration of fever being ten days. During this period the patient did not appear ill despite the fact that a large pulmonary infiltration was observed in the left lung on November 18 (Fig 2). Occasionally he had a slight nonproductive cough. On November 24 physical findings indicative of pulmonary disease were observed for the first time, consisting of slight dullness and increased breath sounds at the base of the left lung. No rales were heard. Although the patient was asymptomatic ten days after admission to the hospital, x-rays of the chest showed exceedingly slow clearing, and at the time of discharge on December 17, there was only about 50 per cent clearing of the pneumonic process (Figs 3 and 4). An x-ray of the chest taken on Jan. 4, 1949, revealed further clearing and a soft nodular density in the fifth left interspace. Furthermore, a small area of greater density was present in the sixth left interspace which appeared to be beginning calcification (Fig 5). On March 21, the infiltration had completely disappeared and minute areas of calcification were present in both the fifth and sixth left interspaces (Fig 6). The last film taken on May 9 showed no significant changes as compared with that of March 21. Skin tests performed on Dec 1, 1948, with histoplasmin and tuberculin showed 20 mm and 10 mm indurations respectively, while tests with blastomycin, coccidioidin, and torulin remained negative.

#### BACTERIOLOGIC STUDIES

On admission the throat culture was positive for *Staphylococcus aureus*, and no fungi were isolated. Blood cultures were negative. A blood culture obtained on November 17 during the second admission was positive for *Histoplasma capsulatum* in the yeast phase after incubation in beef infusion broth.

Fig 1—Roentgenogram of the chest taken Sept 7 1948 at the time of first admission. The hilar lymph nodes appear larger than normal. The lung fields are clear.

Fig 2—Roentgenogram of the chest taken Nov 18 1948 at the time of second admission. There is a large parenchymal infiltration in the left mid-lung field. There is little change in the appearance of the hilar lymph nodes.

Fig 3—Dec 9 1948. Since the previous examination of Nov 18 1948 there has been about 50 per cent clearing of the infiltrative process in the left lung.

Fig 4—Dec 15 1948. Since the examination of Dec 9 1948 there has been only light clearing of the infiltration in the left lung.

1-4-49

3 21-49

Fig —Jan 4 1949. There is still considerable infiltration in the left mid lung field. There is an area of focalization in the region of the fifth left interspace. In the sixth left interspace there is a small circumscribed area of greater density that appears to be beginning calcification.

Fig 0—March 21 1949. There is complete clearing of the infiltration in the left lung. Minute areas of calcification are present in both the fifth and sixth interspaces. There is an increased amount of calcification in both hilar areas.

Fig —Tuberculate chlamydospores of *Histoplasma capsulatum* recovered from the blood on Nov 17 1948

for seven weeks at 37° C (Fig 7) No bacteria were isolated A throat culture at this time showed anhemolytic streptococci and *Alcaligenes faecalis* Repeated gastric washings were negative for acid-fast bacilli or pathogenic fungi in direct smear and culture Bronchoscopic specimens obtained on December 10 were negative for acid-fast bacilli in smear and culture However, one of six mice inoculated with bronchial material and sacrificed six weeks later showed lesions in the liver and spleen from which *H capsulatum* was recovered

#### SEROLOGIC STUDIES (TABLE II)

Complement fixation tests with undiluted serum carried out on December 1 showed a 4+ reaction with the histoplasmin antigen (lot H-15, 1:100 dilution), on December 20 the reaction was 3+ while on April 2, 1949, the reaction decreased to 2+ The technique described by Tenenbeig and Howell<sup>2</sup> and Fulcolow and co-workers<sup>3</sup> was employed in the complement fixation tests Complement fixation tests carried out simultaneously with blastomycin antigen gave negative results Virus and rickettsia complement fixation tests for psittacosis pneumonitis group, Q fever, and influenza A and B on some specimens of this sera were repeatedly negative Serum drawn on December 22 was positive in 1:20 dilution (4+) with lymphocytic choriomeningitis antigen but was negative with serum drawn on April 2 Repeated tests for heterophile and cold agglutinins were negative

#### DISCUSSION

Although a great deal has been written concerning benign histoplasmosis, pulmonary calcification, and recovery from systemic histoplasmosis, relatively little has appeared describing in detail the previously hypothesized primary phase, which in all probability represents the link between the initial infection and pulmonary calcification Mention is made of noncalcified pulmonary infiltrates by Dickie and Clark,<sup>4</sup> but these authors failed to describe the initial infection and the progress of the lesions

Sontag and Allen<sup>5</sup> recently correlated the presence of calcific and precalcific pulmonary lesions with histoplasmin sensitivity in a study of 170 "normal" children These authors, however, mention no attempt to isolate an etiologic agent Serial x-rays were made over a period of many months and it was possible to study progressive changes in the lungs from the onset of the initial lesion through the period of calcification Their studies showed "a

tendency for calcification associated with positive histoplasmin reactions to be (1) multiple in the parenchyma often with calcifications present in upper lung fields and apices, (2) early in onset frequently with the initial lesion appearing before one year of age, the majority before 4 years of age, (3) preceded occasionally by a pneumonic infiltrate early in the infection and (4) progressive with the development of new lesions and calcifications over a period of years "

In discussing the possibilities of secondary infection with histoplasmosis, Peterson<sup>6</sup> states that in some instances it is almost impossible clinically to differentiate the progressive pulmonary form from pneumonia. Furcolow states<sup>7</sup> that areas of pneumonitis are seen in children in relationship to the development of histoplasmin sensitivity. Although these areas of pneumonitis were often asymptomatic, occasionally they were associated with definite clinical symptoms especially where there had been marked regional adenopathy and associated pressure reactions. Some of the lesions have the appearance one would expect around a focal granulomatous lesion at the time sensitivity develops. He further states that these lesions are uncommon and that it is often difficult to establish the diagnosis.

In a study of 16 000 school children in Kansas City, Furcolow, Mantz, and Lewis<sup>8</sup> described the roentgenologic characteristics of persistent pulmonary infiltrations in 72 asymptomatic patients who were sensitive to histoplasmin but not tuberculin. They found that only a few were limited to the lymph nodes, a few were of the disseminated type, while approximately two thirds were nodular, sharply circumscribed foci. The remaining one fourth were diffuse, patchy infiltrations with poorly defined borders, which sometimes developed into nodular lesions. Similar lesions were seen in a few patients whose symptoms appeared to arise from this infection. In some of the lesions a central core of calcification was noted initially or in subsequent films. The lesions tended to calcify slowly, and many infiltrations persisted without complete calcification during the two years of observation.

These authors also stated that up to the present time they had no cases in which the entire progress of events could be observed, i.e. negative chest x-rays, negative tuberculin and histoplasmin sensitivity through the appearance of the parenchymal infiltrate with concurrent change in cutaneous sensitivity, to the final irreversible calcified focus in the lung or node associated with a positive histoplasmin test (and negative tuberculin test). In all probability a longer period of observation would be necessary in order to observe the final period of calcification. However, our patient began to show calcification approximately 4 months after the appearance of the pulmonary infiltrate. They further state that they have seen patients with initially negative x-rays and histoplasmin reactions who later developed pulmonary infiltrates or hilar adenopathy or both together with the development of a positive cutaneous reaction to histoplasmin.

We feel that our case represents the precursor phase of pulmonary calcification and, therefore, completes the hypothetical stage proposed by others. We

were able to demonstrate the progress of the primary phase of histoplasmosis presumably from the onset of the first symptoms and roentgenologic evidence of pulmonary infiltration to final clearing of the lesion and beginning calcification, correlating the clinical progress of the disease with bacteriologic and serologic findings. Radiologic evidence of consolidation was present on Nov. 18, 1948 (Fig. 2), three days after the onset of symptoms and eighty days after the onset of the primary illness (Aug. 31, 1948, when the histoplasmin skin test was positive). It is unfortunate that we failed to do a complement fixation test at this time so that it is difficult to determine exactly when the primary infection took place. Nevertheless, on the basis of the 2+ histoplasmin reaction on November 18 and the subsequent increase in sensitivity associated with the strongly positive complement fixation test, in all probability the primary infection occurred shortly prior to August 31. Thus, one can postulate that the pulmonary infiltration occurred at least eighty-five to ninety days or more from the time of the initial infection.

In our case there may be some question as to the significance of the positive tuberculin test. In all probability there is no correlation between the positive tuberculin and histoplasmin tests. Had we not obtained a positive blood culture and isolated *H. capsulatum* from a mouse inoculated with bronchial secretions, the diagnosis of histoplasmosis and the significance of the positive histoplasmin test would be doubtful.

Fungus skin tests were performed on other members of the family, all of whom are free of pulmonary disease. The mother was histoplasmin and tuberculin positive, and the complement fixation test was negative. The three siblings, 23, 15, and 10 years of age respectively, were positive to tuberculin and negative to all of the fungus antigens. This suggests that in all probability all had a common exposure to tuberculosis.

The complement fixation test apparently is important in distinguishing active and latent or past infections with *H. capsulatum*. Those with recent changes from negative to positive skin sensitivity seem more likely to show positive complement fixation, while those with latent or healed infections are generally negative.<sup>7</sup> The finding of a positive complement fixation test for lymphocytic choriomeningitis (see Table II) was probably due to past infection. No virus was isolated from blood or bronchial secretions obtained during the acute stage and inoculated into mice and guinea pigs. Three other members of the patient's family who were tested at approximately the same time also had positive complement fixation tests for the choriomeningitis virus. The family gave a history of living in a house about six months previously that was overrun with mice. Moreover the complement fixation test became negative when repeated with serum drawn from our patient 101 days after the positive specimen.

#### SUMMARY

A case of primary histoplasmosis in a 12-year old colored boy, with clinical findings of atypical pneumonia, is described. The course of the infection was followed from the onset through the stage of pulmonary infiltration to healing.

as manifested by beginning pulmonary calcification. *H. capsulatum* was isolated from the blood and bronchial secretions obtained during the acute stage. The patient had a positive complement fixation test for histoplasmosis at the height of the pulmonary infiltration which persisted to the time of beginning calcification four months later. He also had a positive histoplasmin skin test. Benign histoplasmosis is discussed with particular reference to precalcific pulmonary infiltrations.

## A NEW MOUNTING FOR THE ELECTROKYMOGRAPH

NATHAN GROSSMAN, M D,\* AND EMIL TIGER  
CHICAGO, ILL

IN 1945 Henny and Boone<sup>1</sup> successfully employed an electron multiplier phototube (RCA, 931-A) as a pickup device for the registration of heart motion, using the fluoroscope to delineate the cardiac silhouette. Motion of the heart borders was translated into a varying electric current which was, in turn, recorded as a deflection tracing on an electrocardiograph of either the string or D'Aisonval type. The apparatus was termed an "electrokymograph." Subsequently Henny, Boone, and Chamberlain<sup>2</sup> developed an improved mounting for the phototube which facilitated its use with the ordinary fluoroscope. In 1948 Luisada and co-workers<sup>3</sup> modified this apparatus and called their device a "fluorocardiograph."

In both instruments positioning of the pickup device with respect to a given part of the cardiac silhouette is of paramount importance. This was accomplished by both groups through the use of a knurled knob which rotated the phototube pickup by means of a pulley and belt. The knob projected from the operator's side of the screen. In the model used by Henny, Boone, and Chamberlain,<sup>2</sup> the phototube was permanently mounted on a bracket which could be rotated out of the way for routine fluoroscopy. The Sanborn model, employed by us, is constructed according to the modifications developed by Luisada and co-workers and consists of a pantograph arm which clamps to the fluoroscopic screen. Our experience has proved this arrangement to be unwieldy. The phototube tends to rotate after it is positioned and the joints of the pantograph arm give way from the weight of the pickup device. In addition, it was found that the cables of the phototube head frequently dislodged the microphone from its position on the chest when heart sounds were being recorded simultaneously with the electrokymograph.

With these difficulties in mind, we mounted the Sanborn pickup device in the center of an aluminum frame which slides into the existing channels of the 1704 A Picker spot-film device belonging to our x-ray unit. This has the advantage of enabling the entire frame and phototube to be readily slid out of the fluoroscopic field when not in use, when the operator has located the heart border desired, a simple movement of the lead frame holder moves the pickup rapidly into position, and thereafter but minor adjustments of the pickup slit are necessary.

Fig 1—A photograph of the electrokymograph pickup device in the new radiolucent aluminum and plastic mounting Described in text.

Fig 2—The new mounting fitted into the spot film device

Positioning of the slit through 180 degrees is accomplished by a long arm (parallel with the slit) similar to that used on a camera mounting. Rotating this arm through a 180 degree arc allows fine orientation of the slit with respect to the cardiac silhouette. Further motion of the phototube is prevented by a screw at the phototube mounting which is operated by turning the handle of the arm. The entire fluoroscopic screen and tube carriage can be locked in any position by the brake on the x ray unit. Since this is a spot

radiographic device, it is possible to obtain 5 in by 7 in spot films of the phototube pickup head in position on the cardiac silhouette for purposes of permanent record. Figs 1 and 2 are photographs of this new modification.

#### SUMMARY

1 A new mounting for the electrokymograph by use of a spot-radiographic device is described.

2 The advantages of this modification are presented.

We are indebted to Mr N G Weidman of Picker X ray Corporation for valuable suggestions.

## METHODS FOR THE DETERMINATIONS OF RADIOACTIVE PHOSPHORUS ( $P^{32}$ ) IN BODY FLUIDS

MARGARET A. ADAMS, A. B. BOSTON, MASS. \* STANLEY M. LEVENSON, M. D., CHICAGO, ILL., † REX G. FLUHRARTY, PH. D., BOSTON, MASS., ‡ AND F. H. LASKEY TAYLOR, PH. D. BOSTON, MASS. §

WITH THE TECHNICAL ASSISTANCE OF MARY I. KENDRICK, B. S.

THE use of radioactive isotopes in tracer amounts in man imposes the problem of the determination of very small quantities of isotopes in the body tissues and fluids. This is particularly true when tracers such as  $P^{32}$  are used since the over all distribution, excretion, and exchange of phosphate are large and rapid. To meet this situation selection and modification of existing methods for the isolation and estimation of the various phosphate fractions, both radioactive and nonradioactive are required.

The purpose of the present communication is to present the techniques developed for the investigations of phosphorus metabolism in man using  $P^{32}$  as a tracer in doses of 100 to 200 microcuries<sup>1</sup> intravenously.

### APPARATUS

The  $P^{32}$  beta radiation<sup>||</sup> was counted with end window (bell type) Geiger Muller tubes and a Tracerlab Autoscaler. Both commercially manufactured Geiger Muller tubes and those assembled by the Massachusetts Institute of Technology were employed. The mean window thickness varied from 2 to 5 mg. per square centimeter. The tubes were shielded with 3 to 6 in. of lead. The background varied from 0.23 to 0.40 counts per second for different tubes, but was essentially constant for any one tube during the period of study. For any given set of experiments one tube was used. The critiques of measurement were those reviewed by Kamen.<sup>2</sup>

Calibration of the Autoscaler was made daily by the use of a standard 60 cycle alternating current and the complete assembly was checked by the use of a uranium standard. A manual sample changer was constructed so that each sample was at a fixed and constant distance from the Geiger Muller tube window. To ensure maximum recording this distance was the minimum required to prevent contamination of the tube by the sample.

### MATERIALS

Only dried samples were used and to approximate similar distribution of materials in all samples the amount of liquid dried was kept constant throughout these investigations. Since 2 ml. was found to be the minimum volume with which accurate counts could be obtained for the least active samples the more active samples were diluted so that 2 ml. contained an appropriate activity.

Bottle caps<sup>¶</sup> prior to the insertion of the cork inlay were used as expendable containers for drying samples. Occasionally such bottle caps were delivered prevarnished. It was found necessary to remove the varnish with a concentrated solution of sodium hydroxide. All bottle caps were washed first with acetone to remove machine oil and grease and subsequently with distilled water and then dried.

¶ $P^{32}$  was supplied by Monsanto Chemical Company Clinton Laboratories Oak Ridge Tenn.

¶From the Armstrong Company Lancaster Pa.

Standards were prepared by drying 2 ml samples of appropriate dilutions prepared from the solutions of  $P^{32}$  which were injected into subjects or added to *in vitro* reaction mixtures. By means of these, corrections for decay of the isotope could be made.

The method used for drying samples varied depending on the physical characteristics and composition of the substance under investigation. The use of the infrared lamp as a source of heat provided the most convenient and rapid way of drying samples. Unfortunately, it could not be used when the sample contained more than a very small amount of organic matter. When plasma, whole blood, or trichloroacetic acid filtrates were dried at a high temperature, the residues were uneven and often elevated, and considerable error in counting resulted. It was found that when samples containing organic matter were dried overnight at 38 to 40° C more evenly deposited dried samples, closely adhering to the sample containers, were obtained.

*Great care must be employed to be certain that the samples are thoroughly dry, since the presence of even small amounts of moisture has been found to lower the counting rate significantly.* After most of the moisture had been removed at 38 to 40° C, heating under an infrared lamp or in a hot oven at about 100° C for one to two hours could be carried out to ensure complete dryness, without causing irregularities in the deposited material.

The thickness, consistency, and density of the samples are important factors in the accurate estimation of radioactivity because of their well known effect on the absorption of the emitted beta rays. Ideally, all phosphorus containing fractions should be separated by suitable chemical methods and then converted by chemical procedures to inorganic phosphorus so that direct comparisons of the radioactivity could be made on the same final substance. However, with the use of tracer amounts of  $P^{32}$  in man, separation and conversion to inorganic phosphate by organic combustion would introduce dilutions so great as to reduce the radioactivity in some of the fractions of phosphorus to the point where unfeasibly long periods of time would be required for accurate counting. Therefore, no attempt was made to convert all fractions to the inorganic form. As a result, measurements were made on dried samples of different physical characteristics. This was dictated by the necessity of using the maximum amounts of material in the samples consistent with ease in preparation and counting. Since the samples consisted of rather large amounts of material in nonstandard geometry and unknown uniformity, the corrections for selfabsorption and other physical properties were made empirically. These measurements were also used as a check upon the reproducibility of the data. These corrections will be discussed below in detail for each fraction.

#### METHODS

Oxalated blood samples, cooled in ice, were centrifuged as soon as possible after the blood was drawn, and the plasma removed as completely as possible. The red blood cells were washed once with ice cold isotonic sodium chloride solution, centrifuged again, and the supernatant washings removed as completely as possible and discarded. The washed red blood cells were frozen to prevent hydrolysis of phosphorus compounds and to produce hemolysis. Plasma and thawed hemolyzed red blood corpuscles were analyzed chemically for total phosphorus, total acid soluble phosphorus, and inorganic phosphorus, and the radioactivity of these phosphate fractions was determined. Corresponding values for the total organic, acid soluble organic, and nonacid soluble organic fractions were calculated.

Quantitative volumetric measurement of samples of hemolyzed red blood cells was somewhat difficult because of their high viscosity. Probably the most accurate way of measuring them is by weight. This technique is indeed necessary if undiluted red blood cells must be used. However, as a technique for handling many samples of red blood cells, weighing is extremely time consuming. Accordingly, the thawed red blood cells were measured with Ostwald-Folin pipettes calibrated to deliver by blowing out the last drop and transferred to volumetric flasks of desired capacity. The red cells adhering to the sides of the pipette were removed by repeated washings with distilled water, the washings were added quantitatively to the volumetric flask containing the pipetted cells, and the mixture was made up to the desired volume with distilled water. Samples from dilutions of five times the original volume of red cells can be pipetted accurately without difficulty and with good duplication of results.

1 *Total Phosphorus in Plasma and Red Blood Cells*—The total phosphorus concentration of plasma and red blood cells was determined in samples of suitable size by the colorimetric molybdate method after digestion with sulfuric and nitric acids, as described by Fiske and Subbarow<sup>3</sup>

The total  $P^{32}$  content of plasma was determined by counting the beta rays from 2 ml samples of plasma dried overnight at 38° C

For the determination of the  $P^{32}$  content of erythrocytes a 1:5 dilution of hemolyzed red blood cells was prepared and 2 ml samples of this dilution were dried overnight at 38° C. The beta particles emitted were then counted.

2 *Total Acid Soluble Phosphorus of Plasma and Red Blood Cells*—To precipitate the plasma proteins, 1 vol of plasma was mixed with 4 vol of 10 per cent trichloroacetic acid. The mixture was shaken well and filtered through Whatman No. 42 filter paper.

In precipitating the protein from red blood cells a 1:10 dilution was made instead of the 1:5 dilution used for plasma in order to permit adequate washing of the pipette used to measure the cells. Five milliliter samples of hemolyzed red blood cells were pipetted into 50 ml volumetric flasks. The pipette was thoroughly washed with water and the washings were transferred quantitatively to the same volumetric flask. Ten milliliters of 20 per cent trichloroacetic acid were added with shaking. The contents of the volumetric flasks were made up to 50 ml with distilled water mixed thoroughly by inversion and filtered through Whatman No. 42 filter paper. This preparation contained the same weight of trichloroacetic acid per milliliter of red blood cells as was used per milliliter of plasma but the final dilution was twice as great in respect to both red cells and trichloroacetic acid. Since it was difficult to adjust the volume accurately because of foam and floating particles of precipitated protein, two preparations of red blood cells were routinely made and a sample was taken from each filtrate for all determinations made on the protein free filtrates.

The total acid soluble phosphorus in the trichloroacetic acid filtrates prepared from plasma and red blood cells was determined by the colorimetric molybdate method of Fiske and Subbarow<sup>3</sup>

To determine the  $P^{32}$  present in the acid soluble phosphate fractions 2 ml samples of the trichloroacetic acid filtrates obtained from both plasma and red blood cells were transferred to bottle caps and dried overnight at 38° C. The emitted beta particles were then counted.

3 *Inorganic Phosphorus in Plasma and Red Blood Cells*—The inorganic phosphorus of the plasma and red blood cells was determined in the protein free trichloroacetic acid filtrates by the colorimetric molybdate method of Fiske and Subbarow<sup>3</sup>

For the measurement of  $P^{32}$  in the inorganic phosphate fraction of plasma and red blood cells, the inorganic phosphate was separated from the other forms of acid soluble phosphate by the calcium precipitation method of Fiske<sup>4</sup> with certain modifications and precautions which were found necessary for the final counting techniques.

Twenty milliliter samples of the trichloroacetic acid filtrate prepared as given in the section on acid soluble phosphorus were pipetted into 25 ml volumetric flasks. One or 2 drops of phenolphthalein were added and the filtrate was carefully neutralized with, first, 90 per cent, then normal, and finally,  $\frac{1}{10}$  normal sodium hydroxide until a small drop of the  $\frac{1}{10}$  normal alkali sufficed to produce a faint pink color. If the end point was passed with one of the stronger alkali solutions trichloroacetic acid was added until the solution was colorless and the end point established again with  $\frac{1}{10}$  normal alkali. It was found to be of the greatest importance to avoid an excess of alkali because of subsequent failure to obtain complete solution of calcium phosphate.

The neutralized filtrate was made up to exactly 25 ml in the volumetric flasks and thoroughly mixed. Two 10 ml samples were measured into conical graduated 15 ml centrifuge tubes. One tenth milliliter of 0.4 per cent sodium phosphate (approximately 0.1 mg of phosphorus) was added to the solution in the centrifuge tube to act as a carrier for the  $P^{32}$  during subsequent manipulations.

Five milliliters of a 10 per cent solution of calcium chloride, saturated with calcium hydroxide were then added to the contents of the centrifuge tubes and the mixture was allowed to stand for ten minutes to ensure complete precipitation of the phosphate as calcium phosphate.

The tubes and contents were then centrifuged for two minutes at 3,000 revolutions per minute. *This speed of centrifuging was found to be absolutely necessary for the quantitative separation of the precipitate from the supernatant liquid.*

The supernatant fluid was carefully decanted from the precipitate and the tubes were drained by standing them inverted on filter paper for a few minutes.

The precipitate was washed once by resuspending in a mixture of 4 ml of distilled water and 1 ml of the  $\text{CaCl}_2 \text{Ca}(\text{OH})_2$  reagent and recentrifuged at 3,000 rpm for two minutes. The supernatant liquid was decanted and the tubes again were drained by inversion.

Two drops of normal sulfuric acid were added to the calcium precipitate. The gelatinous precipitate of calcium phosphite was replaced by a white amorphous precipitate of calcium sulfate. Repeated tests have shown that all of the phosphate ion at this stage is in solution.

The contents of the 15 ml centrifuge tube were made up to 5 ml with distilled water, stoppered, and thoroughly shaken. The stoppers were removed and the tubes centrifuged for about five minutes at approximately 2,000 revolutions per minute.

Two milliliter samples were pipetted from the supernatant fluid into bottle caps and dried. Because of the low salt content and the absence of organic matter in the sample, drying was done rapidly under an infrared lamp. The emitted particles from the dried samples were then counted.

4 *Urine*—Urine samples were collected for various intervals of time depending on the periods of most interest in each individual in vivo experiment. The total volumes were measured, and 2 ml samples of urine were dried and counted with the Geiger Muller counter and Autoscaler. Following the injection of 100 microcuries of  $\text{P}^{32}$ , the urine of normal subjects was found to contain enough radioactive material so that 2 ml samples, diluted or undiluted, gave counts within an accurate range for five or six days following the administration of the isotope. In the first hours the counts were so high that dilution was carried out in order to avoid counting errors while maintaining the 2 ml volume of sample.

CPS Counts per second

Standard deviation of the mean for the entire series is  $\pm 3$  per cent

\*Each figure in the columns Mean (CPS) is the mean of six readings, three on each of two duplicate samples

*Correction Factors—*

Folin<sup>3</sup> recommended that 2 per cent should be subtracted from the values obtained for the chemical estimation of total acid soluble and inorganic phosphate of the plasma in order to correct for the volume occupied by the protein precipitate. This correction was applied to both the chemical determinations and to the counting rates observed for these two plasma fractions.

It was determined experimentally that the protein from red blood cells occupied approximately one tenth of the total volume in the dilution used. Accordingly, 10 per cent was subtracted from the chemical results and also from the counting rates obtained for total acid soluble and inorganic phosphorus in the red blood cells.

As pointed out earlier additional corrections were necessary for some of the radioactive preparations because of errors in counting introduced by the physical characteristics and geometry of the dried samples. In addition all results obtained with a Geiger Muller counter and Auto caler are subject to certain intrinsic instrumental inaccuracies.

Dilutions of aqueous solutions of radioactive sodium phosphate were prepared from which duplicate 2 ml samples were pipetted into the same type of bottle caps used in all subsequent experiments. After the samples were thoroughly dried each of the duplicates was counted three times. In the first column of Table I are given the means of the six readings taken on each of the fifty samples. The standard deviation from the mean of the entire series, after correcting for background was approximately  $\pm 3$  per cent.

Additional errors, most likely introduced by the thickness and uneven surfaces of the dried samples, were present. Kamen<sup>2</sup> has stated that the beta rays from  $P^{32}$  may show significant absorption due to thickness of the sample film when the weight of the sample exceeds 15 to 20 mg per square centimeter. Table II shows the corrections necessary when known amounts of  $P^{32}$  were added to varying concentrations of human serum albumin. The samples were measured into weighed bottle caps, thoroughly dried, and reweighed. From physical measurements the area of the bottle caps was estimated to be 4.9 cm<sup>2</sup>, and the milligrams per square centimeter of albumin were calculated for each sample. In Table III correction factors derived from a similar experiment with trichloroacetic acid are given. In both cases, as expected, the counting rate decreased as the thickness of the dried films increased. These results will be discussed later.

### RESULTS

*Total  $P^{32}$  in Plasma*—To determine the correction factor which should be applied to the results obtained for total  $P^{32}$  in plasma, a series of twenty samples was prepared containing plasma to which known amounts of  $P^{32}$  were added in vitro. The dilution necessarily introduced by the addition of  $P^{32}$  solution was kept as small as possible and never exceeded 2 per cent of the total volume. The readings were compared with those of 2 ml amounts of aqueous solutions containing the same concentrations of  $P^{32}$  as the plasma preparations. Each sample was counted at least three times. The results obtained by counting the emissions from the aqueous preparations were regarded as 100 per cent recovery. Statistical analysis of the results showed the average recovery in the plasma samples to be 89 per cent with a standard deviation of  $\pm 3.95$  (Table IV). On the basis of the recovery experiments, a correction factor of +11 per cent was applied to

all counts observed for total  $P^{32}$  in plasma. Two milliliters of normal human plasma when dried were found to weigh on an average about 34 mg per square centimeter. Table II shows a loss of 12 per cent of added  $P^{32}$  in the presence of albumin of equivalent weight, which agrees closely with the recovery experiments presented in Table IV.

*Total  $P^{32}$  in Red Blood Cells*—The weight of 2 ml of a 1:5 dilution of red blood corpuscles was found to be approximately 21 mg per square centimeter. From Table II it might be predicted that about 94 per cent of the radioactivity

present would be detected. To study this point more thoroughly, twenty eight *in vitro* recovery experiments were performed in which 2 ml samples of red blood cells diluted 1:5 and containing known concentrations of  $P^{32}$  were dried and counted. Each sample was counted at least three times. The average recovery of the added  $P^{32}$  was 95 per cent (standard deviation of  $\pm 3.9$ ) of that observed for dried aqueous solutions containing the same concentrations of  $P^{32}$  (Table V). This is in excellent agreement with the expected recovery. Consequently, a correction of 5 per cent was applied to the observed counts for total  $P^{32}$  in red blood cells.

*$P^{32}$  in the Total Acid-Soluble Phosphate Fraction of Plasma*—To determine the necessary correction factor for the measurements of  $P^{32}$  in the total acid soluble phosphate fraction of plasma thirty two samples were prepared containing known amounts of  $P^{32}$  and 0.16 Gm of trichloroacetic acid in 2 milliliters. This concentration of trichloroacetic acid was the same as that of the plasma filtrates. Each sample was counted at least three times. The average recovery was found to be 83 per cent with a standard deviation of  $\pm 7.48$  as compared with aqueous dilutions containing the same amount of  $P^{32}$  (Table VI). Two milliliter samples of the trichloroacetic acid filtrate prepared from plasma were found to weigh about 37 mg per square centimeter. Table III indicated that a recovery of 82 per cent of the added  $P^{32}$  would have been expected on the basis of film thickness. Thus the observed mean recovery agrees well with this value. The fairly large standard deviation is probably due to the very considerable physical differences in the dried trichloroacetic acid film. Modifications of this part of the procedure are proceeding.

A series of experiments was performed which indicated that filtration through Whatman No. 42 paper did not contribute to losses in radio activity. Consequently the observed counts for the total acid soluble fraction of plasma were corrected on the basis of the *in vitro* recovery experiments presented in Table VI which showed an average loss of 17 per cent of added  $P^{32}$ , together

with the correction of 2 per cent to compensate for the volume of the protein precipitate. Hence, 15 per cent was added to all counts observed for total acid-soluble phosphate in plasma.

*$P^{32}$  in the Total Acid-Soluble Phosphate Fraction of Red Blood Cells—*  
Two milliliter samples obtained from red blood cell protein free filtrates contained 0.08 Gm of trichloroacetic acid and were found to weigh approximately 17 mg per square centimeter. Table III shows a recovery of about 97 per cent for samples of this weight. Eighteen recovery experiments containing known amounts of  $P^{32}$  and 0.08 Gm of trichloroacetic acid in 2 ml amounts were counted and found to have an average of 97 per cent recovery of the added  $P^{32}$  with a standard deviation of  $\pm 6.1$  (Table VII). Again, the fairly large standard deviation is probably accounted for by differences in the physical characteristics of the dried trichloroacetic acid film. Since no counts were considered to be more accurate than  $\pm 3$  per cent, no corrections were made for absorption due to thickness of film, but 10 per cent was subtracted from all counts observed in the total acid soluble phosphate fraction of red blood cells to correct for the volume occupied by protein.

$P^{32}$  in the Inorganic Phosphate Fraction of Plasma and Red Blood Cells—No corrections for loss of  $P^{32}$  by selfabsorption were applied to samples of inorganic phosphate. These samples when dried weighed about 1 mg per square centimeter. Sixteen recovery experiments showed an average recovery of 98 per cent of added  $P^{32}$  with a standard deviation of  $\pm 4.2$  (Table VIII). Two per cent was subtracted from the observed counting rates for plasma to correct for the volume occupied by protein. For the same reason 10 per cent was subtracted from results obtained for red blood corpuscles.

Each figure is based on the average of at least three observations.

$P^{32}$  in Urine—Urine samples appeared to offer no difficulties from the standpoint of counting techniques. Their thickness and consistency did not differ enough from that of the control aqueous solutions of  $P^{32}$  as sodium phosphate to introduce any significant errors. All of the *in vitro* tests performed in which known amounts of  $P^{32}$  were added to urine indicated 97 to 103 per cent recovery of the added  $P^{32}$ . Some modification of the method might be necessary for urine containing large amounts of protein but such complications have not been encountered.

It is apparent from the data presented that numerous corrections principally for selfabsorption, are required in order to make reliable determinations of  $P^{32}$  in plasma and red cells by beta particle counting. The correction factors necessary may be determined experimentally as in the present communication, or selfabsorption correction factors may be approximated from the following equation presented in a simplified theory in an article by Fluharty<sup>6</sup>

$$\frac{N}{N_0} = \frac{1}{\mu g} (1 - e^{-\mu g})$$

where  $N_0$  is the counting rate without absorber,  $N$  is the counting rate with  $g$  grams per square centimeter of absorber, and  $\mu$  is the mass absorption coefficient.

The relation between  $\mu$  and the maximum beta ray energy is given roughly ( $E_{\max} > 0.5$  mev) by

$$\mu = 22/E_{\max}^{4/3}$$

where  $E_{\max}$  is the maximum energy of the beta rays emitted.  $E_{\max}$  is 1.72 mev and  $\mu$  is 10.7 for  $P^{32}$ .

Fig 1 presents a plot of the theoretical ratio  $\frac{N}{N_0}$  as a function of milligrams of sample in each square centimeter assuming that the total activity is contained in each sample, but uniformly distributed throughout. Also plotted are the observed values as found experimentally. It may be seen that the

Fig 1—Relationship between ratio of observed and true counts and milligrams per square centimeter sample counted. Solid line represents the theoretical counts based on the relationship between beta ray energy and milligrams per square centimeter as shown in the equation on the chart.

agreement between theory and experiment is good to within 5 per cent. Except for isolated instances, the fraction of counts observed was greater than the experimental value, but the shape appears proper aside from low quantities of absorbing materials. The discrepancy at low grams per square centimeter is not unexpected, although a satisfactory explanation with experimental proof has not been given. Most likely the variation from theory represents low readings in the standard due to piling up on the edges and subsequent poor geometry with respect to the Geiger tube. The spread in value can be attributed to the differences in the physical character of the different samples.

#### SUMMARY AND CONCLUSIONS

1 Methods are described for the determination of radioactive phosphorus in plasma, red blood corpuscles, and urine following the intravenous injection of 100 to 200 microcuries of the isotope in normal human subjects. These methods also are applicable to *in vitro* experiments.

2 The separation of the total acid-soluble and inorganic phosphate fractions of plasma and red blood corpuscles is described and the procedures used for preparing and counting radioactive samples from these fractions are given.

3 Losses of radioactivity by selfabsorption in thick samples are discussed

4 Certain correction factors are necessary for comparison of counting rates obtained in samples possessing different physical characteristics. The derivation and use of such correction factors are discussed

# A METHOD FOR DETERMINING $\alpha$ -AMYLASE ACTIVITY

E P ZINKER, M A , AND F J REITHEL, PH D  
EUGENF, ORE

UNTIL recently, methods for determining  $\alpha$ -amylase activity in serum or urine were based on the estimation of the reducing sugars formed during the enzymic hydrolysis of starch. From the work of Cattle and Hanes<sup>1</sup> it became apparent that the rate of starch hydrolysis could be followed by determining the decrease in starch concentration as measured by the color of the starch-iodine complex. During the last year, while the present work was in progress, two communications appeared<sup>2, 3</sup> which describe methods based on this principle. It is clear from these investigations, and from our own, that  $\alpha$ -amylase initially catalyzes the production of starch fragments which yield a different color (or none) with iodine than does starch, that the decrease in starch concentration, as evidenced by the starch-iodine complex color, can be estimated accurately photometrically, and that the decrease in starch concentration initially is a measure of  $\alpha$ -amylase activity. Because of the appearance of the latter publications<sup>2, 3</sup> our own experiments concerning the basic principles will not be reported. This paper will be limited to a description of the method developed which seems somewhat simpler than those previously described and appears to be quite suitable for routine work.

## METHOD

*Reagents*—1 Starch solution 0.1000 Gm of Merck soluble starch and 0.3 Gm NaCl were dissolved in 250 ml 0.1M Na<sub>2</sub>HPO<sub>4</sub>, KH<sub>2</sub>PO<sub>4</sub> buffer, pH 7.0. This solution cannot be stored for more than one or two days.

2 Iodine solution 1.27 Gm iodine and 10 Gm KI were dissolved up to 1,000 ml with distilled water. If stored in a glass stoppered bottle the solution is stable for about one month.

*Procedure*—To numbered Klett tubes containing 3.0 ml ice cold starch solution are added 0.5 ml aliquots of whole serum or serum diluted with normal saline. A blank was included. The contents of the tubes are quickly mixed and incubated in a 37° C water bath for exactly five minutes and then placed in an ice water bath. Using the same order of addition, 3.0 ml of the iodine reagent are added immediately and rapidly from a burette. After several minutes, 4.0 ml distilled water are added and the contents well mixed. In exactly fifteen minutes from the time of addition of iodine reagent the color is read with the Klett Summerson photoelectric colorimeter using filter 66. It should be noted that the iodine reagent slows amylase action markedly but does not abolish it completely.

## RESULTS

To assay the sensitivity of the method and linearity of response, the following experiment was performed. Aliquots of a normal serum were diluted with 0.9 per cent saline as indicated in Table I and the  $\alpha$ -amylase activity was determined as described in the previous section. The results indicate that as little as 0.1 ml of serum can be used and that there is a linear relationship between enzyme activity and starch-iodine color.

From the Department of Chemistry, University of Oregon  
Received for publication June 20 1949

TABLE I  $\alpha$  AMYLASE ACTIVITY OF DILUTED SERUM

ML. WHOLE SERUM PER 0.5 ML ALIQUOT OF DILUTED SERUM	OPTICAL DENSITY $\times 1000$
0	350
0.100	256
0.250	192
0.333	164
0.400	135
0.500	104

If it is desirable enzyme activity can be expressed in units. One unit is defined as the amount of enzyme in 1.0 ml which causes the hydrolysis of 0.01 mg of starch in one minute at 37° C. in a phosphate buffer of pH 7.0. Therefore,

$$\frac{12 \left(1 - \frac{A}{B}\right)}{0.01 \times 5 \times 0.5} = \text{units}$$

where A is the density reading of the unknown, B is the density reading of the blank, 12 is the number of milligrams of starch in 3.0 ml of substrate, 0.01 is the number of milligrams of starch hydrolyzed per unit activity per minute, 5 minutes is the duration of incubation and 0.5 is the number of milliliters enzyme solution taken.

TABLE II REPRODUCIBILITY OF  $\alpha$  AMYLASE ASSAY METHOD

SAMPLE	INEXPERIENCED STUDENT		EXPERIENCED STUDENT	
	DENSITY $\times 1,000$	UNITS	DENSITY $\times 1,000$	UNITS
A	151	27.2	150	27.3
	149	27.5	149	27.5
	149	27.5	153	27.0
B	111	32.9	109	33.0
	103	33.9	104	33.8
	104	33.8	102	34.0
Blank	350		350	

In order to judge reproducibility, the results of a student performing the test for the first time were compared with those obtained by one having experience with the method. The data are summarized in Table II. The time required for the analysis of six samples is approximately thirty minutes.

Sera from several students selected at random were assayed for  $\alpha$  amylase activity. Table III indicates the range of normal values obtained.

TABLE III  $\alpha$  AMYLASE ACTIVITY OF NORMAL SERA

SUBJECT	AGE	ACTIVITY IN UNITS
Male	28	27.3
Female	23	33.6
Male	26	32.8
Male	24	28.8
Male	27	28.4

## SUMMARY

A simple photometric method for determining  $\alpha$ -amylase activity has been developed which is applicable as a routine method in the clinical laboratory

# A SIMPLE, INEXPENSIVE APPARATUS FOR THE DESICCATION OF BACTERIA AND OTHER SUBSTANCES

J W HORNIBROOK\*

BETHESDA, MD

THE advantages of desiccation from the frozen state have been mentioned many times in the literature. The principles involved will not be detailed here, as the reader may find these in many excellent reviews such as those of Greaves<sup>1</sup> and Flosdorf and co workers.

The apparatus to be described has the following advantages: (1) the device is simply and easily constructed, (2) the cost of operation is low, (3) it is versatile. Material may be dried at various temperatures and to a definite moisture content. The dried material may be sealed off in vacuo or under various gases.

## CONSTRUCTION

The apparatus as seen in the photograph Fig 1 is quite simple. It consists of a Pyrex cylinder about 2 in in diameter supported horizontally and of a length to suit the convenience of the operator. It is closed at both ends and has a ground glass stopper on the top. Five or more side arms of  $\frac{1}{4}$  in glass tubing extend out on each side at about 10 and 2 o'clock to which are fastened by means of rubber tubing the F tubes and ampules. The cylinder will conveniently hold 100 cc of sulfuric acid which is the drying agent.

## OPERATION

The sulfuric acid is placed in the apparatus with the aid of a funnel. The stopper is greased with silicone stopcock grease and replaced. The F tubes, ampules, and rubber tubing are also lightly coated with silicone grease and placed on the side arms. The small U tube mercury manometer is placed on the special arm at one end and the vacuum pump connected to the other. The ampules are frozen in a bath of dry ice (solid carbon dioxide) and alcohol and the vacuum pump is turned on. When a vacuum of 0.5 mm or more is obtained, the dry ice and alcohol bath is removed and the material allowed to dry. The liquid in the ampules may be "snap frozen" if dry ice is not available. This is done by cautiously opening the connection between the pump and the machine. Air in solution in the material to be dried will be evolved as bubbles. When all this air is expelled the connection between the pump and the machine may then be opened completely. The contents of the ampules then will rapidly fall in temperature and within a few minutes will suddenly freeze. The size of the ampule should be large in proportion to the amount of liquid to prevent bubbles being drawn into the neck of the ampule. After a vacuum has been obtained,

Received for publication June 4, 1949.

Senior Surgeon, United States Public Health Service.

line The next line indicates the temperatures of a condenser which in a closed system will produce these vapor pressures The next seven lines indicate the percentage by weight of sulfuric acid necessary at several temperatures to produce these pressures On the lower left are indicated the final temperatures of the dried milk

If one wishes to dry milk to a moisture content of, for example, 25 per cent at room temperature ( $25^{\circ}\text{C}$ ), one chooses a bar which is the same length as the distance from 0 of the moisture scale to the 25 mark This bar should

Fig. 3—Relationship between moisture content of various substances and vapor pressure at equilibrium (three days at  $35^{\circ}\text{C}$ )

rest on the  $25^{\circ}\text{C}$  line Following vertically upward from the base of this bar, we find a vapor tension of 12 mm of Hg On this same line, we find  $-15^{\circ}\text{C}$ , which is the temperature of a condenser giving this vapor pressure If we wish to use sulfuric acid as a desiccant at room temperature, we find that approximately 69 per cent will be right

In Fig. 2 the moisture content of milk was determined by placing weighing bottles of dried milk in desiccators over various concentrations of sulfuric acid until the weight remained constant They were then held over  $\text{P}_2\text{O}_5$  under a vacuum to constant weight The loss of weight over  $\text{P}_2\text{O}_5$  was considered a water loss Knowing the weight of the sample, the moisture content was calculated The other data included were obtained from standard tables<sup>4, 5</sup>

The chart (Fig 2) was based on skim milk as we have found this a suitable vehicle for drying organisms. The data in Fig 2 will not apply when predicting the moisture content of other substances dried over sulfuric acid.

As shown in Fig 3, nutrient broth, skim milk, rabbit brain, and human plasma have been dried for three days over several concentrations of sulfuric acid. Each concentration of sulfuric acid will produce a different water vapor

Fig 4—Relation between moisture content of milk and time of desiccation on the apparatus described. Moisture contents determined with Fischer reagent. Irregularity at 6 hours probably due to absorption of water into ampule which was removed in the evening and tested the next morning.

tension. It is apparent that for any given vapor tension the moisture content of one substance may differ from the moisture content of another.

Desiccation with this apparatus is quite rapid, as illustrated in Fig 4. It can be seen that equilibrium has been reached in five hours.

Using *Vibrio cholerae* as a test organism, drying runs were made on this apparatus and on another manifold type of apparatus which employed dry ice and Methylcellosolve for moisture removal. On three runs using sulfuric acid, the percentage of organisms remaining viable after drying, as determined by plate counts done before and after drying, was 1.3 per cent, 0.05 per cent, and 0.5 per cent. The percentage of viable organisms on two runs with dry ice was 0.4 per cent and 0.05 per cent.

## SUMMARY

An apparatus is described for desiccation of biologicals and other substances which is cheap in initial and operational cost and which will dry to a pre-determined moisture content. A graph is presented showing the relations between the moisture content of milk, sulfuric acid concentration, condenser temperature, and vapor tension.

ERRATUM

In the article by Innes, Innes, and Moore, "The Hematologic Changes Induced in Guinea Pigs by the Prolonged Administration of Pteroyl Glutamic Acid Antagonists," in the July issue of the *JOURNAL*, Met Fol B was stated to be 7-methyl pteronic acid. That is incorrect. Met Fol B is N<sup>10</sup>-methyl pteronic acid. In the list on p. 885, therefore, and throughout the article, please read N<sup>10</sup>-methyl pteronic acid instead of 7-methyl pteronic acid.

# BLOOD COAGULATION IN LEUCEMIA AND POLYCYTHEMIA. VALUE OF THE HEPARIN CLOTTING TIME AND CLOT RETRACTION RATE

ROBERT L. ROSENTHAL, M.D.  
BERKELEY, CALIF.

## INTRODUCTION

**T**HROMBOSIS and hemorrhage are two of the most prominent causes of complication and morbidity in disease. This is particularly true of leucemia and polycythemia vera. Thrombosis especially of the cerebral and coronary vessels, represents the most serious threat to life in polycythemia.<sup>1-4</sup> Curiously enough hemorrhage also occurs in this disease. It is a frequent symptom in the form of epistaxis and bleeding gums or may be quite severe after any type of surgical operation even tooth extraction.<sup>5-7</sup> In leucemia hemorrhage has long been a widely recognized finding and a therapeutic problem.<sup>1,8</sup>

The value of studying the blood coagulation mechanisms in these diseases is readily apparent. However a review of the literature revealed no adequate or extensive study of blood coagulation in these conditions except for a study on thrombocytopenic purpura in leucemia by Rosenthal.<sup>9</sup>

In acute leucemia and in many cases of chronic leucemia bleeding can be attributed to a marked depression in platelet count and function. In these instances, the usual tests for platelet function such as bleeding time, tourniquet test and presence of clot retraction give abnormal results. Bleeding in the absence of a definite thrombocytopenia or abnormality of the above mentioned clotting or hemostatic tests as is frequently observed in chronic leucemia has never been explained adequately. In his monograph on leucemia Folkner<sup>10</sup> stated: "Frequently no adequate explanation can be advanced as to the cause of bleeding in leukemia. The problem has been studied inadequately."

The general opinion upon coagulation, thrombosis and hemorrhage in polycythemia vera has been well summarized by Hattop and Wintrobe:<sup>11</sup>

"The blood platelets may be normal in number but are frequently increased sometimes to three or four times their normal values. The various tests of the efficiency of blood coagulation reveal no striking abnormality. Bleeding time is usually essentially normal and coagulation time normal. In spite of thrombocytosis clot retraction may be slow and little serum is usually formed probably because of the great increase in the size of the blood mass. These features may explain not only the abnormal tendency to thrombosis in this disease but the blood vessel engorgement and slow clot retraction suggest an explanation for the frequent hemorrhages."

From the Division of Medical Physics and the Donner Laboratory, University of California. This work was supported in part by a grant from the United States Public Health Service.

Received for publication May 31, 1949

It also has been observed that the clot forming from polycythemic blood is fragile and may dissolve or become fluid upon minimal agitation<sup>12</sup>

It is the purpose of this paper to report the results of a one and one half year study of blood coagulation in forty-five patients with polycythemia vera, twenty-eight patients with leucemia and sixteen patients with other diseases. During the course of this study, two new tests of blood coagulation were developed and carefully standardized upon sixty-four normal subjects. These tests are

1 Clot retraction rate A quantitative measure of clot retraction obtained by electric resistance measurements

2 Heparin clotting time A modification and simplification of the heparin tolerance test, which measures the effect of added heparin upon the clotting time of blood

### METHODS

All blood coagulation tests were performed in a water bath regulated at 37° C upon venous blood carefully drawn to avoid tissue juice contamination. A dry syringe and 20 gauge needle were used. The first and last cubic centimeters of blood in the syringe were not used for these tests. Blood counts were performed upon capillary blood.

*Clot Retraction Rate*—A method\* was developed and described by Rosenthal and Tobias<sup>13</sup> by which a quantitative measure of clot retraction, as well as other information, may be obtained by the measurement of the electric resistance of freshly drawn blood, as it clots. Fig 1 shows a typical electric resistance curve with explanations and illustrations of the changes during coagulation.

Since the increase in electric resistance is caused by retraction of the clot around the electrodes, the slope of the rising portion of the resistance curve is comparable to the "clot retraction rate." The resistance increase was usually linear and most rapid during the first forty minutes of measurement. This period also was subject to the least amount of error and variation such as result from the edge of the electrode cutting through the retracting clot. The clot retraction rate is calculated in the following manner:

$$\text{Clot retraction rate in ohm centimeters per minute} = \frac{\text{Specific resistance at 35 min} - \text{Specific resistance at 15 min}}{35 \text{ min} - 15 \text{ min}}$$

Normal range 4 to 10 ohm cm per minute, average value 7.1 ohm cm per minute

*Heparin Clotting Time or Heparin Prolonged Clotting Time*—This test measures the effect upon the clotting time of the addition of 0.04 mg of heparin to 1 cc of venous blood. The use of this amount of heparin was arrived at by an extensive study upon the effects of various amounts of heparin upon the clotting time of blood.

Pyrex test tubes, 100 mm by 13 mm in dimensions, were marked with a scratch at a level coincident with the bottom part of the meniscus of 11 cc of fluid. Heparin† was diluted to provide 0.04 mg per 0.1 cc of isotonic saline, 0.1 cc of this heparin solution was placed in a dry test tube prepared as described. The clotting time was then determined after placing freshly drawn blood in the tube up to the scratch mark, thereby adding 1 cc of blood. The blood and heparin were thoroughly mixed by inverting the tube twice. A stopper was inserted and the tube was examined with minimal tilting and agitation for the formation

\*The method of electric resistance measurement was revised by Dr C W Tobias assisted by Mr L Lipetz. Measurements since June 1948 have been obtained by comparing the potential across the electrodes to a standard potential. A constant current is used and the resultant potential across the electrodes is directly related to the electric resistance. Measurements are recorded automatically by a 6 channel Speedomax (Leeds and Northrup) every twelve seconds for each sample.

†Heparin made by Lederle Laboratories was used in this study. Most commercial preparations which may be used in this test consist of the purified sodium salt of heparin in solution 1 cc containing 10 mg of heparin.

of a firm clot at one minute intervals beginning at twelve minutes. The end point or clotting time occurred when the tube could be completely inverted without any fluid breaking from the clot. Careful attention to three factors in the technique eliminated much error and variation. 1 Precise measurement of the volumes of heparin solution and blood. The use of a

Fig 1—Typical electric resistance curve with explanations and illustrations of the changes during coagulation

pipette for the measure of blood was not necessary if the relation between the scratch mark and meniscus of the blood was consistent. 2 Thorough mixing of the heparin with the blood. 3 Minimal agitation of the blood in the determination of the clotting time. In the course of this study it was possible to obtain good end points for clotting times as long as five hours. Duplicate measurements upon aliquot samples of blood showed an average variation of less than 5 per cent.

Normal range 20 to 35 minutes. Average value 27.5 minutes.

**Clotting Time (Lee White)**—This is a variation of the Lee White clotting time. One cubic centimeter of blood was placed in a dry Pyrex tube, 100 mm by 13 mm. in dimensions. The tube was examined for clot formation by minimal tilting every half minute. Normal range 5 to 10.5 minutes.

**Toluidine Blue Titration Test**—This test measured the effect of a series of concentrations of toluidine blue on the clotting time of recalcified oxalated plasma. Venous blood was mixed with 0.1 molar sodium oxalate nine parts to one and centrifuged for fifteen minutes at medium speed in a small clinical centrifuge. One tenth cubic centimeter of plasma was added to each of six increasing amounts of toluidine blue\* in 0.05 cc of isotonic saline. One tenth cubic centimeter of 0.25 molar calcium chloride solution was added to each tube which was then examined every fifteen seconds for clot formation. A control tube containing saline without toluidine blue was also measured.

**Clot Retraction by Inspection**—The amount of clot retraction was estimated by external inspection of the clots formed in the electric resistance, heparin clotting, and Lee White clotting tubes at four and twenty four hours.

\*Toluidine blue O made by National Aniline Division, Allied Chemical and Dye Corp., New York, N. Y. Total dye content was 69 per cent.

*Bleeding Time*—The method described by Duke<sup>14</sup> was used. The ear lobe was firmly punctured with a pointed scalpel blade and was observed every half minute for cessation of bleeding. Normal range 2.5 to 6 minutes.

*Prothrombin Time*—A variation of the Quick<sup>15</sup> method described by Rosenfield and Tuft<sup>16</sup> was used with a few modifications. Dried rabbit brain thromboplastin (made by Difco Laboratories) was freshly prepared each time measurements were made. 0.125 molar calcium chloride was used. Determinations were made on 100 per cent and 10 per cent plasma, which was diluted with barium sulfate treated plasma. Normal ranges 100 per cent plasma, 14.0 to 18.0 seconds, 10 per cent plasma, 24.0 to 35.0 seconds.

*Tourniquet Test*—A rubber tourniquet was placed snugly around the lower part of the arm for five minutes without obliterating the arterial pulse. A positive test consisted of the appearance of numerous petechiae below the level of the tourniquet.

*Hematocrit*—Heparinized blood was placed in a Wintrobe tube and centrifuged for one half hour at 2,000 revolutions per minute. The reading of the red cell volume in per cent was then made. Normal range 40.5 to 51.0 per cent.

*Sedimentation Rate of Red Cells*—Heparinized blood was placed in a Wintrobe tube and the amount of sedimentation of the red cells was measured in millimeters after one hour.

*Platelet Count*—Red cell pipette and Rees Eekers diluting solution were used. Counts were determined upon capillary blood. Normal range 200,000 to 400,000.

Red and white cell counts and differentials were performed according to routine laboratory technique. A photoelectric method was used for the hemoglobin determinations.

#### MATERIAL AND PROCEDURE OF STUDY

The coagulation and hematologic studies were performed both upon normal, apparently healthy subjects and upon patients seen at the Donner clinic. All the patients were ambulatory and were distributed from a standpoint of diagnosis as follows: polycythemia vera—untreated, thirty-nine, treated (in remission), four; leucemic phase, two; leucemia—acute, two; chronic myelocytic, nine; chronic lymphocytic, sixteen; chronic eosinophilic (?), one; lymphoma, four; multiple myeloma, two; agnogenic myeloid metaplasia, two; secondary polycythemia, two; other diseases (nonhematologic), six.

At various stages of the study, different groups of coagulation tests were performed. In the last two thirds of the study the following tests were routinely performed: clot retraction rate (electric resistance measurement of the blood), heparin clotting time, Lee White clotting time, hematocrit, and platelet count. Bleeding time, tourniquet test, erythrocyte sedimentation rate, and toluidine blue titration were performed on selected patients. The prothrombin time was employed only in the early stages of the study.

Many of the patients have been studied at various intervals in order to relate the coagulation picture to the hematologic and clinical course and the effect of radioactive isotopes and other therapy. However, this report is primarily devoted to the consideration of the initial studies for each patient.

#### RESULTS

The results for each test will be described briefly and then some significant relationships among the coagulation tests, hematologic picture, and clinical status will be presented.

*Clot Retraction Rate*—Fig. 2 shows the results of this test for the normal subjects and various groups of patients. For the normal subjects, the presence of two peaks can be seen at 6 to 7 and 8 to 9 ohm cm per minute. The first range corresponds to the peak of distribution of seventeen female subjects, the second to that of thirty-six male subjects. The average values of each of these groups were not statistically different. Eleven of twenty-five leucemic patients showed clot retraction rates below the lower limit of normal, while twelve of

forty one patients with polycythemia vera had values above the normal range, indicative of increased clot retraction. The distributions for the other groups are apparent.

Fig. —Distribution of results of the clot retraction rate for the various groups of subjects.

The relative effect of various factors involved in clot retraction upon the clot retraction rate was indicated by further analysis of the data and examination of the pattern of the electric resistance curves. The platelet count appeared to be the most important factor showing a high correlation coefficient with the clot retraction rate of +.83. The hematocrit as indicated by the initial blood resistance had only a negligible effect upon the clot retraction rate. The presence of an abnormally rapid red cell sedimentation rate showed its effect upon the pattern of the electric resistance curves as illustrated and explained in Figs. 3, 1 and B. This unusual pattern called the 'atypical electric resistance curve' usually occurred in the blood of leukemia patients with low hematocrits and rapid red cell sedimentation rates. The results indicate how

ever, that the clot retraction rates computed from these curves are not significantly altered by the red cell sedimentation. Fig 3, C and D, gives examples of resistance curves giving low and high clot retraction rates respectively. Twelve duplicate measurements on aliquot samples of blood showed an average variation in clot retraction rate of 10 per cent.

Fig 3—A and B Examples and explanation of the atypical electric resistance curve. C and D Examples of typical electric resistance curves which gave decreased and increased clot retraction rates respectively.

**Heparin Clotting Time**—The results of this test are shown in Fig 4. Thirty-three normal subjects showed a normal distribution of values. Eleven of twenty-one leucemic patients showed a definite prolongation of varying degree up to 155 min., as compared with the upper limit of normal of 35 minutes.

In polycythemia vera, twenty four patients had normal values three values were rapid and eight prolonged. The effect of an elevated hematocrit upon these results merits special consideration. Since the standard amount of heparin is added to a constant volume of blood samples with higher hematocrits will have a correspondingly higher heparin concentration in the plasma. As red cells do not appear to play any active part in the clotting process the higher heparin

FIG. 4.—Distribution of results of the heparin clotting time (or heparin prolonged clotting time) for the various groups of subjects.

concentration in the plasma could conceivably increase the heparin clotting time. This was found to be true for one patient who had hematocrits of 71, 63, 58 and 49 per cent at the times of study. Correction of the heparin clotting times for hematocrit caused a shift of five patients in the normal range to the rapid range.

In the other groups patients with lymphomas and other hematologic disease tended to show prolonged values while all patients without any primary hematopoietic disease were in the normal range.

*Clotting Time (Ice White)*—As shown in Fig. 5, all the patients showed normal values for this test.

In the clot retraction studies inspection of the clots frequently showed little or no evidence of clot retraction, while, at the same time the electric resistance curves indicated abnormally rapid retraction. When the electrodes were removed after twenty-four hours a small, firm clot was often found well retracted between the electrodes. This was surrounded by red cells suspended in serum which composed most of the volume of the sample. This tended to occur chiefly in patients with both elevated hematocrits and platelet counts. These patients also gave poor end points of clotting time and some times a solid clot either never formed or rapidly dissolved.

Four patients in hematologic remission had normal clot retraction rates. Platelet counts were normal in three patients slightly depressed below 200,000 in one. Heparin clotting time was normal in two and prolonged in two. Of the two patients in the leucemic phase of polycythemia one had a depressed platelet count and low clot retraction rate, while the other had normal values for these tests and for the heparin clotting time.

*Other Diseases* Because the number of patients in this category is small and the types of diseases varied only some general observations will be made. Patients with lymphomas and other diseases related to the hematopoietic system generally showed some bone marrow depression as evidenced by anemia and slight thrombocytopenia. None had any sign of hemorrhage. These patients tended to have prolonged heparin clotting times and lowered clot retraction rates. Patients without hematologic disease and without evidence of bone marrow depression had normal platelet counts, clot retraction rates and heparin clotting times. The two patients with polycythemia secondary to congenital cardiac abnormalities had normal values for these tests.

#### DISCUSSION

The results of this study have revealed certain new findings relative to blood coagulation in leukemia and polycythemia vera.

One half of the patients with either chronic myelocytic or chronic lymphocytic leukemia showed a blood coagulation defect characterized by slight

thrombocytopenia (100,000 to 200,000), diminished clot retraction rate, and prolonged heparin clotting time. This defect was closely related to the presence of clinical evidence of bleeding. The severity of the bleeding appeared to be especially related to the degree of heparin clotting time prolongation and, to a lesser extent, to the degree of depression of the clot retraction rate. The platelet count, bleeding time, and tourniquet test showed less relation to the clinical picture of hemorrhage, while the Lee-White clotting time was entirely unrelated. It should be emphasized that these patients did not have the marked purpura, hemorrhages, or thrombocytopenia (below 80,000) frequently associated with acute leukemia or chronic leukemia in the terminal stage. Study of a few patients in these categories indicates the above mentioned clotting changes to be present in even greater degree.

Leukemic patients without any evidence of bleeding showed normal values for the coagulation tests and platelet counts above 200,000. These patients, in comparison with the foregoing group, appeared to be in better condition, both hematologically and clinically. This is further indicated by the fact that one of ten patients in this group had died as of January, 1949, while among those patients showing the coagulation defect, five of eleven had died. This is compatible with the observations of Minot and Buckman<sup>17</sup> and others that the level of platelets appears related to the general status of the leukemic patient, with a progressive thrombocytopenia indicative of a poor prognosis.

In polycythemia vera, it was noted that the blood of patients with elevated hematocrits and platelet counts formed fragile, rapidly dissolving clots which appeared to have poor retraction. Electric resistance measurements and careful inspection, however, often indicated the presence of a small, well retracted clot surrounded by a red cell suspension in serum. With a relatively small amount of serum present, a widely latticed fibrin network clot probably is formed. Under the influence of the large number of platelets, clot retraction occurs at a rapid rate but fewer red cells are caught in the network so that the retracted clot becomes very small, leaving most of the red cells suspended in serum at the periphery to give the appearance of poor clot retraction, as recorded in the literature. This defective clot formation contributes to the bleeding symptomatology in polycythemia. Hence, the thrombocytosis, combined with the high hematocrit and increased blood viscosity, is an important factor in both the hemorrhagic and thrombotic complications. The comparable incidence of history of hemorrhage or thrombosis, increased platelet count, and increased clot retraction rate in 33 per cent of these patients merits particular note. It emphasizes the importance of the platelets and the urgent necessity of reducing an elevated platelet count in the treatment of polycythemia vera to avoid serious complication from thrombosis or hemorrhage. The depressant effect of  $P^{32}$  and other radioactive isotopes upon platelet formation enhances their value as therapeutic agents in polycythemia vera.

The mechanism of the prolongation of the heparin clotting time, which is indicative of an increased clotting sensitivity of the blood to added heparin,

cannot be fully explained. It involves incompletely understood effects of heparin upon the clotting mechanism and the factors in the blood which can either inactivate heparin by combining with it or which directly antagonize its anticoagulant properties. On the basis of the present study and a critical review<sup>18</sup> of the literature it appears that the platelets play a very important role in determination of the resultant effect of heparin upon the clotting time. This is indicated by statistical analysis of the data in the present study which revealed positive correlations between the heparin clotting time and both the clot retraction rate and platelet count. This is further seen in the occurrence of a prolonged heparin clotting time chiefly in patients with hematologic evidence of bone marrow depression, thrombocytopenia and impaired clot retraction. Studies to determine the relative effects of platelets and heparin upon the clotting mechanism are in progress.

The suggestion by Allen and associates<sup>19</sup> that in bleeding associated with thrombocytopenic purpura an increased amount of heparin or similar substance may be in the blood appears unlikely. In two leucemic patients with marked hemorrhages the toluidine blue titration test was negative for free or increased heparin in the blood. One of these patients had a markedly prolonged heparin clotting time of 154 minutes. It is improbable that even a minimal blood heparin increase which is not great enough to be detected by any present method could approach in importance the role of the thrombocytopenia as a causative factor in the hemorrhagic symptoms of these diseases.

The results of this study indicate the relative value of the various coagulation tests or indices. The platelet count, bleeding time and tourniquet test for capillary fragility are liable to both subjective and inherent errors and, at best, give only approximate and qualitative information. The prothrombin time shows significant alterations in a limited type of hemorrhagic dyscrasia as seen in severe liver damage. The Lee-White clotting time reveals clotting abnormalities in only a small fraction of conditions of which hemophilia is the most prominent. The limited value of this widely used test cannot be overemphasized.

The clot retraction rate obtained by electric resistance measurements provides both an objective and quantitative measure of clot retraction, the importance of which has suffered through a lack of adequate means for its measurement. It has been shown that the electric resistance method eliminates the effect of certain variable factors such as hematocrit and erythrocyte sedimentation rate which often prevent reliable evaluation of clot retraction by inspection. There is a high correlation between platelet count and clot retraction rate. Its clinical use is limited by the equipment required but a portable instrument is in the process of development.

The heparin clotting time appears to give an extremely sensitive and quantitative coagulation measurement in close agreement with the clinical findings. The value of this test in the detection of accelerated clotting in thrombotic conditions has long been realized<sup>20, 21</sup> but it has been of little clinical value because of inadequate standardization and simplification. The

method presented in this report has been devised to eliminate these difficulties. The test can readily be adapted to routine clinical use for the detection of either a rapid or slow clotting process. In addition to its diagnostic value, it can serve as a valuable therapeutic guide.

#### SUMMARY

1 Two methods for the measurement of blood coagulation are presented: the heparin clotting time and the clot retraction rate. The heparin clotting time measures the clotting sensitivity of the blood to added heparin. The clot retraction rate is a quantitative measure of clot retraction obtained by electric resistance measurements. Both tests were well standardized on a large number of normal subjects. Clearly defined upper and lower limits of normal were established.

2 In chronic leucemia, both myelocytic and lymphocytic, one half of the patients showed a previously unreported coagulation defect characterized by a prolongation of the heparin clotting time, decreased clot retraction rate, and a slight thrombocytopenia between 110,000 and 180,000. The severity of this defect was closely related to the degree of hemorrhagic symptoms. No free or neutralizable heparin was detected by a toluidine blue titration test in the blood of two patients with marked hemorrhagic symptoms and the foregoing clotting defect. Leukemic patients without this clotting defect and thus with normal values for the coagulation tests showed no evidence of bleeding. These patients were in better condition, both hematologically and clinically, and had a better prognosis than patients with the coagulation defect.

3 Of the untreated patients with polycythemia vera and elevated hematocrits, 33 per cent showed increased clot retraction rates and platelet counts elevated above 400,000. A similar percentage of these patients had histories of either thrombosis or hemorrhage. An explanation is given for the simultaneous presence of an increased clot retraction rate, external appearance of poor clot retraction, and the formation of fragile, readily dissolving clots in many of the patients. These studies indicate that the elevation in platelet count is the most important single factor in the occurrence of both hemorrhage and thrombosis in polycythemia. Therapy should aim toward the rapid reduction of an increased number of platelets.

4 The results of this study provide indications of the relative clinical value of the various coagulation tests. The inadequacies and limitations of the platelet count, bleeding time, tourniquet test, and clot retraction estimated by inspection are shown. The extremely limited value of the widely used Lee-White clotting time cannot be overemphasized. The clot retraction rate provides a useful, quantitative measure of clot retraction but it requires special equipment for its performance. The heparin clotting time appears to be the most valuable single test or index of coagulation. Readily adaptable to both routine clinical and experimental use, it enables the detection of either abnormally increased or decreased clotting ability.

The author wishes to thank Dr. John H. Lawrence for his valuable guidance and continued interest, and Agnes Benedek for her assistance. Dr. H. Jones and Dr. J. Weaver provided assistance in the presentation.

## STUDIES ON THROMBOCYTOPEN

### I A RELIABLE TEST FOR THIS PRINCIPLE IN ORGAN HOMOGENATES AND IN URINE

KARL SINGER, M D, AND ROYAL ROTTER, M D  
CHICAGO, ILL

**I**N 1933 Torrioli and Puddu<sup>29</sup> discovered that an extract prepared from the spleen of a patient with idiopathic thrombocytopenic purpura contained an agent which injured the megakaryocytes in bone marrow cultures. The same principle was then found to be present not only in normal spleens, but in other normal organs as well (liver, lung, heart, lymph nodes, and omentum), although in apparently lesser concentrations. When a protein-free aqueous extract from a normal spleen was injected intravenously into rabbits, a considerable reduction of the platelets in the circulating blood became noticeable. Blood of the splenic vein contained more of this agent in comparison with blood of the splenic artery. Based on these findings, the hypothesis was advanced that thrombocytopenic purpura may be caused by an increased production of a platelet-reducing substance in the spleen. Splenectomy therefore should abolish this factor.

Tiroland and Lee<sup>30, 31</sup> in 1938 demonstrated that acetone extracts of three spleens of patients with Weillhof's disease decreased the platelet count sharply when injected into rabbits. They called the principle responsible for these changes "thrombocytopen." However, these workers were not able to recover thrombocytopen from normal organs (including the spleen), nor from spleens of patients with hemolytic anemia or Banti's syndrome.

Subsequently many investigators have studied this problem. Although some could confirm these findings,<sup>6, 13, 16, 17, 18, 22, 25</sup> others did not observe any platelet reduction<sup>11, 1, 19, 28</sup> or found inconsistent results.<sup>4, 10, 1\*, 3\*, 3\*</sup> The variable responses were often considered to be caused by the mode of preparing the extracts. Most investigators used acetone, although Hobson and Witts<sup>10</sup> found a suspension of the tissue particles in Ringer solution more effective. Interpretation of the results was also difficult because of the spontaneous fluctuations of the platelet counts in the test animals. Most workers used rabbits but rats<sup>4, 32, 3\*</sup> and dogs<sup>3\*</sup> also were employed.

Our approach to this problem was directed by the following considerations. Assuming that a thrombocytopen is manufactured by the spleen in thrombocytopenic purpura, it seems very likely that the liver—being the first organ to receive the blood coming from the spleen—might inactivate this principle. This assumption becomes even more probable when Moolten's hypothesis,<sup>13, 14</sup> that thrombocytopen may be a steroid, is taken into account. The effect of thrombocytopen may then depend not only on its concentration in the extract, but also

From the Department of Hematologic Research, Medical Research Institute, Michael Reese Hospital.

This work was aided by the Sol Kline Fund. The Department of Hematologic Research is also supported in part by the Hematology Research Foundation and the Michael Reese Research Foundation.

Received for publication June 21 1949

on the modifying activity of the liver of the test animal. Consequently, a more reliable test for thrombocytopen may become available by injection of organ extracts into animals with liver cell damage.

These considerations seem to be borne out by our experimental studies. When organ homogenates were injected intraperitoneally into rats in which a high degree of liver cell damage was produced by carbon tetrachloride, a marked reduction of the platelet counts was consistently demonstrable. These results were not only obtained with preparations from normal and pathologic human spleens but also with material from other normal animal organs. A thrombocytopen\* was found also in urine from which it could be extracted with ether.

#### MATERIAL AND METHODS

All studies were performed on albino rats weighing between 150 and 300 grams. Male rats were used since males are more susceptible to intoxication with carbon tetrachloride than are females.<sup>8</sup> The animals were kept in separate metal cages and maintained on Purina dog chow and water. Each rat was used for one experiment only.

Blood was obtained by heart puncture under ether anesthesia, with tuberculin syringes and gauge 23 needles, which had previously been rinsed with a 3.8 per cent sodium citrate solution. About 0.2 cc of blood was transferred into a small paraffin dish containing a few crystals of an ammonium and potassium oxalate mixture.<sup>9</sup> The blood was stirred gently with a paraffin stick to achieve equal distribution of the formed elements. Films were prepared from the last remaining drop of blood in the syringe.

In each instance the red and white cell counts were determined besides the enumeration of the platelets. For the latter the method of Rees and Ecker<sup>21</sup> was used. The hemocytometers were kept for a period of twenty minutes in a wet chamber to assure proper settling of the thrombocytes without loss of fluid. All platelet counts were performed simultaneously by two workers and the results averaged.

Normal values established with these procedures are: RBC 7.36 million  $\pm$  1.3; WBC 16,300  $\pm$  6,000; platelets 500,000 to 900,000 per cubic millimeter. Rarely an animal was encountered showing a platelet count below 500,000. Such rats were considered unsuitable for the experiments. Ether anesthesia did not influence the results.<sup>5</sup>

Evaluation of the platelet count must take into account that the number of thrombocytes in the same animal may vary greatly, the range lying between 500,000 and 900,000. The same figures represent the normal values found in the rat population as a whole. Normal animals used in this study never had a platelet level below half a million. Consequently, a decrease was considered significant only when the thrombocytes were reduced below this value.

**Production of Liver Cell Damage**—Carbon tetrachloride (0.5 cc per kilogram) was injected intraperitoneally on alternate days according to the method of Brauer and Root.<sup>3</sup> This procedure assures severe liver cell damage with only minor injury to the kidneys. Two injections were found to be sufficient to secure adequate responses to thrombocytopen. If desired the liver cell damage may be maintained by repeated administrations of carbon tetrachloride. Blood films from such animals very frequently showed many target cells. Target cells are known to occur also in human parenchymatous liver disease.<sup>1</sup>

**Preparation of Organ Suspensions**—After removal from the organism the organs were immediately wrapped in a clean cloth and placed on dry ice in a deep freeze unit. For preparation of the saline suspension the organs were defrosted, weighed and cut into small pieces. These were mixed with double the volume of physiologic saline solution in a Waring Blender gradually set to maximal speed for a period of ten minutes. The saline suspension

\*For the sake of convenience and because of its use in the literature the term *thrombocytopen* will be used throughout to denote a chemically unknown factor or factors which depress the platelet count in the test animal.

was then filtered first through two layers and then through four folds of gauze. After this the suspension was put back into the freezing unit and defrosted completely for each particular use.

*Procedure for the Determination of the Effect of Organ Suspensions in the Rats With Liver Cell Damage*—Liver cell damage was first produced by two applications of carbon tetrachloride. Two days following the last injection the red cell, white cell and platelet counts were determined. Then each animal was injected intraperitoneally with 10 cc of the organ suspension. Furthermore carbon tetrachloride was given to maintain the liver injury to prevent the development of any infection, 0.1 cc of procaine penicillin (Duracillin Lilly) was also injected subcutaneously. The next day the counts were repeated. If the effect was minimal the animals were reinjected with the homogenate and also with Duracillin. Counts were determined again the following day.

For the evaluation of each suspension a group of at least four rats was used. Significant changes of the red and white cell counts were hardly ever noted. These findings preclude the interpretation that the observed reduction in the number of platelets was caused by hemodilution. Occasionally the organ suspension was quite toxic and the animals died within a few hours after the injections.

The platelet counts of each group of rats before and after the injections were averaged and the decrease was expressed in per cent of the average platelet count. By this procedure the individual variation in the reaction of the animals toward the active principle contained in the material were taken into account.

## RESULTS

*1 Effect of Penicillin and of Carbon Tetrachloride on the Platelet Count*—Procaine penicillin (Duracillin 0.1 cc) which was used prophylactically throughout the experiments does not produce thrombocytopenia (Table I). The apparent increase of the platelet level lies within the range of daily fluctuations.

Carbon tetrachloride was tested in thirty six animals. The slight decline in the average platelet count (Table I) is insignificant since no animal showed a decrease below the range of normal even if four injections of the liver poison were given. Both drugs did not influence the red and white cell counts significantly.

*2 Comparison of the Effect of Injected Organ Suspensions on the Platelet Counts of Normal Rats and Rats With Liver Cell Damage*—Seven organ suspensions were studied. Ten cubic centimeters of the homogenized organs were injected in each instance. Table II summarizes the values obtained. Each value represents the average platelet count of at least four animals.

The organ suspensions when injected into normal rats left the platelet level practically unchanged with the exception of the material prepared from normal dog kidneys. In this experiment (Experiment 7) the first injection brought the thrombocyte count definitely out of the normal range and a second injection produced a further considerable decrease.

In the rats with liver cell damage the first injection consistently lowered the platelet counts significantly. Following a second injection the decrease was still more pronounced with the exception of Experiment 4 in which the platelet level returned to normal. This was the only observation of this kind encountered in this study. Ordinarily a second injection of potent material when given to rats with liver cell damage, either maintains or even further decreases the thrombocytes in the circulation.

\*Each value represents the average of at least four animals

The findings seem to indicate that liver cell damage permits a principle in the organ suspensions to exert its effect on the platelet level. Apparently the normal liver renders this thrombocytopenic agent ineffective. Contrary to our expectations, however, the suspensions prepared from the spleens of patients with normal platelet counts (Experiments 4 and 5) seemed to be as potent as those obtained from the spleens of patients with severe thrombocytopenic purpura (Experiments 1, 2, and 3). Furthermore, thrombocytopen was equally demonstrable in the normal dog spleen and was apparently present in the highest concentration in normal dog kidneys, since the latter material produced thrombocytopenia even in normal rats.

At this point in our investigation it was decided to use only rats with liver cell damage as test animals in further experiments. It also was felt that to secure the evidence so far obtained, more organ suspensions of various types should be tested for the presence of the thrombocytopenic principle.

3 *Effect of Injected Homogenized Normal and Pathologic Spleens on the Platelet Count of Rats With Liver Cell Damage*—Table III summarizes the results

\*Each value represents the average of at least four animals

All spleens were obtained during life with the exception of the case of thrombotic thrombocytopenic purpura<sup>26</sup>. In this instance the organ was received one hour after the death of the patient. The few values previously mentioned in Table II are included in this summary for a more convenient survey of the whole material studied. Regardless of the weight of the spleen and the presence of pathologic tissues (Hodgkin's granuloma, lymphosarcoma, Gaucher's disease, etc.), 10 c.c. of the homogenized suspension were always injected. As can be seen from Table III, all suspensions lowered the platelet level considerably. Usually a single injection produced a reduction of more than 40 per cent. If the decrease was less than 40 per cent of the preinjection level, a second injection was given, which in most instances caused a further decline of the thrombocyte count. The spleens of the patients with spherocytic hemolytic anemias seemed to contain comparatively less of the thrombocytopenic agent, although it still was readily demonstrable. Suspensions from the normal spleens caused approximately the same reduction of the level of thrombocytes as could be achieved with some suspensions prepared from pathologic spleens. No correlations were demonstrable between platelet reduction in the patient whose spleen was used for the injection and the degree of platelet decline in the injected animals. Although various pathologic spleens were used in this series of experiments, none of the homogenates produced any significant changes in the red or white cell counts.

*1 Effect of Normal Organ Homogenates on the Platelet Count of Rats With Liver Cell Damage*—The results are compiled in Table IV. The values show convincingly that the thrombocytopenic agent is not only present in dog and beef spleen, but may also be found in homogenates prepared from lungs, heart, and kidneys of a healthy dog. The suspension of lung tissue caused the severest depression of the platelet level, namely a reduction of 75 per cent of the original count.

TABLE IV EFFECT OF SUSPENSIONS OF NORMAL ANIMAL ORGANS ON THE PLATELET COUNT OF RATS WITH LIVER CELL DAMAGE\*

Beef spleen		623	411	338		

\*Each value represents the average of at least four animals.

*5 The Dose-Response Relationship Between Injected Organ Suspensions and Reduction of the Platelet Count*—For the evaluation of our findings, the problem is of obvious importance whether some correlation exists between the amount of homogenate injected and the demonstrable fall of the platelet level.

Doses of 10, 8, 6, 4, 2, and 1 cc of the same saline suspension prepared from a normal human spleen were injected into groups of at least four rats with liver cell damage. The results are compiled in Table V.

TABLE V DOSE RESPONSE RELATIONSHIP BETWEEN AMOUNT OF HOMOGENATE INJECTED AND DECLINE OF PLATELET COUNT

AMOUNT OF SUSPENSION (NORMAL HUMAN SPLEEN) INJECTED (CC)	RATS USED	AVERAGE % DECREASE OF PLATELETS
10	4	64 $\pm$ 1L
8	4	61 $\pm$ 22
6	5	41 $\pm$ 13
4	4	35 $\pm$ 4
2	4	43 $\pm$ 11
1	4	24 $\pm$ 24

As can be seen from the table the two largest doses (10 and 8 cc) produced the greatest decline of the platelet count 64 and 61 per cent respectively. However, the response to 2, 4 and 6 cc of the suspension was approximately the same (35 to 43 per cent). The smallest dose of 1 cc elicited also the slightest effect, i.e. 24 per cent.

These results show that the dose response relationship is not a linear one but that within certain ranges larger amounts of the suspension produce greater responses. Since these studies were performed with crude homogenates, it was not considered advisable to pursue the problem further. With the isolation and purification of thrombocytopen, the rat with liver cell damage promises to become a reliable test animal for the quantitative bio assay of the platelet reducing agent.

6 *Effect of Hemoglobin Solutions and of Thromboplastin on the Platelet Count of Rats With Liver Cell Damage*—It was noticed that many animals developed hemoglobinuria following the injection of the organ homogenates. In the course of the freezing and defrosting processes employed in the preparation of the suspensions the blood contained in the organs becomes hemolyzed. Thus a relatively large quantity of free hemoglobin and erythrocyte stroma was injected into the rats with liver cell damage together with the homogenized tissues. The question arose whether the thrombocytopenia in the animals might not be caused by this hemoglobinemia. In cases of severe hemoglobinemia in human beings regardless of the etiology thrombocytopenia is frequently observed.<sup>24</sup>

Therefore 10 cc of a 3 per cent suspension of washed dog erythrocytes hemolyzed by addition of distilled water were injected into the animals. As can be seen from Table VI (Experiments 1 and 2) this procedure was followed by an insignificant drop of the thrombocyte level.

The very conspicuous reduction of the platelet level with the lung suspension (Table IV) led us to consider the possibility that thromboplastin may be identical with the thrombocytopenic agent. Thromboplastin is another ubiquitous tissue factor known to be present in particularly high concentration in the lungs. Consequently Thromboplastin Maltine, a rabbit lung preparation as well as rabbit brain thromboplastin made according to Quick's method<sup>25</sup>

TABLE VI EFFECT OF HEMOGLOBIN SOLUTIONS AND OF THROMBOPLASTIN ON THE PLATELET COUNT OF RATS WITH LIVER CELL DAMAGE\*

\*Each value represents the average of at least four animals

was investigated. For each single rat experiment, 200 mg of the lung or brain powder were first suspended in saline and then injected as a whole. In another experiment the same type of organ emulsion was incubated at 56° C for fifteen minutes and then centrifuged at low speed for five minutes. The supernatant milky fluid was injected separately as was a suspension of the granular material found at the bottom of the centrifuge tube. Determination of the prothrombin times revealed that the former contained much more thromboplastin than the latter (13 and 30 seconds respectively).

The results of these experiments may be seen in Table VI (Experiments 1 and 4). Since the supernatant fluid, richer in thromboplastin, is evidently poorer in thrombocytopen, the conclusion seems justified that these two factors are not identical.

These experiments furthermore show that thrombocytopen cannot be extracted satisfactorily from organs by means of acetone since the thromboplastin preparations were made by macerating the organs under acetone and discarding the acetone extract. However, the remaining dry powder still contained a very potent thrombocytopenic agent.

7 *Effect of Normal Urine and the Urine of Patients With Thrombocytopenic Purpura on the Platelet Count of Rats With Liver Cell Damage*—Our experiments have demonstrated that thrombocytopen is inactivated by the liver. Inactivation of metabolites often occurs by conjugation with acids in the liver and subsequent excretion of the substances in the urine. When 10 cc of the concentrated morning urine of two healthy male persons were injected into rats with liver cell damage, definite reductions of the platelet counts were noticeable. The same results were obtained with urine specimens from two female patients with severe thrombocytopenic purpura.

The thrombocytopenic agent could be extracted from the urine specimens with ether. Extraction was performed by adding 3 parts of ether to 1 part of urine in a separatory funnel and shaking for ten minutes. This procedure then was repeated twice. From the combined extracts the solvent was evaporated at room temperature and the dark and sticky residue was dissolved in the appropriate amounts of carbon tetrachloride needed for maintaining the liver cell damage in the rats. By addition of saline a good emulsion could be obtained with shaking, which permitted the application of the correct doses of the various substances. It should be emphasized that no change of the platelet count was seen when carbon tetrachloride and the thrombocytopenic free urine residue were injected (Table VII).

The demonstration that the platelet reducing agent can be completely recovered from the urine with ether will probably permit quantitative estimations of the urinary output of this factor in normal and various pathologic conditions. Such studies will be reported later. So far the experiments summarized in Table VII mainly show that thrombocytopen is excreted in the urine.

When the ether extract of larger amounts of urine was injected into normal rats (extract residue of 175 cc of pooled urine suspended in saline injected per rat) no significant reduction of the platelet level was observed. These results are in agreement with the findings of Tocantins,<sup>28</sup> who could not decrease the thrombocytes of normal rabbits with urinary extracts. The detoxifying action of the normal liver apparently is very efficient. The amount of thrombocytopen able to reduce the platelet count in normal animals remains to be determined. Such studies may better be performed when sufficient quantities of the purified material are available.

*Mode of Action of Thrombocytopen*—Although the reduction of thrombocytes following the injection of organ homogenates is sometimes a considerable one we have never noticed the development of true purpuric lesions in our experimental animals. This finding is not an unexpected one. Roskam<sup>21</sup> as well as Bedson<sup>22</sup> showed that by intravenous injection of gelatin or agar extreme thrombocytopenia may be produced without any increased bleeding tendency. However, if the capillaries were damaged simultaneously (e.g. by antiried cell serum) purpura resulted.

From the experimental observations of Torrioli and Puddu<sup>20</sup> it is likely that thrombocytopen acts directly on the megakaryocytes by inhibiting platelet production. This view is also emphasized by Dameshek and Estren. We have postponed a systematic study of the marrow until a purified thrombocytopen is at hand. In the few instances in which the marrow was examined after injection of organ homogenates a slight increase of the more immature basophilic megakaryocytes was noted occasionally.

In a few animals the recovery phase following a single injection of an organ homogenate was studied. If after the production of thrombocytopenia all applications were stopped the platelet count returned to normal within twenty four to seventy two hours.

## DISCUSSION

The results of our experiments seem to indicate that a thrombocytopenic agent can be obtained from many different normal organs (spleen, lungs, heart, kidneys, and brain). Since consistent lowering of the platelet count is demonstrable only in animals with liver cell damage and since it also can be produced by the injection of urine, one may speculate that physiologically thrombocytopen is rendered innocuous in the liver and then is excreted in the urine. Since it can be recovered from the ether extract of the urine, this factor is probably lipid in nature. Thus the metabolic behavior of thrombocytopen resembles closely the well known pattern found with many steroid compounds.

The role which the liver plays in the inactivation of thrombocytopen may also partly explain the inconsistent or negative results of many investigators (ten out of nineteen) who worked with organ or urine extracts and injected them into normal animals. Our results permit the statement that the rat with liver cell damage is well suited for the demonstration of the thrombocytopenic agent.

Thrombocytopen has been of interest to most investigators on account of its hypothetical role in the pathogenesis of thrombocytopenic purpura. Torrioli and Puddu<sup>2</sup> have emphasized that the principle which injured the megakaryocytes in bone marrow cultures is also present in many normal organs. If thrombocytopen is identical with this factor of the Italian authors, who used a 'protein free aqueous extract' our findings confirm their observations. We have, however, not been able to demonstrate any significant differences in the degree of thrombocytopenia produced in the animals by the homogenates prepared from the various types of pathologic spleens. The results obtained with the sixteen human spleens used in this study (Table III) may be grouped in relation to the hematologic status of the splenectomized patients. With normal spleens the average platelet reduction in the animals following a single injection was 57.5 per cent; with spleens from patients with severe idiopathic or symptomatic thrombocytopenic purpura (Table III, Experiments 3 to 9) the decrease was 45 per cent; and with spleens of patients without thrombocytopenia but with other hematologic disorders (Table III, Experiments 10 to 16) the lowering of the platelets amounted to 41.7 per cent.

Since the suspensions always were prepared in the same manner and the injected dose was kept constant, these results indicate that the concentration of the platelet reducing principle per gram of tissue apparently was not increased in the spleens from patients with thrombocytopenic purpura. Furthermore, there was no splenomegaly in the patients with Werlhof's disease, which fact rules out the possibility that the absolute amount of thrombocytopen with these extirpated organs may have been abnormally large.

On the other hand it must be realized that crude homogenates are not too well suited for exact quantitative evaluation, as may be seen from our study of the dose response relationship (Table V) in which a saline suspension prepared from a normal spleen was used. Furthermore, the quantity of a biologic agent present in an organ at any given moment does not directly reflect on its

production within this organ, or on its release into the circulation. Since our demonstration of the thrombocytopenic principle in the urine did not include any quantitative estimation of the output per day, this problem requires further investigation. Nevertheless, if one takes into consideration that so many normal organs contain at least a similar concentration of thrombocytopen as can be found in normal as well as in pathologic spleens, there is no evidence available from our data to support the hypothesis that this agent may definitely be involved in the pathogenesis of thrombocytopenic purpura. However, we are not yet able to explain why some investigators, although using normal animals for testing, could demonstrate the principle more readily in pathologic spleens than in normal organs.

In this respect the work of Moolten<sup>13, 14</sup> is of particular interest. This author reported that normal and also certain pathologic spleens (e.g. in Hodgkin's disease) contain not only thrombocytopen but also another lipoid factor which has the opposite effect on the platelet level. He called this antagonist of thrombocytopen, capable of increasing the thrombocyte count, "thrombocytosin." Both thrombocytopen and thrombocytosin could be obtained as relatively purified substances and formed ether-insoluble digitonides in the manner of steroids. Thrombocytosin also was found in high concentrations in fatty tissues and in egg yolk and was effective when given orally. Normal urine and particularly the urine of a splenectomized patient sometimes contained large amounts of the platelet-increasing agent. Moolten speculates that thrombocytopen may be concerned in balancing the thrombocytosis produced by the dietary factor thrombocytosin. Under the conditions of our experiments with rats with liver cell damage we have not yet encountered any results suggestive of an effect of thrombocytosin.

Ungai<sup>33, 34</sup> has isolated two substances from the spleen capable of influencing the bleeding time of guinea pigs. "Splenin A" decreases, whereas "Splenin B" definitely increases, the bleeding time. Splenin B is considered to be possibly identical with the thrombocytopen of Tioland and Lee.<sup>31</sup> However, no experimental evidence is yet available demonstrating the ability of Splenin B to reduce the platelet level. It should be of interest to test these substances in rats with liver cell damage.

So far we have assumed that the thrombocytopenic agents found in the various organ homogenates as well as in the urine are one and the same principle. There is actually no proof for such an assumption, and this approach should be considered primarily a working hypothesis. We are, however, convinced that the thrombocytopenia in the rats with liver cell damage is a specific response to a single factor or to several factors. Such an interpretation is supported by the finding that the reduction of the platelets was not accompanied by any change in red and white cell counts.

The physiologic significance of thrombocytopen is at present unknown. It should be kept in mind that the demonstration of a powerful biologic agent obtained from animal tissues does not necessarily indicate any "physiologic activity." Heparin, for instance, is certainly a very potent anticoagulant but its role in the normal coagulation process is still debatable.

The use of the rat with liver cell damage should provide a reliable tool for the study of many problems related to 'thrombocytopen'. Whatever the outcome may be, the doubts concerning the reality of such a factor or factors may now be abandoned. Their existence at least seems to be assured.

#### SUMMARY

1 Thrombocytopen is the name which has been given to a principle, present in the spleen which when injected into laboratory animals, is said to decrease their platelet count. This principle is believed to play an important role in the pathogenesis of thrombocytopenic purpura. So far nine out of nineteen investigators have confirmed the existence of this thrombocytopenic agent whereas the others obtained either inconsistent or negative results.

2 Our approach to this problem was directed by the following considerations. Assuming that thrombocytopen is manufactured predominantly by the spleen it seems very likely that the liver—being the first organ to receive blood coming from the spleen—may be involved in the inactivation of this principle. The effect of thrombocytopen may then depend not only on its concentration in the organ extracts but also on the modifying activity of the liver in the test animals. Consequently a more reliable test for thrombocytopen may become available by injection of organ suspensions into animals with liver cell damage.

3 When organ homogenates were injected into rats with a high degree of liver cell damage produced by carbon tetrachloride, a considerable drop of the platelet count was consistently produced. The same organ suspensions did not reduce the platelet count of normal animals. Neither penicillin (used for prevention of infection) nor carbon tetrachloride by themselves influenced the platelet levels. No changes in the red or the white cell counts were observed.

4 Two normal human spleens, seven spleens from patients with thrombocytopenic purpura (idiopathic and symptomatic) and seven spleens from patients without any thrombocytopenia but with other hematologic disorders were tested. All these organs contained thrombocytopen in approximately similar concentrations. The platelet reducing agent also was found in at least the same amount in normal organs (lung, heart, kidney, brain) obtained from dogs, cattle or rabbits.

5 When urine specimens of normal individuals or from patients with thrombocytopenic purpura were injected into rats with liver cell damage a significant reduction of the platelet level also occurred. The platelet reducing agent could be extracted with ether.

6 These results may indicate that physiologically thrombocytopen is rendered innocuous in the liver and then excreted in the urine. Since it can be recovered from the ether extract this factor is probably lipid in nature. Thus the metabolic behavior of the thrombocytopenic agent resembles the well known pattern of steroid compounds.

7 There is at present no evidence available from our data which would support the hypothesis that thrombocytopen is definitely involved in the pathogenesis of thrombocytopenic purpura. However, further studies are necessary.

8 The thrombocytopenic agents found in the various organ homogenates, as well as in the urine have been assumed to be one and the same principle. This approach should be considered primarily a working hypothesis.

9 The use of rats with liver cell damage should provide a reliable tool for the study of many problems related to thrombocytopenia. Whatever the outcome may be, the doubts concerning the reality of such a factor or factors may now be abandoned. Their existence at least seems to be assured.

# THE FIBRINOGEN B TEST AND INTRAVASCULAR THROMBOSIS

CAPTAIN ARTHUR B VOORHEES, MEDICAL CORPS,  
ARMY OF THE UNITED STATES, AND MAJOR EDWIN J PULASKI,  
MEDICAL CORPS, UNITED STATES ARMY

IN RECENT years intravascular thrombosis has assumed a prominent position on the list of postoperative complications as other more common complications have been brought under control. A laboratory method for determining the presymptomatic thrombosis would be of great value in reducing the mortality rate and serious sequelae of intravascular thrombosis. Our interest in the fibrinogen B reaction was stimulated by the possible relationship it might hold to the diagnosis of intravascular thrombosis. The fibrinogen B reaction described by Cummine and Lyons<sup>1</sup> was studied for a six-month period on the Surgical Service of Brooke General Hospital. The data set down in the report were derived from patients who had been hospitalized during this period of study.

Cummine and Lyons accepted the earlier hypothesis of Berquist,<sup>1</sup> who stated that just prior to the formation of an intravascular thrombus a "pre thrombotic state" exists during which there is a significant reduction in venous clotting time. Although these investigators employed slightly different methods of clotting time determination, the critical zone was considered to be 3 to 4 minutes, or less.

Cummine and Lyons introduce the concept of an intermediary product in the fibrinogen-to-fibrin reaction, to which they give the name fibrinogen B. The presence of fibrinogen B in the circulating plasma is considered abnormal. They correlate its presence in the plasma with the production of intravascular thrombosis. They note that fibrinogen B appears in the plasma whenever tissue necrosis is present, especially in the case of pyogenic infection. Lyons has demonstrated in vitro that platelet fragility increases in the presence of fibrinogen B and has postulated the following possible mechanism<sup>1</sup>

From the Surgical Research Unit Brooke General Hospital Brooke Army Medical Center  
Fort Sam Houston Texas  
Received for publication July 5 1949

Cummie and Lyons studied 580 patients and catalogued the results of their investigation as follows<sup>1</sup>

Group 1—In these patients free fibrinogen B does not occur in the plasma and the coagulation graph is of normal type. Intravascular thrombosis does not develop in these cases.

Group 2—Free fibrinogen B may be found in the plasma either persistently or intermittently but the coagulation graph is of normal type. Providing that no previous thrombosis has occurred and is remaining as an intravascular foreign body and that venous stasis is prevented thrombosis does not develop in these cases.

Group 3—Free fibrinogen B occurs in the plasma and the coagulation times remain persistently low in the order of 3 to 4 minutes. Intravascular thrombosis appears to be inevitable in these cases either in the legs or at the lung bases.

Group 4—No free fibrinogen B is found in the plasma but the coagulation graph is consistently low. This combination of the two factors has not occurred in any of the patients studied as a primary phenomenon but has been seen on several occasions after an intravascular thrombosis has occurred. In each instance it is significant that the thrombosis recurred at the initial site and can be interpreted as a local exacerbation due to the presence of an intravascular foreign body in association with venous stasis.

We have undertaken a study for the purpose of estimating the practical value of the fibrinogen B test in a military medical establishment.

#### METHODS AND MATERIALS

*Clotting time determinations* were performed after the method outlined by Cummie and Lyons with only slight modification, i. e. the capillary tube filled with fingertip blood was broken every thirty seconds rather than every sixty seconds during the first four minutes.

*Fibrinogen B determinations* were performed as follows. The reagent was prepared by dissolving 2 Gm  $\beta$  naphthol in 100 ml of 50 per cent alcohol. If the solution turned brown, it was exposed to oxygen in order to return it to the colorless state. Blood was withdrawn from the antecubital vein in a dry sterile syringe and 4.5 ml were mixed immediately with 0.5 ml of 11 per cent solution sodium oxalate. The blood sample was taken usually mid way between breakfast and lunch; however we found no evidence to suggest that the results were influenced by food intake. The specimen was centrifuged and 1 ml plasma was placed in a 13 by 100 mm tube. Five drops of the reagent were added to the plasma and the mixture was allowed to stand at room temperature for ten minutes. If a gel formed a value of from 1 to 4+ was assigned depending on the quantity of gel present. If no gel formed during that period the test was recorded as negative for fibrinogen B.

#### RESULTS

A total of 553 fibrinogen B determinations and 337 capillary clotting time determinations were made on forty-eight hospital patients and four normal subjects. The maximum length of time an individual case was followed was fifty days and the minimum one day.

The cases chosen were selected deliberately for anticipated demonstration of a wide latitude of response to the test. Table I lists by diagnosis the types of cases studied and the results of the survey in terms of 'positive', 'doubtful' and 'negative'. The extent or severity of the pathologic changes is not correlated, nor is any quantitative estimate of the amount or duration of fibrinogen B present stated. In general however the quantity of fibrinogen B present was in direct proportion to the severity of the disease.

Columns three and four show the results obtained at room temperature and at 6° C. The description of the test set down by Lyons states that room temperature is to be used. We noted that certain tests negative at room temperature would become positive if repeated at 6° C. On further investigation, it was demonstrated that as the quantity of fibrinogen B rose it could be detected earliest at 6° C and then later at room temperature. Conversely, as the plasma content of fibrinogen B fell, the test first became negative at room temperature and later at 6° C. Correctly or not, we assumed that the gel formations at room temperature and at 6° C represented the same substance, and we used this finding as a rough quantitative index.

TABLE I

DIAGNOSIS	NUMBER OF CASES	RESULTS						
		ROOM TEMPERATURE			6° C			
		P	D	N	P	D	N	
Normal subjects	4	0	0	4	0	1	3	
Thrombophlebitis, deep	12	3	4	5	11	0	1	
Thrombophlebitis, superficial	1	0	0	1	1	0	0	
Soft tissue trauma	2	1	0	1	2	0	0	
Acute infections	6	0	1	5	5	0	1	
Acute thermal and chemical burns	3	1	0	2	2	0	1	
Chronic infection	9	0	1	8	6	3	0	
Carcinoma (brain, stomach, cervix)	3	0	0	3	3	0	0	
Abdominal stab wounds, contaminated	2	1	0	1	2	0	0	
Uncomplicated postoperatives	5	1	0	4	2	3	0	
Cirrhosis, periportal	1	0	0	1	1	0	0	
Common duct obstruction	1	1	0	0	1	0	0	
Myocardial infarction	1	0	0	1	1	0	0	
Congestive failure	1	0	0	1	1	0	0	
Late pregnancy with pyrexia	1	0	0	1	1	0	0	
(unknown origin)								
Prolonged bed rest with hip fracture	1	0	0	1	0	1	0	

P positive D doubtful N negative

Examination of the results in Table I indicates that there is no specificity of response peculiar to cases of intravascular thrombosis. Suggestive trends are poorly defined. One finding is outstanding, namely, that whenever tissue necrosis is present, the test is usually positive.

In the twelve cases of deep thrombophlebitis, only one patient demonstrated a positive test at room temperature for fibrinogen B on the day of clinical diagnosis. Subsequent positive results at room temperature were inconstant and afforded little recognized clinical value. In this series three of the twelve patients gave a clotting time of 4 minutes or less on the day of clinical diagnosis.

In the entire series of fifty-two cases, only two patients fulfilled one of the criteria of Cummine and Lyons, i.e., lowering of clotting time and the appearance of fibrinogen B in the plasma as indicative of inevitable thrombosis. Neither patient developed clinical symptoms of intravascular thrombosis.

#### DISCUSSION AND SUMMARY

Over a six-month period at Brooke General Hospital, the incidence of deep thrombophlebitis on the Surgical Service was less than 1 per cent. To conduct a survey for the purpose of extensively confirming or denying the hypothesis of

Cummie and Lyons, it would be necessary to follow daily every individual admitted to the Surgical Service that is, to make in the neighborhood of 20,000 to 25 000 tests. In the experience reported herein, 553 tests were made. In only two instances the criteria of Cummie and Lyons for inevitable thrombosis were fulfilled but neither patient developed clinical evidence for intravascular thrombosis. On the basis of experience to date the test would appear to be of no particular value in the confirmation of a diagnosis of thrombophlebitis suspected clinically. While the present small series neither confirms nor denies the concepts expressed by Cummie and Lyons it places some doubt on the precision of interpretation of low clotting times.

In light of the present good results of anticoagulant therapy in intravascular thrombosis initiated on clinical evidence alone the practicality of this test is open to question as a routine examination on all surgical patients.

The fact that the test is more sensitive at 6° C is not explained. The results are interesting but are difficult to assess.

We are in agreement with Cummie and Lyons in noting an apparent relation between the presence of tissue necrosis and the appearance of fibrinogen B in the circulating plasma. In fact this relationship is the only constant finding. We have noted also, as have Cummie and Lyons that there is a persistently negative test for fibrinogen B in thrombophlebitis after it is initially positive.

#### ADDENDUM

Dunn, Jackson and Lyons report a high percentage of positive fibrinogen B tests in congestive cardiac failure (97 per cent) recent coronary occlusion (100 per cent) thrombotic states (100 per cent) acute sepsis (100 per cent), and chronic sepsis (90 per cent).

# DETERMINATION OF PROTHROMBIN BY THE DILUTION METHOD STABILITY AND ACTIVITY OF HUMAN AND BOVINE PROTHROMBIN-FREE PLASMA

WALTER B. FROMMEYER, JR., M.D.\*  
BOSTON, MASS

WITH THE TECHNICAL ASSISTANCE OF HELEN CORRIGAN

THE reporting of plasma prothrombin activity in terms of the time in seconds required for coagulation represents incomplete data since prothrombin activity does not vary as a linear function of the time of coagulation. However, prothrombin activity is reported properly in terms of concentration in per cent of the average concentration of pooled normal plasma. Plasma prothrombin concentration can be determined by one of two basic methods. The two stage method of Warner, Binkhous, and Smith,<sup>18</sup> an excellent research method, is too demanding on the basis of time and reagents required to be of routine clinical use. The one stage method of Quick<sup>11</sup> is generally employed because of its simplicity and rapidity of performance. The Quick method, however, determines only the prothrombin time or the speed of the reaction comprising coagulation. In order to convert the prothrombin time to prothrombin concentration it is necessary to determine the prothrombin time of known concentrations of prothrombin. By arbitrarily considering that pooled normal plasma has a prothrombin concentration of 100 per cent, then any particular dilution of the pooled plasma theoretically is equivalent to a corresponding dilution of prothrombin. In practice the prothrombin times of several known dilutions of plasma are determined and a reference curve is made, plotting the prothrombin time in seconds along the abscissa and the prothrombin concentration, in terms of per cent of normal, along the ordinate. Such a curve is then used for conversion of prothrombin time in seconds to prothrombin activity in terms of per cent concentration of prothrombin.

Because of the significant variations in the shape and slope of the reference curves using various diluents of pooled normal plasma, Rosenfield and Tuft<sup>14</sup> suggested the use of a diluent that is theoretically ideal, namely, normal plasma treated with barium sulfate to remove prothrombin. Because the resulting reference curve, using such a diluent, has a steep slope from a prothrombin concentration of 100 to 20 per cent and a flat linear slope from 15 to 1 per cent, it becomes necessary to reduce the prothrombin concentration in a given plasma to approximately 10 per cent in order to determine accurately its prothrombin concentration. This dilution is required to reduce to a minimum the error that results from variations of a few seconds when converting prothrombin time to prothrombin concentration.

From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard) Boston City Hospital and the Department of Medicine, Harvard Medical School.  
Received for publication July 7, 1949.

\*Research Fellow in Medicine, Harvard Medical School. Assistant Resident Physician, Thorndike Memorial Laboratory.

The dilution method for prothrombin determination is outlined by Rosenfield and Tuft<sup>14</sup> is accurate and reproducible and is therefore desirable. However, there have been two technical limitations of the method. The first is the rapidity with which prothrombin free plasma becomes altered on standing and the second is the unavoidable reduction of certain prothrombin accelerators<sup>15</sup> by treatment of plasma with barium sulfate. Both of these alterations of barium sulfate treated plasma may result in prolongation of the prothrombin time of diluted fresh normal plasma that may be incorrectly interpreted as indicating a reduction in prothrombin concentration. The purposes of this paper are (1) to report a method whereby prothrombin free plasma can be maintained in stable form for many weeks and (2) to offer a procedure for correction of decreased content of the 'prothrombin accelerators'.

#### MATERIALS AND METHODS

**Thromboplastin**—Lyophilized acetone extracted rabbit brain (Difco) was used. Activation of the material as outlined by Difco Laboratories was effected by suspending 0.15 Gm of the lyophilized material in 4 ml of a solution of sodium chloride (0.95 Gm per 100 ml) and 0.05 ml of sodium oxalate solution (1.34 Gm per 100 ml) and incubating at 45°C for ten minutes with agitation every three minutes. After completion of incubation large particles of suspended tissue were removed by crude filtration through cotton placed loosely over the tip of a 20 ml volumetric pipette which was then lowered into the suspension and filled by gentle suction. The thromboplastin solution so obtained was stored in a deep freeze at -20°C in 0.1 ml aliquot. In this form it remains stable for many months.

**Calcium Chloride**—A solution of 0.05M calcium chloride was made by dissolving 2.77 Gm of purified anhydrous  $\text{CaCl}_2$  in 1000 ml of single distilled water.

**Anticoagulants**—One part of either of the following solutions was used to render 9 parts of whole blood incoagulable.

(a) 0.1M sodium citrate was made by dissolving 20.412 Gm of sodium citrate ( $\text{Na}_3\text{C}_6\text{H}_5\text{O}_7 \cdot \text{H}_2\text{O}$ ) in 1000 ml of single distilled water.

(b) 0.1M potassium oxalate was made by dissolving 18.432 Gm of crystalline potassium oxalate ( $\text{K}_2\text{C}_2\text{O}_4 \cdot \text{H}_2\text{O}$ ) in 1000 ml of single distilled water.

**Citrated Pooled Normal Plasma**—Citrated plasma was used for prothrombin determinations because of the greater stability of prothrombin and prothrombin accelerators<sup>15</sup> with this anticoagulant as compared with oxalate.<sup>16</sup> Blood samples were obtained from ten normal subjects each taken separately using 1 part of 0.1M sodium citrate for 9 parts of venous blood. The plasma obtained by centrifugation at 2000 rpm for ten minutes was pooled and designated as pooled fresh normal plasma (citrate).

**Prothrombin Free Plasma**—Oxalated plasma was used since the prothrombin cannot be removed satisfactorily from citrated plasma.<sup>17</sup> Blood samples were obtained from ten normal subjects each sample taken separately using 1 part of 0.1M potassium oxalate for 9 parts of venous blood. Plasma was obtained by centrifugation of the oxalated blood samples at 2000 rpm for ten minutes. The samples of plasma were then pooled and 100 mg of powdered barium sulfate (Merck) were added for each 10 ml of plasma. This mixture was incubated at 37°C for ten minutes with agitation every three minutes and finally centrifuged at 3,000 rpm for thirty minutes and the supernatant removed. Such plasma is designated 'prothrombin free plasma (barium)'. It was stored at 4°C and used immediately unless otherwise stated.

Oxalated bovine plasma from bovine blood obtained by venipuncture from the living animal was rendered prothrombin free by the same process and designated prothrombin free plasma (bovine).

stable when frozen and maintained at  $-20^{\circ}\text{C}$  for relatively short periods of time, but even at this temperature of storage alteration in activity is observed after several days. The prolongation of prothrombin time is not due to quantitative changes in fibrinogen. When stored in the fluid state for limited periods, no change occurred in the fibrinogen content of prothrombin-free plasma and there was no apparent decrease in the fibrinogen "reactivity," as suggested by Loomis and Seegers,<sup>6</sup> since a "normal" thrombin time can be obtained by increasing the concentration of thrombin in the reaction mixture or by reducing the pH.<sup>1</sup> In addition, Alexander<sup>1</sup> has shown that the plasma of a patient with congenital afibrinogenemia exhibited prolongation of the prothrombin time similar to that of normal plasma under the same conditions of storage.

The observed alteration in stored prothrombin-free plasma (human) appears to be related in part to the development of antithrombic activity possibly resulting from treatment with barium sulfate per se, since untreated oxalated and citrated plasmas containing prothrombin do not develop antithrombin activity at the same rate of speed or to the same extent when stored at  $30^{\circ}\text{C}$ . The observed prolongation of the prothrombin time and apparent antithrombic activity have been shown to occur concomitantly with a rise in pH by Tantum and Wetzel.<sup>12</sup> They have reported a prompt reduction in antithrombic activity in prothrombin-free plasma following the lowering of the pH to 7.6 to 7.8. In addition to this observation, the formation of fibrin by the action of thrombin on fibrinogen has been shown, by Morrison,<sup>8</sup> to be intimately concerned with the pH of the reaction mixture. Below a pH of 5.7 no fibrin will form,<sup>8</sup> while between a pH of 6 and 7 there is a noticeable increase in the rate of reaction as the pH rises. As the pH is further increased above 7, there is less obvious increase in the rate of reaction.<sup>2</sup>

From the available data reported here, it is impossible to conclude that pH changes alone are responsible for the antithrombic activity since prothrombin-free plasma (human) stored at  $-20^{\circ}\text{C}$  in the frozen state for twenty-four hours showed an increase in pH when thawed without antithrombic activity. This is further borne out by the observations of Tantum and Wetzel<sup>15</sup> who have shown that the antithrombic activity can be abolished without lowering the pH of the reaction mixture by the addition of protamine sulfate. They have suggested from this that stored prothrombin-free plasma may have an increased heparin content. For clarification of the relationship between pH changes and antithrombic activity further work is required.

It has been suggested<sup>15</sup> that the observed antithrombic activity of stored prothrombin-free plasma is responsible for prolongation of the prothrombin time of fresh plasma diluted with it. This would seem true only in part since other factors also are involved. If the pH of nonlyophilized stored prothrombin-free plasma (human) is adjusted to 7.4 and the plasma tested for labile factor activity (Quick),<sup>13</sup> there is found a progressive reduction in the amount of this substance as the duration of storage lengthens even though a pH of 7.4 is maintained. The lower the temperature of storage, the less tendency there is for such a reduction to occur, as noted elsewhere.<sup>12</sup> There would thus appear to be

at least two factors responsible for the prolongation of the prothrombin time of fresh normal plasma (citrate) diluted with stored nonlyophilized prothrombin free plasma. Initially, an apparent antithrombin develops causing mild delay in the speed of coagulation. After a relatively short period of storage at 37.5° C and 30° C there occurs gradual inactivation of the "prothrombin accelerators"<sup>13, 10</sup> which results in further slowing of the speed of coagulation. The additive effect of these two changes presumably results in a significant prolongation of the coagulation time to a limit after which time the antithrombic effect becomes stabilized as does the pH. The 'prothrombin accelerators' finally become completely inactivated.

By lyophilizing prothrombin free normal plasma (human) as outlined by Florsdorf and Mudd<sup>5</sup> observing then precautions to establish the proper relationship between total volume of material and available surface during the process so as to insure proper lyophilization, it is possible to maintain such material in stable form for many weeks. By reconstituting it to a pH of 7.3 to 7.4 a diluent is obtained that is quite active and which possesses no antithrombic activity or additional loss of prothrombin accelerators when used promptly. Other observers<sup>15</sup> have reported increases in pII and antithrombic activity to occur in lyophilized prothrombin free plasma. Such findings have not been observed here over a period of storage of ten to twenty weeks. Why this discrepancy exists is unknown since we have observed the same results of stability when using unbuffered distilled water for reconstitution of the lyophilized prothrombin free plasma. It is possible that the cause of such altered activity in the material studied by others<sup>15</sup> is incomplete lyophilization.

Using barium sulfate as an adsorbing agent of prothrombin there also occurs a reduction in certain plasma components that are intimately concerned with the speed of the coagulation reaction. To what extent barium sulfate removes the "accelerator substances" is unknown but it is reported that approximately 50 per cent of Owren's Factor V is removed although the amount of BaSO<sub>4</sub> required to effect this removal is not stated.<sup>10</sup> The difficulty of simultaneously depleting plasma of its prothrombin and certain of the accelerator substances can be eliminated by using as a diluent bovine plasma treated with barium sulfate. Owren<sup>10</sup> and Seegers<sup>9</sup> both have shown that bovine plasma contains much greater quantities of their factors than does human plasma. Because of this observation Owren<sup>10</sup> advocates the use of prothrombin free bovine plasma as a diluent of human plasma so as to insure an excess of Factor V. Since it appears likely<sup>3</sup> that Factor V of Owren<sup>10</sup> plasma accelerator globulin of Seegers<sup>10</sup> and labile factor of Quick<sup>13</sup> are the same activities it is possible to have excesses of these activities as well as an excess of plasma thromboplastin and fibrinogen in the dilution method of Rosenfield and Tuft for the determination of prothrombin concentration by using prothrombin free bovine plasma as a diluent of fresh citrated human plasma.

In the lyophilized state prothrombin free bovine plasma maintains unaltered activity as a reconstituted diluent of fresh human citrated plasma and no antithrombic activity or pII changes were observed over a storage period of twenty

weeks. Because of the greater "prothrombin accelerator" activity in bovine plasma, it is necessary to establish a prothrombin time concentration curve using prothrombin-free bovine plasma as a diluent. The shorter prothrombin time obtained at a 50 per cent concentration of prothrombin (see Fig 1) using prothrombin-free bovine plasma as a diluent is most likely due to the greater "prothrombin accelerator" activity of this diluent.

By lyophilization of prothrombin-free normal human or bovine plasma, there is thus placed within easy reach of many laboratories and physicians a reagent whereby more accurate determinations of prothrombin can be accomplished. With proper reconstitution of a stable (lyophilized) thromboplastin and a stable (lyophilized) prothrombin-free diluent of fresh normal citrated plasma prothrombin determinations can be performed reproducibly.

#### SUMMARY AND CONCLUSIONS

Experimental data are presented showing the great instability of normal human plasma rendered prothrombin-free by treatment with barium sulfate and stored at various temperatures in the liquid state. Such instability is shown to result in prolongation of the prothrombin time of mixtures of fresh normal citrated plasma and stored prothrombin-free plasma. This instability is thought to be due to the occurrence at  $37.5^{\circ}\text{C}$  and  $30^{\circ}\text{C}$  of antithrombic activity as well as inactivation of the "prothrombin accelerators." The mechanism of development of antithrombic activity is not well understood. Lyophilized prothrombin free human and bovine plasma stored at  $-20^{\circ}\text{C}$  for ten and twenty weeks respectively are shown to possess unaltered activity as diluents when reconstituted with buffered distilled water and used immediately. A discussion is given of the advantages of using a dilution method for the determination of prothrombin concentration, employing prothrombin-free bovine plasma as a diluent of fresh normal citrated plasma. Prothrombin time concentration curves using three different diluents are included and the need for selection of a proper diluent is obvious. It is recommended that lyophilized prothrombin free bovine plasma, reconstituted with buffered distilled water, be used as the diluent of fresh normal citrated plasma in the determination of prothrombin concentration, as a means of supplying an excess of certain "prothrombin accelerators" to a coagulation system in which prothrombin thus remains as the only variable.

It is concluded that prothrombin-free human and bovine plasma (1) maintain stability when properly lyophilized and stored at  $-20^{\circ}\text{C}$  for ten and twenty weeks respectively, and (2) when reconstituted to pII 7.3 are ideal diluents of fresh plasma for the determination of prothrombin concentration.

## BIOLOGIC STUDIES WITH ARSENIC<sup>76</sup>

### III THE EFFECT OF ARSENIC<sup>76</sup> UPON THE CLINICAL COURSE OF PATIENTS WITH TUMORS OF THE HEMATOPOIETIC TISSUES

MATTHEW BLOCK, M D , PH D ,\* LEON O JACOBSON, M D , AND  
WILLIAM NEAL, M D  
CHICAGO, ILL

#### INTRODUCTION

SINCE both stable arsenic and radiation have been used independently in the treatment of tumors of the hematopoietic organs it was thought that it might be advantageous to utilize radioarsenic ( $\text{As}^{76}$ ), a substance which is metabolized like stable arsenic, exerts a similar chemotherapeutic effect, and is at the same time a source of radiation

$\text{As}^{76}$ , which has a half-life of 26.8 hours and which emits energetic beta and gamma rays, was prepared by pile radiation of arsenic trioxide, and later in higher specific activity by pile radiation of cacodylic acid. It was injected intravenously as sodium arsenite. The stable arsenic content usually varied from 3 to 10 mg of arsenic per single injection of 1 to 80 mc of  $\text{As}^{76}$ . Cacodylic acid, as obtained after pile radiation at the Argonne National Laboratory, is prepared for injection by remote control from behind lead shields because of its penetrating gamma radiations. The details of the preparation of  $\text{As}^{76}$  and its metabolism have been given in two preceding reports.<sup>1,2</sup>

Arsenic is distributed rapidly to all tissues after intravenous injection. Highest levels are reached within twelve to twenty-four hours in the spleen, liver, and kidney. Fifty per cent is excreted within seventy-two hours, primarily by the kidney. It is estimated that 1 mc of  $\text{As}^{76}$  will deliver about 1 r of total body radiation.

#### METHODS

Twenty-four patients with tumors of the hematopoietic tissues, two with polycythemia rubra vera, and one with a metastatic carcinoma form the basis of this study. The diagnosis was substantiated microscopically in every case. Many of the patients had repeated biopsies of bone marrow, liver, lymph node, and spleen, which will be made the subject of a future report (Table I).

The first few patients in this study were treated with extremely small amounts of  $\text{As}^{76}$  as far as specific radiation effect was concerned, although receiving at the same time enough stable arsenic probably to exert a mild chemotherapeutic effect. The first doses attempted were about 0.5 to 2.0 mc, but within a short period of time this was increased, partly because of experience with the inadequacy of these doses and partly because of the availability of arsenic with a higher specific radioactivity. As much as 90 mc with about 5 mg of stable arsenic were administered in a single injection to the recently treated patient. In addition, each patient received such supplemental treatment as transfusions, antibiotics, Digiloid and mercurials, and toluidine blue or protamine sulfate as indicated.

TABLE I DIAGNOSIS DOSAGE AND RESPONSE TO TREATMENT WITH AS<sup>76</sup>

DIAGNOSIS	CASE	MILLICURIES OF AS <sup>76</sup>	RESULTS
Acute leucemia	1	24 on 10/24/47 60 on 11/12/47	No remission, died of hemorrhage
	2	69	No remission died of hemorrhage
Subacute myelogenous leucemia	3	13.5 on 10/3/47 12 on 10/10/47 45 on 1/31/48 47 on 5/14/48	Three remissions of 2 to 3 mo each
	4	17	Inadequate dose died of intracranial hemorrhage
	5	90	Remission of 1 wk then steady downhill course
Chronic myelogenous leucemia	6	30	Symptomatic improvement for 2 wk until death from cerebral hemorrhage
	7	30 on 3/31/47 34 on 2/1/49	First remission of 5 mo, second of 2 mo
	8	60	Good remission for 4 mo
	9	40	Good remission for 19 mo
	10	32 on 6/11/48	Six week remission on inadequate dose, second remission of 2 mo
Subacute lymphatic leucemia		39 on 1/28/49 69 on 2/4/49 36 on 2/11/49	Symptomatic improvement 1 mo
	12	36 on 1/30/48	Little improvement concurrent hemolytic anemia
	13	39 on 2/6/48 60	Remission of 2½ mo but had series of pyogenic abscesses
	14*	14	Remission of 1 mo then died of hemorrhage
	15	72	Remission of 1 mo then died of generalized tuberculosis
Chronic lymphatic leucemia	16	38	No response in severe mental depression at time of treatment
	17	38	Died of cerebral hemorrhage after 4 wk of symptomatic improvement
	18	80	Two week remission died of pericardial effusion
	19	76	Five month remission until death from congestive heart disease
Polycythemia rubra vera	20	45	Three month remission
Multiple myeloma	21	15 on 8/28/47	Six month remission (unusually benign type of case)
	22	12 on 9/3/47 88	Seven month remission
Mycosis fungoides	23	80 on 9/10/48 80 on 9/24/48	No response later responded to x ray
Metastatic carcinoma primary in stomach	24	80	Decrease in size of liver but progressive downhill course

## RESULTS

*Hodgkin's Disease*—Each of four patients with Hodgkin's disease received from 10 to 130 mc of As<sup>76</sup> and up to 52 mg of stable arsenic in divided doses. The longest remission two months was obtained in a patient receiving 52 mg of stable arsenic and 13.6 mc of As<sup>76</sup>. However it was felt that the amount of stable arsenic was such as to be sufficient in itself to produce a remission and that the As<sup>76</sup> had not been given in adequate trial in this group.

*Acute Leucemia*—Both patients experienced a sharp drop in the white count and platelets but no significant change in the differential count (Fig 1) Case 1 developed a severe hemorrhagic process and Case 2 had a terminal rise in the white count to 180,000. Both patients had an intractable anemia which failed to respond to therapy of any nature including massive transfusions.

Fig 1

It is clear that these two patients failed to show any better response to  $As^{76}$  than has been noted in the past to urethane,<sup>3</sup>  $P^{32}$ ,<sup>4, 6</sup> nitrogen mustard,<sup>7, 9</sup> or x-ray.<sup>10</sup> It is probable that Amnopterin<sup>11, 12</sup> will have more to offer than  $As^{76}$  in the treatment of acute leucemia.

*Subacute Myelogenous Leucemia*—Case 4 did not receive enough  $As^{76}$  to exert a therapeutic effect. Case 5 had an extremely short remission but the patient was in very poor condition when treatment was begun. If the result obtained in Case 3, in which there were three remissions varying from about four months to two months in spite of an intractable osteomyelitis, can be duplicated in other cases of subacute myelogenous leucemia, it would appear that  $As^{76}$  may be about as effective as Amnopterin<sup>12</sup> and superior to the more common therapeutic agents<sup>4, 7, 10, 13</sup> and radiosodium<sup>14</sup> in the treatment of this condition.

Fig

*Chronic Myelogenous Leucemia*—Four (Cases 6, 8, 9, and 11) of the six patients were previously untreated and one (Case 7) had one course of methine and should also be classified as in early case. Four patients responded with remissions from four to sixteen months in duration (Fig 2) and two (Cases 7 and 10) responded in a similar manner to a second course of  $As^{76}$ . The other untreated patient (Case 11) had only slight symptomatic improvement. The sixth patient (Case 6) refractory to x-ray therapy, died

of a cerebrovascular accident. However, his anemia failed to respond to transfusions following  $As^{76}$  and he may be classified as a therapeutic failure as is usually the result in patients of this type.<sup>4</sup>

Chronic myelogenous leucemia is a disease with great variations in its course. Patients have been known not to develop any subjective symptoms for as long as five years after the diagnosis was established.<sup>10, 16</sup> However, only a minority (16 per cent) of patients have spontaneous remissions once the disease produces anemia or subjective symptoms.<sup>10</sup> Therefore, any good result obtained in patients who were treated merely on the basis of a positive diagnosis may be ascribed to the benign nature of the disease rather than to the direct effect of therapy.

With this reservation in mind it would appear that even the greater differences in response reported in previously untreated patients following x-ray,<sup>16, 18</sup>  $P^{32}$ ,<sup>4, 5, 18</sup> urethane,<sup>3, 19</sup> Fowler's solution,<sup>20</sup> and  $Na^{24}$ <sup>14</sup> may well be due to variation in the biologic nature of each patient's disease. It would, therefore, appear that remissions of four to sixteen months in our untreated cases represent no better than an average response (Fig. 2). Like other generalized methods of therapy,  $As^{76}$  is not as efficacious in reducing the size of a huge spleen as local x-ray therapy,<sup>4</sup> but like  $P^{32}$ ,<sup>4, 5, 18</sup> and  $Na^{24}$ <sup>14</sup> it rarely produces any toxic symptoms.

*Subacute Lymphatic Leucemia*—Two of the four patients (Cases 13 and 14) were previously untreated and had symptoms of comparatively short duration. One patient, Case 15, had received x-ray therapy with very little benefit and one, Case 12, had received urethane without improvement. Three (Cases 13, 14, and 15) responded to therapy with an improvement in appetite, decrease or absence of fever, decrease in lymphadenopathy, and lowering of the white count for about two months. However, two (Case 13 and 15) of these three experienced the onset of a severe infection, furunculosis in one, tuberculosis in the other.

The fourth patient (Case 12) had a hematologic response with a drop in white count and a decrease in fever, but because of an associated hemolytic anemia he continued as an invalid until his death one year later following splenectomy in another institution.

These results are, in general, comparable with those reported in the literature following Aminopterin.<sup>12</sup> Possibly subacute lymphatic leucemia may show a better response to  $As^{76}$  than that reported after  $P^{32}$ ,<sup>4, 5</sup> urethane,<sup>3, 19</sup> or nitrogen mustard.<sup>13</sup> The occurrence of two severe infections (Cases 13 and 15) at the time of greatest depression of the white count should warn against the use of  $As^{76}$  in the presence of any generalized infection, especially tuberculosis. We have been impressed by the occurrence of a flare up in cases of previously quiescent tuberculosis following generalized cytotoxic therapy such as  $As^{76}$  and nitrogen mustard in the treatment of leucemias and lymphomas.<sup>1</sup>

*Chronic Lymphatic Leucemia*—Four patients were treated with fairly adequate amounts of  $As^{76}$ . Only one (Case 16) was previously untreated. He was in a severe mental depression and failed to respond to therapy. Two patients (Cases 17 and 18), each of whom had been subjected to extensive x-ray

Fig 3

therapy in the past, succumbed to complicating diseases. A spectacular result was obtained in the last patient (Case 19) since an intractable anemia was relieved and massive lymphadenopathy and splenomegaly were decreased (Fig 3).

Our results, in general, are not as favorable as those reported after x-ray<sup>16, 22</sup> or  $P^{32}$ ,<sup>4</sup> nitrogen mustard,<sup>7</sup> urethane<sup>3, 19</sup> or  $Na^{22}$ .<sup>14</sup> Particularly discouraging was the complete failure in the patient, Case 16, who was previously untreated. However, Reinhard<sup>4</sup> has encountered a similar result after  $P^{32}$ , as we have after nitrogen mustard.<sup>21</sup> The response of Case 19, who had remained severely anemic in spite of massive transfusions and several types of therapy, was most encouraging since this is the type of case which is notoriously difficult to manage.

*Polycythemia Rubra Vera*—The response of Case 20 was fairly satisfactory and also was qualitatively similar to that described after  $P^{32}$ .<sup>4, 23</sup> However, much longer remissions are not at all unusual after  $P^{32}$  so that  $As^{76}$  has little to offer that is superior to the results already achieved by  $P^{32}$ . Another patient was treated with a total of 2.4 mc of  $As^{76}$  and phlebotomies. Since this amount of  $As^{76}$  is too small to be effective, the brief remission probably was due to the phlebotomies.

*Multiple Myeloma*—This disease is almost always characterized by a rapidly progressive downhill course with unrelenting pain in untreated cases, although occasional chronic cases such as Case 21 have been recognized.<sup>4</sup> Remissions similar in extent to that experienced in Case 22 have been reported after urethane<sup>23</sup> and Stilbamidine.<sup>26, 27</sup>

*Mycosis Fungoides*—In many respects the therapeutic results in this disease are similar to those achieved in Hodgkin's disease. In Case 23, treated four months before death, it was quite clear that the skin and pulmonary lesions were still in part amenable to local x-ray therapy after they had failed to respond to  $As^{76}$  or nitrogen mustard.

*Metastatic Carcinoma*—The results in Case 24, in which the patient had a carcinoma of the stomach, are difficult to interpret. Carcinoma of the stomach may occasionally give rise to masses that respond to x-ray therapy by a decrease in size as did this patient's liver metastases. There was little else in the patient's course to suggest that  $As^{76}$  would prove curative or even beneficial in carcinoma of the stomach.

#### DISCUSSION

It appears, therefore, that  $As^{76}$  resembles numerous other therapeutic agents such as x-ray, urethane, nitrogen mustard, radiophosphorus, radio sodium, and Fowler's solution in that it is capable of producing a remission in certain of the more chronic and benign tumors of the hematopoietic tissues and that it is not a cure for these diseases. The more acute forms of these diseases, with the possible exception of subacute leucemia, do not seem particularly amenable to  $As^{76}$  therapy.

In evaluating the clinical usefulness of  $As^{76}$  one is forced to consider whether it is more effective than previously used materials in producing a re-

mission, whether it will produce a remission where other agents have failed, and whether the advantages if any are sufficiently great to warrant using a substance that is so difficult and expensive to prepare and so dangerous to handle. Unfortunately, because of numerous factors, such as intercurrent disease, variations in the clinical course of patients with the same disease, duration of disease previous therapy supplemental therapy, and rest and psychic factors it is very difficult to compare any series of patients. One cannot but be impressed by the occasional patient who responds to therapy in a manner that is entirely unexpected and inconsistent with the usual response characteristic of patients with that disease.

The criteria for evaluating a clinical remission are not similar. For example, depression of the white count has frequently been used as a means of estimating the response to therapy. However, particularly in acute leucemia and the terminal stages of chronic leucemia the height of the white count may bear no relation to such response. In this study we have followed the blood counts carefully and have noted a depression of the white count varying from 20 per cent to 80 per cent of the pretreatment figure in almost every patient treated without an invariable improvement in the clinical condition of the patient. Consequently the white counts have not been reported in detail. There has been no marked tendency of the peripheral blood differential count to return to normal following treatment except in a few cases of chronic myelogenous leucemia. An alleviation of the anemia is generally acceptable as an indication of a good therapeutic response. Since practically every one of the patients in this study received numerous transfusions this criterion was rendered unreliable.

In general we have felt that the ability of the patient to live a more comfortable and more useful life was the best indication of a response to therapy.

On this basis our results seem to have been unusually good in a single case of chronic lymphatic leucemia characterized by severe anemia possibly favorable in subacute lymphatic leucemia and worthy of further evaluation in multiple myeloma. In the other diseases treated the recognized agents such as x-ray,  $P^{32}$  methane and nitrogen mustard which are more readily available, less expensive, and less hazardous will give similar if not superior clinical results.

It is of importance to note that we have not yet attained a maximum safe clinical dosage level of  $As^{76}$  nor have we fully explored the combination of stable and radioarsenic or the effect of repeated small doses of  $As^{76}$ . It is possible that when these are attained a better clinical response may be achieved. However, the problems of handling the amounts of  $As^{76}$  we have used are so great that it hardly seems practical or worth while to attempt to use larger quantities of  $As^{76}$  on the basis of the response of the patients in this study.

#### CONCLUSIONS

1. Twenty four patients with tumors of the hematopoietic tissues, two with polycythemia rubra vera and one with metastatic carcinoma have been treated with intravenous injections of radioarsenic ( $As^{76}$ ).

2 This radioisotope, under the conditions used in this study, appears to offer no advantages over the types of therapy already in use for these conditions

We wish to thank Mr Howard Ducoff and Mr Robert L Straube of the Argonne National Laboratory for their cooperation in the preparation of the  $As^{66}$  used in this study

# THE USE OF RADIOACTIVE SILVER FOR THE DETECTION OF ABSCESSES AND TUMORS

## I THE CONCENTRATION OF $\text{Ag}^{111}$ IN SPONTANEOUS AND EXPERIMENTALLY INDUCED ABSCESSES

HAROLD D WESI, PH D, ALFONSO P JOHNSON, MS, AND  
CHARLES W JOHNSON, MS  
NASHVILLE, TENN

IN A recent communication from this laboratory<sup>1</sup> it was pointed out that tracer doses of the long half-life silver isotope,  $\text{Ag}^{108-110}$  (half-life 225 days) could be caused to concentrate at particular localities in the bodies of albino rats by the simple expedient of inducing infection (experimentally) in the form of abscesses. It also appeared that the radioactive isotope concentrated itself in areas of spontaneous infection. It seems possible that if the short half life radioactive isotope,  $\text{Ag}^{111}$  (half-life 7.5 days) could be concentrated at or near the site of a lesion in sufficient amounts it might prove of value in therapy of tumors in human beings.

It is clear that if radiosilver can be caused to concentrate in abscesses, induced by injection of a suspension of bacteria, or in areas of spontaneous infection the procedure may become a very valuable method for the detection or location of hidden or obscure abscesses. The existence of the 8.2 day half life  $\text{Ag}^{106}$  and the newly developed, highly sensitive, directional Geiger-Muller counters make the procedure ideal as a tool for diagnosis in the patient with an obscure focus of infection.\*

In the part which follows it will be shown that the  $\text{Ag}^{111}$  behaves similarly to the  $\text{Ag}^{108-110}$  (as would be expected from the electron configurations), viz it concentrates in spontaneously or experimentally induced infected areas. The directional Geiger-Muller counter was not used in these experiments with  $\text{Ag}^{111}$ . It was necessary to conduct the assay through actual ashing of the tissues and chemical isolation of the radiosilver.

### EXPERIMENTAL

The  $\text{Ag}^{111}$  was separated from the irradiated palladium target obtained from the pile at Oak Ridge by a procedure developed in the Cancer Research Laboratory of this Institution by Rouser and Hahn.<sup>2</sup>

The test organism used was a strain of *Streptococcus hemolyticus* isolated from the throat of a hospital patient. The organism was used after sixteen hours of incubation in proteose peptone broth at 37° C. One tenth of a milliliter of the undiluted culture was injected into the right legs of albino rats and forty eight hours later 0.5 milliliter of

From the Departments of Biochemistry and Bacteriology, Meharry Medical College.  
Received for publication July 11, 1949.

\*The  $\text{Ag}^{101}$  isotope is the isotope of choice for this purpose since it produces gamma rays and unlike  $\text{Ag}^{111}$  which is a pure  $\beta$ -ray emitter should be amenable to external survey. Pure  $\beta$ -ray emitters are useless for this purpose since their particles travel only short distances. The 225 day half-life isotope  $\text{Ag}^{108-110}$  while it emits gamma rays and thus would be detectable in external surveys is excluded for this purpose on account of the danger of prolonged irradiation resulting from its long half-life. This would be particularly hazardous if for some reason the isotope is not promptly excreted. On the other hand  $\text{Ag}^{111}$  has a relatively short half-life of 7.5 days.

$Ag^{111}$  in the form of the nitrate was injected either into the same leg or into the left one. Three days after injection of the isotope the animals were sacrificed and the legs, kidneys, livers, lungs, hearts and testes or ovaries were ashed and the silver was isolated and subjected to radioassay as described previously.<sup>1</sup> The results with five animals are given in Table I. Each tissue was subjected to bacteriologic examination before assay.

TABLE I. DISTRIBUTION OF  $Ag^{111}$  IN VARIOUS TISSUES 72 HOURS FOLLOWING ITS INJECTION IN LEFT OR RIGHT LEG IN THE PRESENCE OR ABSENCE OF INFECTION EXPERIMENTALLY INDUCED IN THE LEFT LEG  
(DOSE 0.5 C WITH  $3.62 \times 10^4$  COUNTS PER MINUTE)

RAT	RIGHT LEG	LEFT LEG	KIDNEY	LIVER	LUNG	HEART	TESTES OR OVARY	RIGHT LEG	LEFT LEG
1		Isotope	310	820	85	55	780	1 220	2 620

4	Isotope	Organism	492	1 690*	91	80	20	1 620	4 000
5	Isotope	Organism	472	1 261	97	49	27	1 026	3 221
		Isotope	472	1 097	101	52	23	1 262	1 415

Bacteriologic test positive indicating infection

It was of interest that the concentrations of radiosilver were uniformly high in livers. To confirm this observation three additional animals were given injections of  $Ag^{111}$  alone and the concentrations of the isotope in kidney, liver, lung, heart and testes or ovaries were determined. The results are shown in Table II where it is to be seen again that the livers have a uniformly high count.

TABLE II. DISTRIBUTION OF  $Ag^{111}$  IN VARIOUS TISSUES 72 HOURS AFTER ITS INJECTION INTO RIGHT LEG

RAT	RADIO-SILVER INJECTED I TO RIGHT LEG (COUNTS PER MIN.)				
	KIDNEY	LIVER	LUNG	HEART	TESTES OF OVARY
1	389	1 031	41	0	0
2	381	924	51	0	0
3	403	964	55	0	0
Control sample	36 147				

An additional three animals were studied for normal distribution of the isotope. In this instance the studies were extended to include as much of the muscle, bone, and blood as could be obtained and the feces and urine were collected. The stomachs and intestines were assayed together as well as the major portion of the skin. The heads and tails were not studied. The results are shown in Table III. Rat 1 must not be compared with Rats 2 and 3 since a massive infected area was found in the left leg (right leg injected with  $Ag^{111}$ ). The predominating organism in this infected organ was a strain of *Str. hemolyticus*. The tissue placed under the Geiger-Müller tube for radioassay was found to be highly radioactive.

#### DISCUSSION OF RESULTS

The experimental findings given in Table I indicate in line with our previous results with the 225 day half life isotope, that  $Ag^{111}$  also concentrates in the tissue with the experimentally induced abscess. They demonstrate also that this will occur even if the isotope is injected into an organ quite remote from the focus of infection. The result with Rat 1 Table III was extremely fortunate, though unexpected. The radiosilver was injected into the right leg. When the

animal was sacrificed a massive infection of the left leg was discovered. The high count in the muscle fraction for this animal was chiefly due to the silver concentrated in this area. This result emphasizes the probable value of the method, if employed, for detection of obscure or hidden abscesses.

The uniformly relatively high count in the livers of the animals studied deserves some comment. The counts in the infected tissue are some three to four times as great as those seen in the livers and thus would hardly be cause for confusion in the search for a focus of infection. These relatively high counts after three days are apparently related to excretion of the silver. The high counts seen in the feces, the absence of silver from the urine, and the relatively high values for liver lead to the conclusion that tracer doses of radiosilver are excreted by the liver, presumably by way of the bile, into the intestines and excreted in the feces. These results confirm those of Scott<sup>3</sup> recently available from the Atomic Energy Commission.

Previous attempts to develop procedures for the detection of abscesses have been made by Kioll, Strauss, and Neeheles<sup>6</sup> and Strauss, Neuwelt, Rovner, and Neeheles.<sup>4</sup> In a recent publication<sup>6</sup> these authors suggest the use of the bis-azo dye, disodium-1-amino-8-hydroxy-naphthalene-3,6-disulfonate (H acid) monobrominated with radioactive bromine for localization in experimentally induced abscesses in dogs. The preliminary experimental results reported here would suggest that the employment of radiosilver nitrate in tracer doses may be a more simple procedure.

These studies are being extended to animals with the turpentine sterile abscess and with tumors.

#### CONCLUSIONS

- 1 The radioactive  $\text{Ag}^{111}$  isotope concentrates in areas of infection.
- 2 This isotope is excreted by the liver into the intestine presumably by way of the bile and the feces.

3 Since both  $\text{Ag}^{108}$   $^{110}$  and  $\text{Ag}^{111}$  concentrate in areas of experimentally induced and spontaneous infections it is to be expected that other silver isotopes such as  $\text{Ag}^{106}$  for example, would behave similarly. Since  $\text{Ag}^{106}$  has a short half life (82 days) and also emits gamma rays and is thus amenable to external survey it is suggested that it might prove to be of value as a tool for the detection of obscure foci of infection in the animal body.

The senior author wishes to express his gratitude to Dr P F Hahn of the Cancer Research Laboratories of this College for his assistance in the initiation of the program of isotope research.

# THE MINIMAL SODIUM DIET A CONTROLLED STUDY OF ITS EFFECT UPON THE BLOOD PRESSURE OF AMBULATORY HYPERTENSIVE SUBJECTS

MILTON LANDOWNE, M D,\* WALTER S THOMPSON, JR, M D,† and  
BARBARA RUBY, B S  
CHICAGO, ILL

## INTRODUCTION

DESPITE the extensive studies on the place of diet low in sodium chloride in the therapy of hypertension,<sup>1-5</sup> there is as yet no complete agreement as to the efficacy or explanation of this therapy. Recent re-examination of this subject might lead one to the conclusion that the administration of diets which are low in sodium is sometimes attended by a reduction in blood pressure.<sup>6-9</sup> Thus, it has been claimed,<sup>6-9</sup> as a reason for the success<sup>10</sup> of the rice diet therapy. Dietary restriction of sodium (including the rice diet) has again become widespread and is generally being applied in clinical practice without adequate control. Several carefully controlled studies have dealt with patients in the hospital after they have reached a stabilized, or nearly stabilized, blood pressure level and in whom a period of sodium restriction has then been alternated with a period of more normal sodium intake.<sup>11, 12, 13</sup> From these studies has come the observation that in some patients a fall in blood pressure may occur during a period of severe sodium restriction, but that this fall may be slight and may occur only when the twenty-four hour intake of sodium is kept extremely low.

It is not satisfactory to carry over the results of these studies by attempting to apply them generally to the clinical treatment of hypertension. First of all, a hospital environment is not the usual environment for a human being. The factors which may relate to the maintenance (and perhaps the establishment) of hypertension are considerably modified by the simple fact of being in a hospital as a patient. Therefore, a form of therapy which is ineffective or relatively ineffective in the hospital might conceivably be more effective when the patient is under "normal" living conditions.

Second, it is possible that severe sodium restriction might serve to reduce blood pressure in the hypertensive patient only under certain circumstances. For instance, sodium restriction may be unable to further lower a blood pressure that has come down under influence of other factors to a minimum or "base line." If the patient had been treated at a higher level of blood pressure than this "base line," an effect might have been noted, even though the therapy is ineffective in lowering the "floor" of blood pressure.

Most important of all the administration of a diet which is rigidly restricted in any factor may influence the habits and reactions of the patient quite profoundly. In this manner it may produce physiologic changes unrelated to the removal of the particular agent under study. In order to control this most prominent feature of dietotherapy it is mandatory to administer a diet identical to the experimental diet in every way, except for the factor under study. Moreover this must be done in such a way that the subject remains unaware of the difference. In addition in any study where the interests, emphasis or bias of the investigator might modify the results he too, should not know whether his observations relate to the experimental or the control period.

Two recent studies have been reported on the effect of rigid sodium restriction upon ambulatory patients in which favorable results are claimed.<sup>7,8</sup> These reports do not include controls either of the diet in terms of the degree to which the diet was followed or of the factors in the treatment other than lack of sodium which might be responsible for the results.

#### PLAN OF STUDY

For these reasons a controlled study was planned in which all patients would be placed upon the same dietary regimen—one which would be rigidly restricted in sodium content to less than 200 mg of sodium per day. The experiment was divided into three periods of six weeks each. Schedules were prepared for twenty four patients covering the administration of either sodium chloride 4 Gm per day or an identically designed lactose preparation to these patients during the three experimental periods. (A construction based upon three periods was chosen to make it impossible to be certain whether the medication was being changed or not at the conclusion of any one period.) Of the eight different combinations of periods possible these four were selected: 1 Lactose sodium, lactose 2 sodium lactose lactose 3 lactose lactose sodium 4 sodium lactose sodium.

A schedule was selected in random fashion by the pharmacist and assigned to each patient, the medication to be issued from the pharmacy according to this schedule and without knowledge of the patient or the clinic personnel. Although occasionally a patient had gastrointestinal distress which might suggest that he was receiving sodium chloride in the main there was no indication as to which medication was being taken.

The subject was seen throughout by the same investigator, who, following a uniform technique each week recorded the blood pressure on one particular arm after the patient had rested in the recumbent position for at least five minutes averaging two or three determinations. The recommended technique for blood pressure measurement was followed.<sup>10</sup>

Adhering to the diet as planned was not an easy task. As a practical check, twenty four hour urine samples were collected usually once a week for sodium analysis with creatinine analysis to establish the completeness of the sample. While urinary sodium will not parallel dietary sodium during retention in diuresis or other state of negative sodium balance, the length of the observational periods makes it unlikely that any significant storage or loss could occur and not be reflected by weight change.

The technician alone had access to the records of medication. Accordingly if the sodium excretion exceeded the estimated intake the doctor and dietitian could be so informed. The checking procedure resulted in some delay and this explains why a number of patients were permitted to continue the experiment although their sodium intake was so high that they

<sup>10</sup> These were initially provided as gelatin capsules containing 0.5 Gm through the courtesy of Dr. L. L. Joslyn and the Abbott Laboratories, North Chicago, Ill. Subsequently specially coated sealed tablets were used obtained through the courtesy of Dr. K. G. Kohlschütter and Lilly Chemical Company, Indianapolis, Ind.

<sup>11</sup> We are greatly indebted for the able cooperation of Mr. W. L. Lettering and her staff.

cannot now be considered to have been on a rigid sodium restriction. While some patients will follow the diet with precision and have no difficulty in maintaining a urinary twenty-four hour sodium well below 300 mg, other patients cannot be made to understand, or do not want to accept, the limitation of a diet so constructed.

*Selection of Diets*—The diets were individually prescribed after interview. They attempted to meet the doctor's prescription as to caloric level (maintenance was desired) and as to protein content (usually as high as the patient would accept), to consider the patient's tastes, and still to have the calculated sodium content below 300 milligrams. A commercial preparation of salt depleted reconstituted milk\* was employed where indicated. Commercial salt substitutes were permitted if they contained no sodium†. Iron and vitamin deficiencies were corrected by medication where necessary. Water was allowed ad libitum, the sodium content being known or determined to be insignificant. In several instances "holidays" were permitted for Christmas or New Year's Day. Although these were followed by a mercurial diuretic and when necessary an additional urinary collection, relaxation to this degree was a mistake, at least in the handling of the experiment. We did feel at the time that it kept the cooperation of the subject. We were aware of the variation in sodium content of foods according to selection and preparation, as well as differences in values cited by different authorities<sup>17, 18</sup>.

*Selection of Patients*—†Twenty-four patients were selected on the basis of the existence of definite diastolic hypertension (above 90 mm Hg) after several clinic visits. More than half of the patients had long records of previous attendance at the Clinic. A group was chosen who expressed themselves as willing to follow the procedure with the understanding that they were participants in an experimental study. Since the experiment contained its own inherent control it was not thought necessary to observe these patients for any period on a normal diet prior to placing them on the experimental regime. In addition, a type of incomplete control was available in the records of those patients who had been attending the clinic previously, but in these cases blood pressures were not taken always in the same manner or by the same observer. A second type of control was offered in the several patients in whom diet was begun before the "special" medication was available, and these patients, therefore, had a period of sodium restriction during which time they were not given medication. In one or two instances after the experiment was completed and it was determined that the patient had not followed the diet correctly, a final experimental period was added during which no "special" medication was given and the patient was observed on the salt restriction alone. The ages of the patients were between 28 and 70. Nine were men. The etiology of hypertension was considered to be known in two cases, one of glomerulonephritis and one of pyelonephritis with nephrolithiasis. Two patients previously had undergone sympathectomy. None of the patients were in congestive heart failure, renal insufficiency, showed hypoproteinemia or lowered serum sodium or chloride concentrations, or had visible edema. Of the twenty-four subjects selected, twenty-one continued the study for at least two experimental periods and twenty of these for at least three periods. In some instances repeated determinations were made of the heart size by roentgenogram, the electrocardiogram, blood volume, and thiocyanate available space, but not enough information was obtained over the short period of this study to warrant any attempt at analysis. Other forms of medication which did not augment sodium intake (digitalis, phenobarbital, thiocyanate) were either discontinued at the outset, or continued unchanged during experimental and control periods.

## RESULTS

The entries, representing the average of the blood pressures recorded at each visit, were averaged for each experimental period. The values obtained are considered to represent the blood pressure for the subject under the conditions

\*Generous supplies of Lonalac were made available by Dr. C. E. Pills of Mead Johnson & Company, Evansville, Ind.

†Neocortical Winthrop Chemical Company, Inc., New York, N. Y. K. Salt, Chicago Dietetic Supply Co., Chicago, Ill.

‡Dr. A. S. Alving and Dr. R. M. Becker referred several of the patients to this study.

of the experiment (If, as has been claimed, an effect of sodium restriction may not appear for some time after the restriction of diet and may persist after discontinuance of the regime then the averages thus taken will diminish the apparent effect )

As a first analysis the blood pressures were averaged for all lactose periods for each patient and compared with the blood pressure obtained during the period or periods when sodium chloride was given. This construction assumes that the experiment was carried out as it had been planned originally. An analysis of the diastolic pressures according to this grouping fails to reveal any significant differences between intended experimental and intended control periods in the group as a whole. The subjects were then reclassified according to the results of the averaged twenty four hour urinary sodium assay. It is recognized that a single twenty four hour urinary collection may not represent the average of the excretion of sodium for a seven day period but by the same criterion the observations of blood pressure made one day in the week and only during one part of the day do not necessarily represent the average blood pressure of that patient over the entire week. With this realization, the experimental periods have been arranged under three headings. Where the twenty four hour urinary sodium samples averaged less than 0.5 Gm during a period the patient was considered to have been on rigid sodium restriction (A). When the average of the samples of twenty four hour urinary sodium was greater than 0.5 Gm but less than 1.05 Gm the degree of sodium intake was considered to have been intermediate (B). When the twenty four hour sodium samples averaged 1.05 grams or more the sodium intake was not considered restricted (C). On this basis only nine patients were observed to have actually maintained a rigid restriction for at least one complete period on an average basis. Two of these patients were on the restricted diet for two periods apiece. One patient was carried for only two periods and during both of these was on a restricted sodium intake.

There emerges therefore a group of eight patients who were under severe sodium restriction for at least one period and by comparison had at least one period of intermediate or relatively unrestricted intake of sodium. Table I indicates the average blood pressure during the experimental and the control periods for each of these subjects together with the experimental difference produced by the substitution of sodium chloride for lactose. The observed mean change in diastolic pressure was -4.7 mm of mercury with a standard deviation of 7.6. The mean difference between the average of systolic pressures was -8.7 mm of mercury with a standard deviation of 10.1.

It may be argued that these differences are entirely due to chance. As a test of the adequacy of our method of sampling blood pressures the observations on twenty one patients used in this study may be employed. While only eight of the group had been suitable to compare in experimental and control situations, twenty one of the subjects had been followed for at least *two life* periods. These may have been periods each of low sodium excretion, or periods

of intermediate or unrestricted sodium excretion. Study of these twenty one pairs (Table II) indicates that two consecutive periods on a like regimen of sodium intake were associated with an average recorded difference in blood pressure averaging 0.6 mm of mercury diastolic and 1.1 mm of mercury systolic. Considerable variation in the differences observed between like periods in each subject was noted here and also was present in the eight subjects comprising the experimental group.

To determine the likelihood that the differences in the eight subjects of the experimental group might be due to chance alone, a "t" test of statistical reliability was applied\* using the formula

$$t_{.1} = \frac{\sum dp}{\sqrt{\sum p \sum r^2/t}},$$

\*We are indebted to Dr. L. J. Savage of the Department of Radiobiology and physics for direction advice and assistance with this analysis and also for his well-tempered foil to our efforts.

where  $d$  = experimentally observed difference in blood pressure between periods of unlike sodium excretion

$p$  = weighting factor for  $d = \frac{n \times n'}{n + n'}$  in which  $n$  = the number of entries during the lactose period and  $n'$  = the number of entries during the sodium period

$r^2$  = the similarly weighted square of the difference between pairs of like periods, and

$a$  = the number of pairs of like periods or 21

This formula relates the experimental differences in the eight subjects to the variance of the blood pressure of the entire group of twenty one subjects. The  $t$  values obtained for 21 degrees of freedom were 2.93 for diastolic pressure and 3.17 for systolic pressure. On this basis the probability that a difference of the degree experimentally observed would occur by random variation alone is less than one in one hundred for both systolic and diastolic values.<sup>10</sup>

A tendency to lose weight was noted probably because of fluid loss and the difficulty of maintaining caloric intake. Every effort was made to keep the weight loss minimal. Some subjects even gained in weight and these were not exclusively the ones who were unable to restrict their sodium intake. The average weight loss was greater (2.0 Kg) in the twelve subjects whose sodium excretion was above 0.5 Gm than the weight loss (0.1 Kg) in the eight subjects who were able to rigidly restrict sodium. (Tables III and IV)

Generally the patients who could adhere to the diet claimed the most subjective benefit. Several could hardly be kept from continuing the regimen. One of these died abruptly three days after agreeing to liberalize her salt intake. The cause of death was presumed to be a cerebrovascular accident.

No evidence of undue salt deprivation was encountered. The study was not carried out during the summer months. It was the observers' impression that respiratory infections seem to be followed by undue degrees of asthenia. One patient developed pneumonia together with a condition resembling salt depletion. Her participation in the experiment was terminated and inquiry into the schedule revealed that she had been receiving supplemental salt. No abnormalities were noted in serum electrolytes in this or any other case.

Certain collateral information was obtained by analyzing the Clinic records of our subjects prior to and following the controlled experiment. Blood pressures taken by the same or by other observers and without uniform technique have been averaged for over three periods: (1) before 1943, (2) 1943 through 1945 and (3) 1946 and 1947 until the subject was selected for study. In certain instances the experiment was preceded also by a short period on diet alone and in some instances there was a further period of observation on unrestricted sodium intake at the conclusion of the study. The technique followed in these last two periods was essentially comparable to that used during the study except for the omission of the disguised sodium chloride or lactose.

The average results of this evaluation are recorded in Tables III and IV. For comparison, the experimental data are entered according to the level of urinary sodium as A, B, or C. The cases are arranged into three groups. The first group (Table III) includes the eight patients who completed at least an A and a B or C period. The second group (Table IV) includes twelve patients with no A period, and the third group consists of a single patient with A periods alone. The change in blood pressure in the first two groups is averaged, using the value for 1946 and 1947 as a base. The averaged sodium excretion also is shown for the experimental periods. The experiment in the third group was terminated by intercurrent illness. The comparison reveals an apparent fall in blood pressure in all groups during the periods of study. This fall is of a magnitude much greater than that experienced within the controlled portion of the experiment. For the study periods of lowest averaged blood pressure, in the eight experimental subjects used for evaluation of sodium restriction the average fall in systolic pressure was 30 mm. of mercury and in diastolic pressure 20 mm. of mercury. A similar comparison for the group of patients who did not follow a period of strict sodium limitation as defined shows an average maximum fall of 28 mm. of mercury systolic, and 16 mm. diastolic. There is a general tendency for the pressure to vary with the salt excretion. (It must be recalled that periods A, B, and C were not necessarily consecutive in any patient.) However, the sodium excretion after termination of the experiment was comparable to that of an unrestricted diet and, nevertheless, blood pressure average remained below the 1946-1947 level for both groups.

#### DISCUSSION

The average of the differences in blood pressure which can be ascribed to sodium restriction alone under the conditions of the study is shown to be quite small, 9 mm. systolic and 5 mm. diastolic. It should not be inferred from this that a regime of sodium restriction is ineffective or unwarranted therapy in uncomplicated hypertensive vascular or cardiovascular disease. Two important considerations should be emphasized in this regard.

(1) While the average response in the group of patients studied is small, certain individuals showed a greater response than others. Patient Ia, on the controlled portion of the study, evidenced a fall in diastolic pressure of 19 mm. of mercury. A fall of between 12 and 22 mm. of mercury in systolic pressure was evidenced in four cases. It is probable that there are individual differences in responsiveness among patients. Perhaps, also, the degree of response to sodium restriction is modified by other factors not herein controlled. It is to be emphasized that there may be different varieties of the disorder which is called "essential" hypertension in our ignorance of its homogeneity or etiology. When a large number of patients has been examined and the responsiveness of these patients to variation in sodium intake alone has been analyzed it may be possible to group the type of patient who responds into a separate category. The size of the present study does not permit deductions of this nature. Nor can we identify our responsive patients as being of the "pseudo Cushing's" type reported by Schroeder.<sup>12</sup>

(2) It will be noted by comparing the collaterally obtained information with that obtained during the experimental part of the study that all patients even those who responded very little to restriction of sodium alone had a reduction in blood pressure over the period encompassed by the study. This maximum change in pressure is the figure that would be obtained from an entirely "clinical" evaluation of these patients and represents the overall effect of all procedures used plus the spontaneous variations in blood

Fig 1—For the eight subjects in whom the effect of sodium restriction alone can be determined the blood pressure change ascribed to this restriction is compared with the maximum fall in pressure from the clinical records. Each dot represents one subject the cross represents the average of all subjects (All illustrations courtesy of the Veterans Administration Washington D C)

pressure, differences between observers etc. If no analysis had been made of the change in blood pressure associated with sodium restriction alone this entire effect could have been ascribed mistakenly to the therapeutic value of sodium restriction. In Fig 1 the fall in blood pressure ascribed to sodium restriction alone is compared with the maximum clinical fall in blood pressure based on the records. It will be noted that there is no correlation between the two sets of observations. Several individual records are presented in Figs 2 to 8. One patient whose blood pressure rose during the period of sodium restriction as compared with a period of liberal administration of sodium nevertheless had the greatest fall in blood pressure of any of the group on an overall basis (Fig 2). Moreover this patient claimed great symptomatic improvement on this regimen. Her blood pressure was lowest during the six week period in which the urinary sodium averaged 1.25 Gm per day (equivalent to 3.2 Gm of sodium chloride). The absence of correlation between the fall ascribable to sodium restriction alone and the general reduction in blood pressure that occurred during the course of the study

Fig. 3—Patient L-63 Q with previously recorded diastolic pressures over 110 showed a fall to normal levels during sodium restriction and a rise during supplementation with salt. Little weight change occurred.

Fig. 5.—Patient Ca. an elderly man who adhered to his diet strictly showed no effect of salt restriction upon his blood pressure although he claimed great symptomatic benefit

evaluation of the effect of sodium restriction upon her blood pressure

and the small number of cases of the experimental group make it rather pointless to present the individual cases in a search for the factors which make some patients susceptible to sodium restriction and others not. If the effect of this regimen is considered as the resultant of the two components i.e. the effect of sodium restriction per se and the effect of all other factors probably variation exists between individuals in each of these effects. It would be important to know how to select those patients who might have a good response to sodium restriction. It would appear of even greater importance to have criteria for selection of patients who respond to the factors other than sodium restriction. Both necessitate extension of our studies.

The foregoing comments deal only with the response of the blood pressure under the described regimen. A further factor of therapeutic importance arises when it is considered that the symptomatic effect of this regimen did not always parallel the change in blood pressure nor the variation in sodium intake. There were patients who felt better although the blood pressures did not fall and there were patients who felt better during a period when the sodium intake was higher than it had been before regardless of any change in blood pressure. Our brief studies do not permit analysis of these relationships nor do they control spontaneous variations in the level of the patient's symptoms.

We have been quite arbitrary in selecting the level of sodium excretion by which our patients have been grouped. Previous workers have maintained that a urinary sodium or chloride excretion equivalent to more than 0.5 Gm of sodium per day should not be considered an adequate degree of sodium restriction for the treatment of hypertension. It is quite possible that the blood pressure in some patients may fall with much more moderate sodium restriction than that which we have attempted. The average blood pressures for periods at different levels of sodium excretion reveal to some extent the individual and average response of patients when the degree of sodium restriction is varied. A more important objection to the conclusions of the study lies in the fact that the period of observation was arbitrarily limited to six weeks. In several instances it appeared that a change in blood pressure was becoming manifest toward the end of the six week period. This is in accord with the results of others who have pointed out that a delay in response may be noted. This is said to occur particularly during desalting. Such a phase displacement commented on previously will minimize any apparent effect of sodium restriction alone in this study. We do not feel that our data permit division of the experimental periods each into two periods of three weeks although this would be a way of approaching this valid criticism.

The study was designed to evaluate only one point and that was whether sodium restriction *alone* was capable of significantly reducing the blood pressure of hypertensive patients. Here 'significant' does not mean the significance to the patient or any therapeutic significance but simply whether sodium restriction had a *statistically significant* effect upon the blood pressure. This must be established before one can view in its proper light the result of the

complex alterations which ensue when a patient comes to the doctor's office or to the clinic and is advised to go on a rigidly restricted diet. It is important for the doctor to know whether the diet he advises is effective because of its sodium restriction, because of its specific composition, because of its psychological implication, or whether the patient appears to benefit because some active therapeutic effort is being made in his behalf or simply because the doctor is taking an interest in him. From the point of view of some patients (and physicians), the mechanism may not seem to be of importance, it often sufficing that the patient feels better and that the response satisfies his physician in whom he places his trust to keep him well. For the physician, this is self-deception.

There is great need for a wider realization of the profound physiologic, psychologic, psychiatric,<sup>20</sup> social, and economic alterations which may result from a diet such as this, apart from the biochemical and physiologic effects of sodium chloride depletion.

#### SUMMARY

An attempt was made to provide a maintenance diet with a sodium content restricted to less than 300 mg per twenty-four hours. This diet was offered to twenty-four ambulatory hypertensive patients on an experimental basis. In addition the subjects received either 4 Gm of sodium chloride or lactose in identical form over three periods of approximately six weeks each according to planned schedules. Neither the subjects nor the investigators were aware of the schedule being used and the subjects were not aware of the nature of or alteration in the medication. The criterion adopted for rigid restriction was the average excretion of less than 500 mg of urinary sodium in a weekly twenty-four hour sample. Blood pressures were recorded by a standardized technique approximately once each week. Eight subjects presented data for a period of restriction which could be compared with a period of greater sodium excretion. In these subjects the average diastolic blood pressure was 47 mm of mercury lower and the average systolic pressure 87 mm of mercury lower during the restricted period than during the period of sodium supplementation. Twenty-one subjects yielded data for at least two periods of a like order of sodium excretion from which the variances of the blood pressure for the group were determined. On this basis the probability that a difference as large as that experimentally observed would occur by random variation is less than one in one hundred for both the diastolic and the systolic values.

#### CONCLUSIONS

- 1 A diet rigidly restricted in sodium is difficult to administer successfully to ambulatory hypertensive subjects.
- 2 A difference of less than 5 mm of mercury in the average diastolic blood pressure was observed, which could be ascribed to the effect of the sodium chloride restriction alone.
- 3 This difference cannot reasonably be assigned to random variation.

4 Reduction in blood pressure observed when hypertensive patients are placed upon a diet which is restricted in sodium may be only partly due to sodium restriction. Some of the other factors which may be involved are pointed out but not analyzed in this study

# INFLUENCE OF VARIOUS DISEASE STATES UPON THE FEBRILE RESPONSE TO INTRAVENOUS INJECTION OF TYPHOID BACTERIAL PYROGEN

WITH PARTICULAR REFERENCE TO MALARIA AND CIRRHOSIS OF THE LIVER

ALBERT HEYMAN, M D , and PAUL B. BEFSON, M D  
ATLANTA, GA

CLINICAL experience during fever therapy has shown that patients given a series of injections of a bacterial pyrogen, such as that present in typhoid vaccine, develop a remarkable tolerance to the pyrogen, so that increasing doses must be given in order to produce comparable elevations in body temperature. This type of immune reaction or tolerance is of short duration and is apparently not dependent on the presence of specific antibodies<sup>1</sup>. Experiments in rabbits indicate that it is related to an increased ability of the reticulo-endothelial system to remove the pyrogen from the circulation<sup>2</sup>. The question arises whether a similar tolerance develops in human beings during the course of certain febrile diseases. If such alterations do occur, patients convalescent from these diseases would be expected to show very little febrile reaction to intravenous injection of a bacterial pyrogen. One observation pertinent to this problem was reported by Howard<sup>3</sup> who, in studying the effect of fever on protein metabolism, found that he was unable to elicit an appreciable febrile response to typhoid vaccine in a patient who had recently recovered from malaria. Morgan<sup>4</sup> reported that patients convalescent from typhoid and paratyphoid fever showed no significant febrile reactions to intravenous injection of purified extracts of *Escherichia typhosa* and *Shigella dysenteriae*. This material, however, produced marked febrile reactions in normal individuals. The present report summarizes observations on the febrile response of patients with various diseases to intravenous injection of a small dose of typhoid vaccine.

## METHOD

The vaccine employed was a suspension of heat killed *E. typhosa* containing approximately one billion organisms per milliliter. The standard dose was 0.5 ml injected intravenously. Previous experience with this vaccine had shown that this dose produced little symptomatic discomfort other than a sensation of chilliness followed by a rise in temperature of 1.5° F to 3° F with temperature returning to normal in four to six hours. Temperature measurements were made with a constant recording rectal thermometer. Readings were begun one hour previous to the injection and continued at thirty minute intervals for eight hours afterward. The febrile response was plotted on graph paper and the temperature previous to injection was taken as the base line. The area between the base line and the course of the febrile response was measured with a planimeter. The size of this area, expressed in square units of the planimeter, was called the "fever index".

The subjects studied can be divided into five main groups:

1. A 'normal' group of sixteen afbrile patients receiving penicillin treatment for asymptomatic neurosyphilis.

From the Department of Medicine of Grady Memorial Hospital and Emory University School of Medicine.

Received for publication July 12, 1949

2 Twenty two patients convalescent from a variety of acute infectious diseases, including seven with pneumonia four with gonorrheal arthritis three with typhus fever three with tularemia, two with typhoid fever two with meningitis and one with rheumatic fever. The vaccine was administered to these patients two or three days after they had recovered from their illnesses and had become afebrile.

3 Twenty patients who had just completed a course of malarial fever therapy for neurosyphilis. The test was carried out on the second or third day following the last malarial paroxysm.

4 Fourteen patients with cirrhosis of the liver.

5 Thirteen patients with jaundice ten of whom had viral hepatitis and three of whom were thought to have biliary obstruction. All of the patients with liver disease were tested at a time when their temperatures had been normal for two or three days.

Fig. 1.—The febrile response to typhoid vaccine in various disease states. The arrow indicates the mean response in each group of patients.

## RESULTS

The febrile responses following injection of typhoid vaccine in the different groups are shown in Fig. 1. It will be observed that in the "normal" subjects the range of the fever index varied from 43 to 262, the mean being 132. This quantitative expression of both the height and the duration of fever indicates a rise of  $1.5^{\circ}\text{F}$  to  $3^{\circ}\text{F}$ , the temperature returning to normal usually within six hours.

In patients recently convalescent from acute infections the febrile responses were comparable to those of the "normal" subjects, the mean value of the fever index in this group being 148. The four highest values were in two patients with typhoid fever and two with tularemia. The two patients with typhoid fever, the only ones in this study with this condition, exhibited

an increased sensitivity to pyrogen, a finding at variance with that of Morgan<sup>7</sup> who reported a decreased febrile response in a larger number of patients convalescing from this illness. One other patient with tularemia showed a febrile response similar to that appearing in the normal subjects.

The twenty patients who had recently recovered from malaria reacted to the typhoid vaccine with less fever than the preceding groups, their mean fever index being only 63. This finding is similar to that noted by Howard in one case. Comparable observations were made by Habetm,<sup>9</sup> who found that the injection of pyrogenic nuclei, made from yeast, failed to produce any febrile response in a few patients with malaria.

Patients with cirrhosis of the liver showed greater than normal response, the fever indices ranging from 140 to 352, the mean value being 236.

In the group of thirteen patients with jaundice, twelve showed response within the "normal" range, whereas one with infectious hepatitis had an exaggerated febrile response. This person had been ill for approximately four months, and liver function tests showed considerable evidence of hepatic insufficiency at the time the test was performed.

#### DISCUSSION

The increased sensitivity to pyrogen observed in patients with chronic liver disease may possibly be caused by impaired reticuloendothelial function in the liver and spleen, or may be related to some metabolic disturbance. Patients with cirrhosis have been observed to develop fever following the intravenous administration of salt-poor albumin.<sup>7</sup> There is also a definite impression that certain preparations of albumin produced febrile reactions in persons with cirrhosis, but not in patients with hypoalbuminemia due to other causes.<sup>8</sup> The patients in the present study with acute hepatitis or obstructive jaundice, however, did not exhibit abnormal responses to typhoid vaccine. Experiments with rabbits in this laboratory have also shown that acute liver damage, produced by chloroform, did not lead to abnormal febrile response to typhoid pyrogen.

The diminished response to the pyrogen in patients with malaria may possibly be associated with the great proliferation in reticuloendothelial elements known to occur in this infection. The stimulation of the reticuloendothelial system produced by malarial fever and typhoid vaccine fever therapy has been offered as an explanation for their curative effect in neurosyphilis.

The patients in this study with febrile diseases other than malaria developed little if any tolerance to bacterial pyrogen. Morgan,<sup>7</sup> however, has observed that patients convalescent from typhoid and paratyphoid fevers showed tolerance to injection of purified extracts of typhoid and dysentery bacilli, whereas the reaction observed in five patients recovering from other febrile diseases was comparable to that of normal subjects. Bennett found that rabbits surviving pneumococcal and colon bacillus infection did not show a diminution in febrile response to typhoid or colon bacillus pyrogens.<sup>9</sup>

## SUMMARY

The febrile response to typhoid bacterial pyrogen was observed in a group of eighty five patients with various diseases. The mean response elicited by patients with a variety of infections, such as pneumonia, hepatitis, typhus fever, and tularemia, was the same as that observed in normal individuals. Patients with malarial fever, however, appeared to be comparatively resistant to the pyrogen. Patients with cirrhosis of the liver exhibited an exaggerated response.

# THE IN VIVO ACTION OF AUREOMYCIN ON PLEUROPNEUMONIA LIKE ORGANISMS ASSOCIATED WITH VARIOUS RHEUMATIC DISEASES

THOMAS MCP BROWN, M D , RUTH H WICHELHAUSEN, M D ,  
LUCILLE B ROBINSON, A B , AND WILLIAM R MERCHANT, M D  
WASHINGTON, D C

THE efficacy of gold compounds in animals experimentally infected with animal strains of pleuropneumonia-like organisms has been demonstrated by various observers<sup>1-6</sup>. A strain of *Streptobacillus moniliformis* recovered from the joint fluid of a patient produced arthritis in mice with great regularity. Arthritis could be prevented by the simultaneous administration of gold and the infecting agent, but arthritis once established was unaffected by the use of gold. The transformation of this strain of *S. moniliformis* into the pleuropneumonia-like form was readily demonstrated.

A patient with nonspecific urethritis and prostatitis from whom pleuropneumonia-like organisms were recovered has been treated with Myochrysin without improvement<sup>8</sup>. Sulfonamides and penicillin have been found ineffective both in vitro and in vivo in animal and human infections with these organisms<sup>7-9</sup>. Streptomycin has been observed to have an effect on L organisms and has produced a rapid disappearance of symptoms in patients with an associated infection due to these organisms<sup>8-10</sup>. However, pleuropneumonia like organisms have been observed to persist in a case of nonspecific urethritis following streptomycin therapy<sup>8</sup>. It has been pointed out repeatedly that L organisms may be of significance in human joint diseases but a definite correlation has not yet been established<sup>8-11-12</sup>.

## OBSERVATIONS

In the present study, patients with rheumatoid arthritis, from whom cultures of prostatic secretion yielded pleuropneumonia like organisms, were observed for one year or more. An effort was made to determine whether or not under prolonged gold therapy for the rheumatoid arthritis the organisms could be eliminated in vivo in human beings. In all patients of this group, L organisms could be recovered with great regularity in spite of continued gold therapy and satisfactory clinical remissions.

In one of these patients, each of fourteen successive prostatic cultures obtained over a period of eighteen months was positive for L organisms. After thirteen months of gold therapy (10 mg the first week, 25 mg the second week, 50 mg weekly for nineteen weeks, 50 mg monthly for eight months, total dosage, 1,385 mg), myochrysin was discontinued because of toxicity. Three

Received for publication July 14, 1949

months after cessation of therapy the rheumatoid arthritis relapsed and aureomycin\* therapy was instituted. There was a complete disappearance of pleuropneumonia like organisms on six successive culture attempts during and following aureomycin therapy.

Disappearance of *L* organisms from the genital tract under aureomycin therapy has been demonstrated in a total of nine patients (three men, six women; two cases of erythema nodosum, one of rheumatic fever, five of rheumatoid arthritis, one of nonspecific urethritis). In two of the female patients *L* organisms reappeared after discontinuation of the drug, indicating either insufficient dosage or bacteriostatic rather than bactericidal activity of aureomycin. One of these patients was re-treated with aureomycin and again prompt elimination of the organisms was achieved.

Four patients with nonspecific urethritis have been treated with aureomycin. Two of these patients had joint and muscle complaints in addition to the urethritis. In only one patient cultures of prostatic secretion yielded abundant growth of pleuropneumonia like organisms. There was prompt response to aureomycin (20 Gm per day for four days) confirming the observation of Collins and co-workers.<sup>12</sup> Complete relief of symptoms occurred after forty-eight hours of therapy. Cultures taken thirty-six hours and one ten and eleven weeks after institution of aureomycin therapy were negative for pleuropneumonia like organisms. In spite of negative cultures the patient had a recurrence of burning on urination but no return of urethral discharge. The burning sensation has persisted in the absence of further treatment. This observation, a recurrent clinical symptom and negative cultures in a patient in whom *L* organisms were demonstrated previously, supports the impression that absence of demonstrable *L* organisms does not rule out the possibility that disease was initiated by infection with them. The inability to demonstrate pleuropneumonia like organisms may be due to the inadequacy of the present culture methods. This failure to culture organisms may also parallel the findings in *S. moniliformis* infections in which in the later stages of the disease it may be impossible to recover the organism although clinical activity persists. These speculations would explain the frequently noted lack of correlation between clinical and laboratory findings.

In three of the four patients with nonspecific urethritis pleuropneumonia like organisms could not be demonstrated in repeated cultures prior to aureomycin therapy. One patient was treated for an attack of three months duration which had not improved under penicillin therapy. One gram of aureomycin was given daily for seven days. The patient was asymptomatic on the last day of treatment. Burning on urination recurred two weeks after cessation of therapy and four weeks after discontinuation of aureomycin morning discharge was again present. A second course of aureomycin was given consisting of 1 Gm daily for five days and 20 Gm daily for three weeks. The discharge ceased after five days of therapy, burning diminished during treatment and cleared completely a few days after cessation of therapy. The patient has remained asymptomatic during a five week follow up period. A second patient

\*We are indebted to the Lederle Laboratories for part of the aureomycin used in this study.

became asymptomatic following forty-eight hours of treatment (10 Gm per day for seven days), but mild burning on urination developed one week after aureomycin had been discontinued. This patient has not been re-treated. The third patient presented a two-year history of urethritis. Burning and urethral discharge were present at the onset of the disease. After three months of the illness the discharge cleared spontaneously, but burning and frequency of urination persisted with the gradual development of arthralgia, myalgia, and fatigue. Aureomycin therapy (0.5 Gm per day for four weeks, 1.0 Gm per day for ten days) appeared ineffective. However, when the dose of aureomycin was increased to 2.0 Gm per day striking improvement was noted. After the patient had been on this larger dosage for three weeks, he noted for the first time in two years absence of burning on urination and was completely free of myalgia, joint pain, and fatigue. Treatment was continued for a total of ten weeks. There was no recurrence of symptoms. There has been inadequate time for follow-up studies.

Twenty-five patients representing a variety of rheumatic diseases (rheumatoid arthritis, Marie-Strumpell spondylitis, rheumatic fever, erythema nodosum) have been treated with aureomycin (Tables I and II).<sup>14</sup> Cultures from the cervix and prostatic secretions yielded pneumopneumonia like organisms in eight of these patients. Cultures were negative for L organisms in seventeen patients.

Subjective and objective improvement was observed in seventeen of these twenty-five patients. Two (Patients R. H. and E. V.) were symptomatically improved. One case of rheumatic fever (Patient J. T.) could not be evaluated because salicylates were given simultaneously. Two patients with Marie-Strumpell spondylitis (Patients D. T. and L. A.) showed no demonstrable improvement after five and eight weeks of treatment. One individual with Marie-Strumpell spondylitis and peripheral joint involvement (Patient J. B.) experienced temporary marked symptomatic improvement followed by an acute

TABLE II EFFECT OF AUREOMYCIN THERAPY ON RHEUMATIC FEVER AND ERYTHEMA NODOSUM

Minus sign denotes that the determination was not made

exacerbation of the disease. Two persons (Patients F W and J 1) with rheumatoid arthritis did not improve. It may be of significance (Table I) that the aureomycin blood serum levels were uniformly low in those patients in whom little or no clinical improvement was noted.

The relation between dosage of aureomycin, aureomycin blood serum levels, temporary or permanent elimination of L organisms and clinical response will require further study. Disappearance of L organisms in the patients with positive cultures was more rapid than the clinical improvement noted in any single case with the dosage of aureomycin and the route of administration employed. In one case of erythema nodosum as little as 0.25 Gm of aureomycin daily was all that was necessary to eliminate pleuropneumonia like organisms from the cervix. In this case 10 Gm per day of the antibiotic was required to produce a favorable clinical response. One patient in whom L organisms disappeared promptly failed to show clinical response. The patients with negative cultures for L organisms responded as well as those from whom the organisms could be recovered.

There was an initial exacerbation of the illness in a number of cases of rheumatoid arthritis and Marie Strumpell spondylitis comparable with that frequently observed by us in rheumatoid arthritis treated with gold. This exacerbation of muscle and joint symptoms varied in intensity and duration, but uniformly disappeared under continued therapy. Two patients who had fever prior to therapy developed an initial transient additional rise in temperature on 20 Gm of aureomycin daily. The three other febrile patients in the rheumatic fever erythema nodosum group in whom aureomycin did not exceed 10 Gm per day did not have this additional febrile response.

It was observed early in the course of this study that some patients who failed to improve on 1 Gm of aureomycin daily responded favorably when the dosage was increased to 20 Gm per day. Therefore the 2 Gm dose was selected whenever the patient could tolerate this amount. In most patients improvement was noted one to four weeks after initiation of therapy and continued in a manner comparable to that observed with successful gold therapy of rheumatoid arthritis. The high incidence of favorable response to aureomycin suggested an effect which was more than a coincidental finding. Aureomycin therapy may not be suitable in cases of rheumatic fever because of the initial exacerbation of symptoms noted. Smaller initial doses than those employed in the present study may eliminate this exacerbation.

Kuzell<sup>1</sup> has reported that the effect of aureomycin was similar to that of gold in the control of rat arthritis experimentally produced with the L<sub>4</sub> strain. Brown<sup>16</sup> has noted the effect of aureomycin in human beings with rheumatic diseases. It would appear that aureomycin and undoubtedly other antibiotics with a similar effect on L organisms may assume an essential role in the understanding of the relationship of pleuropneumonia like organisms to rheumatic diseases. Preliminary studies indicate that the effect of chloromycetin may be comparable to that of aureomycin. In one female patient with severe progressive rheumatoid arthritis repeated cervical cultures were done before and

after administration of 1.0 Gm of chloromycetin daily. Prompt elimination of L organisms was achieved. There was an exacerbation of symptoms followed by rapid major clinical improvement within three weeks.

#### SUMMARY

1. Oral administration of aureomycin has produced uniform disappearance of demonstrable pleuropneumonia-like organisms from the genitourinary tract of individuals with and without joint disease. L organisms were not eliminated by gold therapy.

2. Elimination of L organisms by aureomycin or by other antibiotics producing a similar effect may be of importance in the understanding of the possible relationship of pleuropneumonia-like organisms to articular diseases.

3. The effect of aureomycin therapy in twenty-five cases of rheumatic disease has been reported.

4. The ultimate value of aureomycin in the treatment of rheumatic diseases must await prolonged clinical trial and follow-up study.

We are indebted to Dr. W. D. Jarman for permitting the use of his case in this study (one case of nonspecific urethritis).

# SONIC VIBRATION LEPTOSPIRAE AS ANTIGENS IN THE COMPLEMENT FIXATION TEST FOR THE DIAGNOSIS OF LEPTOSPIROSIS

RAYMOND RANDALL D V M \* PSYCH W WETMORE B A , AND  
ALBERT R WARNER JR  
WASHINGTON, D C

IT IS recognized that in the majority of cases of human and animal leptospirosis a diagnosis cannot be made without recourse to one or more laboratory procedures

Leptospirae can be demonstrated by dark field microscopic examination of the blood during the septicemic stage of the disease which usually lasts for seven days. Also at this time inoculation of young hamsters with whole blood from patients infected with *Leptospira icterohaemorrhagiae* and *Lept. canicola* generally results in a fatal leptospirosis in the test animal<sup>1</sup>. The leptospirae disappear from the patient's blood stream during the second week and then appear in the urine. Agglutinins, lysins and complement fixing antibodies usually begin to appear in the patient's serum toward the end of the first week and are present in readily measurable amounts about the twelfth to fourteenth day after the onset of illness. The maximum titer is reached within three to four weeks and in most instances antibodies are detectable for several months to years.

The tests most frequently used for the demonstration of antibodies in the patient's serum are the macroscopic<sup>2</sup> and microscopic agglutination<sup>3</sup> and agglutination lysis tests<sup>4</sup>. These procedures require personnel properly trained in the techniques and necessitate the maintenance of suitable cultures of leptospirae. For this reason their use is limited to only a few laboratories.

Because a simple and reliable diagnostic test for leptospirosis was not available a study was undertaken to develop an antigen for use in a complement fixation test that could be performed in any laboratory conducting the Wassermann or similar complement fixation tests. In the past, the complement fixation test for the diagnosis of leptospirosis has received little attention apparently because of the difficulty of preparing suitable antigens. Pot and Dorniel<sup>5</sup> and Boerner and Lukens<sup>6</sup> have reported on two different methods of preparing antigens for use in the complement fixation test for the diagnosis of Weil's disease. However, Boigen<sup>7</sup> concludes that the lack of agreement between the agglutination reactions and the complement fixation test is due to sources of error in technique or to unstable or inefficient antigens. Where we utilized antigens prepared by present available methods our results also have been unsatisfactory. Therefore experiments were undertaken to produce a suitable antigen and it was found that leptospirae ruptured by sonic vibration yielded an antigen of considerable specificity and sensitivity.

## MATERIALS AND METHODS

*Preparation of Antigen*—Although there are sixteen serologically recognized species of leptospira, only two, *Lept icterohaemorrhagiae* and *Lept canicola*, are known to infect human beings and dogs in the United States, therefore, antigens were prepared from these two species. Antigens were prepared from strains of *Lept icterohaemorrhagiae* and *Lept canicola* isolated in this laboratory from young hamsters inoculated with whole blood from naturally infected dogs.<sup>1</sup> Erlenmeyer flasks of 250 ml capacity containing 50 ml amounts of Stuart's medium<sup>8</sup> were inoculated with 5.0 ml of a 3 day old culture of leptospira and incubated at 29 to 30° C for six days. At the end of this period 0.05 ml of formalin was added to each flask and the cultures were held at 29 to 30° C for an additional twenty four hours. The killed cultures were transferred in 50 ml amounts to plastic tubes and centrifuged at 17,000 r.p.m. for fifteen minutes in an International Model PR 1 refrigerated centrifuge maintained at 0 to 3° C. The supernatant fluid was decanted and the packed leptospirae were collected and washed three times with 0.85 per cent saline solution buffered at pH 7.0. The washed organisms were then resuspended in buffered saline solution to one tenth of the original volume of the culture medium. Twenty milliliter aliquots of the concentrated suspension of the leptospirae were exposed to sonic vibration at 9,400 cycles per second for ten minutes in a water cooled Ryttheon Type R 22 magnetostriiction oscillator maintained at 100 volts. The material was then pooled and Methylolate added to 1:1,000 final concentration to constitute the species specific stock antigen. Antigens refrigerated at 4° C have remained stable and specific for at least six months.

*Complement Fixation Tests*—The complement fixation technique used at the Army Medical Department Research and Graduate School is employed.

*Complement Titrations*—The 1:30 dilution of complement is titrated to determine the unit and two full units contained in a 0.5 ml volume are used for the test. (For example, if hemolysis is just complete in the tube containing 0.14 ml of complement, then 0.16 ml is taken as the unit.)

*Antigen Titrations*—Titrations have shown the optimum dilution of the stock antigen to be 1:15, with the unit ranging from 0.02 to 0.05 ml of this dilution. Three exact units of antigen contained in a 0.25 ml volume are employed.

*Inactivation of Sera*—Human sera are inactivated at 56° C for twenty minutes, dog and rabbit sera at 62 to 63° C for forty minutes in a dilution of 1:1. In the routine test, 0.25 ml of twofold dilutions, from 1:1 through 1:32 and in a quantitative test 1:1 through 1:1,280, of the inactivated serum is used.

*The Test*—To 0.25 ml amounts of the sera dilutions three units of antigen and two full units of complement are added. The tubes are refrigerated at 4 to 6° C for sixteen to eighteen hours. On removal, the tubes are left at room temperature for fifteen to twenty minutes and 0.5 ml of sensitized cells consisting of 0.25 ml of a 3 per cent suspension of sheep cells and 0.25 ml of amboceptor containing three units is added. The tubes are incubated at 38° C for thirty minutes in the water bath and the test is read.

*Controls*—The usual hemolytic and positive and negative control sera are set up.

## RESULTS

Parallel complement fixation and microscopic agglutination tests were made on three groups of human sera. Group I consisted of twenty-five random serum specimens submitted to this laboratory from a wide variety of disease processes other than proved cases of Weil's disease. Group II included ten sera from syphilitic patients giving positive Wassermann reactions. Group III included sera from twenty-one proved cases of Weil's disease. In none of the random specimens in Group I were either complement-fixing or agglutinating antibodies against either leptospira antigen detected.

All of the ten positive Wassermann sera of Group II likewise failed to react with leptospira antigens in either type of test

On the other hand, definite antibody responses were elicited in all of the sera of patients diagnosed as having Weil's disease (Group III). Two examples are shown in Table I

TABLE I. THE OCCURRENCE OF COMPLEMENT FIXATION AND AGGLUTINATION ANTIBODY IN TWO CASES OF HUMAN LEPTOSPIROSIS

SERUM FROM CASE	DAYS SINCE ONSET OF DISEASE	TITER OF COMPLEMENT FIXATION TEST		TITER OF MICROSCOPIC AGGLUTINATION TEST	
		LEPT CANICOLA ANTIGEN	LEPT ICTEROHAEMORRHAGIC ANTIGEN	LEPT CANICOLA ANTIGEN	LEPT ICTEROHAEMORRHAGIC ANTIGEN
1	5	1 8	1 8	0	0
1	28	1 128	1 128	1 10 000	1 1 000
2	6	1 16	1 16	0	0
2	17	1 32	1 32	1 10	1 300
2	42	1 64	1 128	1 100	1 1 000

Case 1 was a patient whose first symptoms of illness were general malaise, headache, conjunctival injection and pyrexia. Five days after onset, the serum showed a complement fixation titer of 1 8 against both *Lept canicola* and *Lept icterohaemorrhagiae* antigens. Another specimen of serum obtained on the twenty eighth day of illness showed a rise in complement fixation titer to 1 128 against both antigens. The microscopic agglutination test on the first specimen was negative while the second specimen reacted with *Lept canicola* and *Lept icterohaemorrhagiae* antigens at 1 10 000 and 1 1 000 dilutions respectively.

Case 2 was that of an attendant in a small animal hospital who developed general malaise, chills and fever. His serum fixed complement with both leptospira antigens at a dilution of 1 16 on the sixth day of reported illness. By the seventeenth day the titer against both antigens had risen to 1 64 and on the forty second day the complement fixation titer against *Lept canicola* was 1 64 and that against *Lept icterohaemorrhagiae* 1 128. Parallel studies with the microscopic agglutination technique showed negative results on the first specimen of serum while the second reacted with *Lept canicola* at 1 10 and *Lept icterohaemorrhagiae* at 1 300. The third serum specimen had a positive agglutination titer of 1 100 for *Lept canicola* and 1 1 000 for *Lept icterohaemorrhagiae*. These observations suggest that antibody formation in leptospirosis may be detectable by the complement fixation test before it is demonstrable by the microscopic agglutination test.

Nineteen of the sera in Group III from human cases of leptospirosis occurring in the Far East were obtained through the courtesy of Dr Pierre Lepine of the Pasteur Institute. These cases had been diagnosed at point of origin by use of the agglutination lysis test. Unfortunately serial specimens were not obtained for comparative studies but the positive findings obtained on single specimens as shown in Table II were in accord with the comparative results of the complement fixation and microscopic agglutination tests noted in Table I.

# EXPERIMENTAL VASCULAR DISEASES DUE TO DESOXYCORTICOSTERONE ACETATE AND ANTERIOR PITUITARY EXTRACT

## I COMPARISON OF FUNCTIONAL CHANGES

GEORGES M C MASSON, PH D, A C CORCORAN, M D, AND IRVINE H PAGE, M D  
CLEVELAND, OHIO

**I**NJECTIONS of crude anterior pituitary preparations elicit in rats morphologic and physiologic changes similar to those caused by desoxycorticosterone acetate (Selye, 1944). Hence Selye (1944) has suggested that the pathogenesis of hypertension, nephrosclerosis, periarteritis nodosa, and certain myocardial lesions can best be explained on the basis of pituitary adrenal activities. The postulated chain of events would be stress  $\rightarrow$  anterior pituitary (ACTH)  $\rightarrow$  adrenal cortex (desoxycorticosterone like compounds)  $\rightarrow$  kidney, blood vessels, heart. The posited identification of the effects of anterior pituitary preparations with those of desoxycorticosterone acetate is lacking in detail. Thus hypertension was estimated either from heart weight (Selye and Stone, 1946) or from single direct measurements of carotid arterial pressure (Dontigny, Hay, Prado, and Selye, 1948).

As part of a more definitive comparison, the present report embodies a survey of the functional effects of anterior pituitary preparations and desoxycorticosterone acetate accomplished by serial measurements of arterial pressure and water diuresis in groups of animals treated with these substances singly or in combination. Diuresis as well as blood pressure was a major criterion in the comparison because of the well-known diuretic effect of desoxycorticosterone. Organ weights also were measured and compared.

## I EFFECTS OF CRUDE ANTERIOR PITUITARY PREPARATION AND DESOXYCORTICOSTERONE ACETATE

### *Experimental—*

Spigague Dawley female albino rats were fed a high protein diet (75 per cent Purina fox chow plus 25 per cent casein) and given 1 per cent saline solution as drinking water. Further "sensitization" (Selye, Stone, Nielsen, and Leblond, 1945) to the hormones was effected by unilateral nephrectomy. Rats were divided into four groups. Group I served as control, Group II received 25 mg of desoxycorticosterone acetate (DOCA) a day, Group III, 30 mg of a suspension of anterior pituitary powder (APP), Group IV, a combined treatment of DOCA and APP at the same dosage levels as in Groups II and III respectively. Group IV was added in order to see whether the two hormonal preparations would act additively or synergistically.

The steroid was suspended in water in a concentration of 10 mg per cubic centimeter. The anterior pituitary powder, prepared by lyophilization of cattle glands, was suspended in a concentration of 50 mg per cubic centimeter in 1 per cent saline containing 10 per cent of

From the Research Division of the Cleveland Clinic Foundation and the Frank E. Bunt Educational Institute.

This study was supported in part by a grant from the United States Public Health Service (National Heart Council).

Received for publication July 14 1949

alcohol and filtered through gauze. The solution was kept in the icebox and made up weekly. Injections were begun immediately after unilateral nephrectomy. The animals were placed in metabolism cages in order to measure diuresis.

Blood pressure was measured by the plethysmographic method of Williams, Harrison, and Grollman (1939) as modified by Kempf and Page (1942). Each value recorded is an average of two to three consecutive readings. Reproducible results are obtained in nonanesthetized rats under the following conditions: (1) Animals are kept constantly at a temperature of about 30° C. (2) at the time of the determination each rat is placed in a constant temperature (40° C) box for a period of three minutes and (3) the tail is

Fig. 1—Effect of desoxycorticosterone acetate and anterior pituitary preparations on urine formation.

compressed and emptied of blood in the plethysmograph just prior to increasing pressure in the air cuff. From repeated observations on 132 rats blood pressure was found to vary from 70 to 130 mm Hg (average 99) with 68 per cent of the animals in the 90 to 110 mm Hg range. Some of these measurements were compared with those of an electrically recording plethysmograph (Olmsted, Corcoran, Gilmer and Page, 1948) from time to time as a further check.

Unless otherwise stated animals were sacrificed on the sixty first day and autopsied. Heart, kidney, ovaries, and adrenals were weighed and sectioned for histologic studies after fixation in Zenker's solution. These detailed histologic observations will be the subject of another paper.

### Results —

Observations summarized in Figs. 1 and 2 and in Table I are averages of two series of experiments in which the mean initial body weights of the rats were respectively 103 and 219 grams. Results were the same in the two series, so that they are reported jointly. Weights of heart and adrenals are expressed in milligrams per 100 grams of body weight and kidney weights in milligrams per 100 sq cm of body surface. The body surface was calculated according to the formula  $S.A. = Wt^{0.66} \times 11.23$ .

TABLE I EFFECTS OF DESOXYCORTICOSTERONE ACETATE (DOCA) AND ANTERIOR PITUITARY PREPARATION (APP) ALONE OR IN COMBINATION

GROUP	NUMBER OF RATS	MEAN BODY WEIGHT CHANGES	HEART (MG /100 GM BODY WEIGHT)	ADRENALS (MG /100 GM BODY WEIGHT)	KIDNEY (MG /100 CM BODY SURFACE)
I, Control	21	+13	310 (270 370)	27 (23 30)	315 (286 343)
II, DOCA	20	+17	425 (380 480)	30 (21 37)	513 (426 573)
III, APP	32	+47	402 (250 540)	77 (40 99)	515 (328 613)
IV, DOCA + APP	17	-15	505 (352 608)	64 (38 83)	587 (318 653)

*Growth* As seen from Table I, all animals gained weight except those of Group IV which received combined treatment with DOCA and APP. In this group, weight loss was noticeable from the beginning of the experiment, the rats became shabby and asthenic, lost interest in food, and began to die around the twenty-first day, so that this experiment had to be terminated on the twenty-ninth day. This effect is surprising because DOCA alone produced a slight inhibition and APP a stimulation of growth. Presumably as a result of anti-hormone formation, the growth hormone effect of APP was much more evident around the twenty-fifth day than on the sixty-first day.

*Diuresis* Each point on the curves of Fig. 1 represents an average of collections during a period of five days, so that individual variations are eliminated and the curves accurately portray the trend in each group. The increase in diuresis in Group II (DOCA) appears very early and reaches a maximum around the thirty-fifth day. There is no difference in diuresis between control and APP groups, urine formation in both increases slowly but regularly during thirty-five days and then levels off. It is interesting to note that maximum diuresis is reached at the same time as in the DOCA group. Quantitatively, the curve of Group II contrasts markedly with those of Groups I and III.

*Blood Pressure* Mean blood pressures with individual extremes for Groups I, II, and III are represented graphically in Fig. 2. Blood pressure in the controls was stable during the first six days, after which the trend was variable and slightly upward. The DOCA group showed a definite rise in pressure after the tenth day which reached a maximum at about the twenty-fifth day, at which level it persisted. It is to be noted that *all* the animals in this group became hypertensive. In the APP group, the shape of the curve was more irregular, because of the small proportion of hypertensive animals, it never reached values as high as in the preceding group. Only nine rats out of thirty-two in Group III had pressures higher than 150 mm Hg, and out of these nine, the two most hypertensive showed pressures of 190 and 195 mm Hg respectively. These last two rats died on the fortieth day, this accounts in part for the decrease in pressure mean after this time. In this group, pressures in some animals were always within the normal range. This contrasts with what occurred in the DOCA group.

We have not graphed here the blood pressures of Group IV (DOCA and APP) because this experiment terminated on the twenty-ninth day. Also, the curve did not differ significantly from that of Group II. The mean blood

Fig. —Effect of desoxycorticosterone acetate and anterior pituitary preparations on blood pressure

pressures were day 0, 93 mm Hg, day 6, 115, day 12, 140, day 17, 147, and day 29, 161. Thus the combined treatment had no more effect on blood pressure than DOCA alone.

*Organ Weights* Heart weight was greater in all experimental groups than in the controls, but did not have any consistent relationship to blood pressure levels. Thus mean heart weights in Groups II and III were the same, although the terminal blood pressure averages were, respectively, 190 and 127 mm Hg. Similarly, kidneys were heavier in the experimental than in the control groups, although growth hormone was administered to Group III only. Adrenal weights were increased in Groups III and IV but unchanged in Group II. The absence of atrophy in Group II was probably due to the low dose of DOCA administered. The adrenal stimulation in Group III is consistent with a relationship between adrenocortical activity and high blood pressure; indeed, it was noticed that the animals presenting the most hypertension were those with the heaviest adrenals. However, closer examination of these glands frequently revealed hemorrhages and necrosis.

#### *Summary —*

From these experiments we see (1) with regard to blood pressure, that the effects of DOCA and APP differ significantly in that hypertension is more severe and much more consistent with DOCA than with APP, (2) concerning diuresis, the expected increase is observed with DOCA, administration of APP does not have this effect, (3) that combined treatment with APP and DOCA has no additive or synergistic effect and is in fact rapidly lethal. From this it seems that the mechanisms of the action of DOCA and APP are basically different. However, before concluding, the effects of APP must be examined in more detail.

## II EFFECTS OF PARTIALLY PURIFIED ANTERIOR PITUITARY EXTRACT

With APP, the maximum rise in mean blood pressure was obtained around the twenty-fifth to the fortieth day and was followed by a decline. Also, a certain degree of resistance and adaptation occurred, evidenced by a decrease in body growth and ovarian weight, toward the end of the experiment. Therefore, it seemed possible that the effects of APP might have been altered by the action of antihormones. To evaluate this possibility, the following experiment was devised in which rats were given progressively increasing doses of pituitary hormones.

#### *Experimental —*

Female albino rats weighing between 106 and 138 grams (average, 124 gram) were fed a high protein, high sodium diet and were partially nephrectomized. Thirty-six animals were divided equally into three groups. Group I served as control, Group II received subcutaneously the suspension of anterior pituitary powder (APP), Group III received an alkaline anterior pituitary extract (APE). This last group was added in order to test the hypertensive properties of a partially purified anterior pituitary extract, since it has been claimed (Hay and Segun, 1946) that such preparations cause less kidney damage than crude APP.

This extract was prepared by bringing a water suspension of lyophilized anterior pituitary powder to pH 9 with dilute NaOH. The mixture stood overnight at 10° C, it was

centrifuged the precipitate discarded and the pH of the supernatant adjusted to 7 with dilute acetic acid. The volume of this solution was adjusted so that 1 cc contained the equivalent of 50 mg of the dry powder.

Animals of Groups II and III received during the first thirteen days a daily dose of 40 mg of powder or its equivalent in extract in two injections; the dose was raised to 40 mg or equivalent until the twenty-third day and to 60 mg until the fiftieth day of the experiment at which time the animals were sacrificed and autopsied.

### Results —

Effects on blood pressure are summarized in Fig 3. In the control group again the blood pressure had a tendency to increase slightly during the thirteen days and then to remain relatively stationary. This confirms the observation of Grollman (1946) who noticed a rise in blood pressure following unilateral nephrectomy and administration of NaCl. The blood pressure curves of Groups II and III do not differ significantly as in the former series with APP the pressure rose rapidly during the first fifteen to twenty days then tended to level off. In contrast to our former series with APP, all of the animals showed some increase in pressure although many were no higher than in the control group. There were few animals with pressures higher than 150 mm Hg, of these there were two rats in Group II (154 and 176 mm Hg) and three rats in Group III (150, 185 and 186 mm Hg).

Organ weights are summarized in Table II. In accordance with the hypothesis that antihormone activity might be overcome by increasing doses of hormones, a sustained stimulation of body growth persisted to the end of the experiment with no difference between Groups II and III. Heart weights were not significantly different in the three groups. Kidneys were heaviest in Group II and heavier in Group III than in Group I. Stimulation of adrenal growth occurred only in Group II.

TABLE II COMPARATIVE EFFECTS OF CRUDE (APP) AND PARTIALLY PURIFIED (APE) ANTERIOR PITUITARY PREPARATION

GROUP	BODY WEIGHT		HEART (MG/100 GM BODY WEIGHT)	ADRENALS (MG/100 GM BODY WEIGHT)	KIDNEY (MG/100 GM BODY SURFACE)
	INITIAL	FINAL			
I Control	127 (120-136)	183 (155-225)	320 (284-405)	23 (20-26)	290 (202-358)
II APP	123 (106-138)	237 (228-245)	330 (289-428)	33 (26-46)	456 (393-671)
III APE	124 (118-138)	239 (210-280)	346 (312-428)	25 (18-40)	384 (297-665)

The lack of adrenal stimulation in Group III (APE) can be explained partly by the removal of impurities from the original powder which would act as nonspecific damaging agents in Group II. The difference in the content in impurities between APP and APE was evident at autopsy: abscesses in subcutaneous tissues were present only in APP treated rats. Further, the relatively low content in adrenocorticotrophin of beef pituitary is well known. The comparative adrenal weights and blood pressures in Groups II and III show a clear dissociation of these functions. Furthermore increased adrenal weight does not imply increased function since the adrenals weighing more than 100 mg. were very often hemorrhagic or necrotic.

Fig. 3—Effect of crude and partially purified anterior pituitary preparations on blood pressure

*Summary —*

These facts demonstrate a lack of relationship between adrenal growth and blood pressure level which contrasts with observations in animals given crude APP. It follows that the effects on blood pressure of APP may not be wholly the result of adrenal stimulation. Rather with crude APP the changes in blood pressure and adrenals although concurrent may be unrelated.

## DISCUSSION

Hypertension following DOCA treatment has been observed in rats (Selye, Hall, and Rowley 1943; Green 1948; Friedman, Polley and Friedman, 1948). While Knowlton and co-workers (1946) have reported normal blood pressure in rats treated for ten weeks with 25 mg of DOCA daily and given 0.2 per cent saline solution as drinking water, this apparent inactivity can be attributed to an insufficient supply of sodium. In our experiments the same amount of DOCA plus 1 per cent saline solution uniformly produced severe hypertension within a period of three weeks. Actually, the amount of DOCA utilized was less than 25 mg. For at autopsy small deposits of crystal line material were still visible at the sites of injections. Hypertension can therefore be elicited by DOCA as long as the animals are given a high sodium diet.

Injections of anterior pituitary preparations stimulate physiologic body and organ growth when given in conjunction with a normal diet (Selye and associates 1945), however pathologic changes (hyalinization and enlargement of glomeruli, hyaline casts, arteriolonecrosis) occur if the animals are partially nephrectomized and maintained on a high protein and sodium diet (Selye, 1944). The latter changes are accompanied by a rise in blood pressure which in our experience seldom reaches the levels obtained following DOCA treatment, experimental pyelonephritis (Pige 1939), compression of the renal artery (Wilson and Byrom 1941) or partial renal infarction (Loomis 1946). Severe pathologic changes and hypertension are seen only in some of the experimental animals even though large doses are given to all. This is not in accord with the known dose responses of either steroid or protein hormones. The question arises: Are the pathologic effects of anterior pituitary hormones truly hormonal or do they represent nonspecific effects of foreign proteins or some combination of these actions?

Selye (1944) postulated from observations in rats that anterior pituitary preparations act through the adrenals by releasing DOCA like compounds. However, a variety of observations made in rats tends to negate this view. (1) Recent studies indicate that it is the zona glomerulosa and not the cortex as a whole which supplies the body with DOCA like compounds (Sarrison 1943; Greep and Deane 1947). (2) The zona glomerulosa does not atrophy following hypophysectomy (Smith 1930). (3) The activity of the glomerulosa depends in part at least on the Na/K ratio of the blood (Deane Shaw, and Greep 1948; Nichols 1948). (4) Anterior pituitary preparations and stress stimulate the inner zone of the adrenocortex which is considered

to be the site of production of glucocorticosteroids (Swann, 1940, Nichols, 1948) (5) There is no proof that glucocorticosteroids have blood pressure raising properties in normal animals (6) Adrenocorticotrophin and adrenal extract tend to decrease blood pressure in hypertensive rats (Corcoran, 1948) Finally, (7) our present observations show a lack of similarity between DOCA- and APP-induced hypertension and a dissociation between adrenal weight and blood pressure level in rats given APE

Thus we recognize and confirm but cannot fully explain the hypertension caused by DOCA in rats That this may be a renal hypertension is suggested by its consistent association with renal lesions We also confirm the fact that hypertension can be produced in rats by injections of APP However, the view that this hypertension is caused by excessive secretion of DOCA like compounds from the adrenal is not supported by our data As to its mechanism, we again point to its association with renal lesions

The factors which produce these lesions are probably multiple In the rat, conditions such as high protein diets which greatly increase the renal functional load can result in morphologic lesions (Blatherwick and Medlar, 1937) The renal lesions caused by APP can thus be attributed to the combined effect of a diet rich in protein and sodium, which places a great functional demand on the kidney, and hormonal factors which stimulate renal growth (growth hormone, thyrotrophin, possibly a nephrotrophin\*) (Selye, Stone, Nielsen, and Leblond, 1945, White, Heinbecker, and Rolf, 1949) If it can be accepted that a cell does not function effectively during mitotic fission, it is clear that these superimposed factors will result in a relative renal insufficiency And, under other conditions of renal insufficiency, such as subtotal nephrectomy (Chanutin and Ludwig, 1939, Adair, Barrett, Lew, Poo, and Yuen, 1946) or serum nephritis (Smadel and Fair, 1939), high protein diets are known rapidly to precipitate morphologic regression Another mechanism of renal damage may be the foreign proteins contained in the pituitary preparations, since injections of proteins are known to cause degenerative renal lesions in rodents (Masugi and Sato, 1934, Oberling, 1943)

#### SUMMARY AND CONCLUSIONS

1 Desoxycorticosterone acetate (DOCA) and anterior pituitary preparation (APP) were tested in unilaterally nephrectomized female rats fed a high protein and a high sodium diet

2 DOCA (25 mg a day) elicited hypertension in all animals, APP had this effect in only a relatively small proportion of animals tested Combined treatment with DOCA and APP had no more effect on blood pressure than DOCA alone, rather, the animals rapidly sickened and died

3 DOCA caused severe diuresis, while control and APP treated groups showed only a slight increase in urine formation at the beginning of the experiment

\*We suggest this term as etymologically preferable to the term "renotrophin"

4 In rats treated with crude APP there is an association between hypertension and increased adrenal weights. But these large adrenals are often hemorrhagic or necrotic. The relationship of adrenal weight to blood pressure disappears when animals are treated with a partially purified APP extract.

5 The hypothesis that APP hypertension in rats depends on hypersecretion of DOCA like compounds thus appears unlikely.

The authors are indebted to Dr E Henderson of the Schering Corporation, Bloomfield, N J, for the desoxycorticosterone acetate used in this study.

The lyophilized pituitary powder was obtained from Desbergers Laboratories, Montreal, Canada.

Our thanks also to Miss L Hunter for technical assistance.

## REGRESSION OF ATHEROSCLEROTIC LESIONS ON CESSATION OF CHOLESTEROL FEEDING IN THE CHICK

LOUIS HORLICK M.D. \* AND LOUIS N. KATZ M.D.  
CHICAGO, ILL.

DESPITE the multitude of experiments in which cholesterol has been fed to many species in order to induce atherosclerosis little is actually known concerning the natural history of the lesions so produced. The observations recorded in the literature are few and fragmentary<sup>1,2</sup> based on small groups and in some instances on individual animals. In view of the large volume of work in the field of experimental atherosclerosis the need for a standard base line for comparison is imperative. With this end in view we have already reported on the relationship of atheromatosis to the amount of cholesterol added to the diet in the chicken.<sup>3</sup> We demonstrated a semiquantitative relationship between the per cent of cholesterol in the diet and the duration of feeding on the one hand and the severity of the resultant atheromatosis on the other. It was found that for concentrations of dietary cholesterol above 1/2 per cent there was no increase in the degree of atherosclerosis upon prolonging the feeding period from ten to fifteen weeks. We therefore decided to investigate the effects of cessation of cholesterol feeding on the hypercholesterolemia and atherosclerosis resulting from moderate periods of cholesterol feeding.

### METHODS

One hundred and fifty five 6 to 8 week old white leghorn cockerels were placed on a diet of chick starter mash enriched with 2 per cent cholesterol in 20 per cent cottonseed oil and fed ad libitum. In our experience when given for ten weeks this diet produces atherosclerosis in 100 per cent of chicks.<sup>3</sup>

After ten weeks of feeding the surviving cholesterol fed chicks were subdivided into three groups. Thirty one chicks continued to receive cholesterol for an additional fourteen weeks. Twenty five were placed on a diet of chick starter mash and the third group of twenty five received specially prepared mash† from which the fat and cholesterol had been extracted by a commercial degreasing process. By this means the fat content of the mash was reduced from 4.5 per cent to 0.2 per cent and the cholesterol from approximately 100 mg per cent to 0. Vitamin supplements and sucrose were added to make this diet equivalent in caloric value to normal mash.<sup>7</sup> Twenty five control chicks were maintained on commercial chick starter mash throughout the entire experimental period.

Chicks were sacrificed at the conclusion of the ten week period of cholesterol feeding and at intervals of three to four weeks thereafter. Because of spontaneous deaths among the

flock, it was not possible to adhere to a rigid schedule of sacrificing. However, attempts were made to obtain comparable samples from all the groups. All birds were autopsied, the organs inspected and the hearts and aortas dissected out en bloc, opened, and graded for extent and severity of atherosclerosis. A sketch of the lesions was made on a specially prepared form, and they were graded 0 to 4 on the basis of criteria in use in our laboratory.<sup>6</sup> The thoracic and abdominal portions of the aorta were graded separately but have been combined in our tables for simplicity in presentation. Tissues were preserved in formalin. Sections were taken from the most severely involved areas in the aorta of each bird, and wherever possible specimens were taken from both the thoracic and the abdominal aorta. Hematoxylin and eosin stained specimens and frozen sections stained with sudan IV were prepared and studied.

Blood was drawn from the alar vein for cholesterol determination by the method of Schoenheimer and Sperry.<sup>8</sup> Samples were taken at five and ten weeks after commencement of the experiment, and then at weekly and biweekly intervals until the conclusion of the experiment.

## RESULTS

*A Morphologic Observations in the Various Groups*—It seemed a worthwhile procedure to discuss the morphology in some detail because (a) this is the longest period of cholesterol feeding undertaken in the chick, along with an equally adequate group of controls for comparison, and (b) this is the first time, in a species other than the rabbit, that the opportunity has been afforded for observations over an extended period on the effects of cessation of cholesterol feeding on the arterial intima of the chick.

*Controls Receiving No Cholesterol Throughout Study* Of the four control chicks which showed gross lesions, one had a lesion of the thoracic aorta alone, two had lesions of the abdominal aorta, and one had lesions in both portions of the aorta. Of the gross lesions, those in the thoracic aorta were flat, nonraised, whitish or light yellow areas, varying in size from a few millimeters to 1 cm. in their greatest dimension. In the abdominal aorta the lesions appeared as a prominent ridge like area lying between the renal arteries on the posterior wall of the aorta. They are characterized by a light yellow staining of this area. Microscopic lesions were far more common. Nine out of twelve aortas from which frozen sections were made showed evidences of spontaneous atherosclerosis. The lesions have already been described fully by Dauber<sup>9</sup> and Charkoff and associates,<sup>10</sup> and we are in full accord with their findings.<sup>11</sup> Typical lipid deposits were found in the thoracic aorta in our cockerels. Microscopically the hematoxylin and eosin sections of thoracic aorta showed only scattered focal areas of loosely arranged ground substance which had almost the appearance of mucoid degeneration. These foci lay between the elastic and collagenous fibers of the intima and between the elastic laminae of the media. On frozen section, these areas were strongly sudanophile, and the stained material lay free in the ground substance (Fig 1, A). Charkoff and co-workers<sup>10</sup> have examined these deposits under polarized light and believe them to be free of cholesterol, containing only fat. Fatty material was most commonly found in the inner third of the media. The myocardium and coronary arteries were not involved in any way. The most striking changes were seen in the abdominal or muscular section of the aorta. As described by Dauber,<sup>9</sup> the primary lesions were to be found in the ridge like prominence in the intrarenal region. The lesions are characteristically fibrotic, being made up of collections of collagenous bundles and fibroblasts, with small to moderate amounts of sudanophile material in the depths of the plaques, usually next to the intimal medial boundary. An excellent illustration of such a lesion is Fig 1, B.

*Birds Maintained on 2 Per Cent Cholesterol Diet Throughout* The earliest gross lesions were observed in the brachiocephalic vessels and the elastic aorta (referred to as the thoracic aorta). They appeared in the form of flat, nonraised, white or whitish yellow areas next to

Fig 1—A Bird 9 control on normal mash diet twenty four weeks. Spontaneous lesion of the thoracic aorta. There is focal accumulation of sudanophilic material in the intima and media (note dark staining areas). (Frozen section  $\times 10$  sudan IV.) B Bird 37 control on normal mash diet fourteen weeks. Spontaneous lesion of the abdominal aorta. There is marked fibrous and fibroblastic thickening of the intima. Region near intimal medial boundary contains small amount of sudanophilic material. (Frozen section  $\times 10$  sudan IV.) C Bird 167 on cholesterol fourteen weeks. Early cholesterol induced lesion of the thoracic aorta. Note deposition of sudanophilic material in intima and inner portion of media. (Frozen section  $\times 10$  sudan IV.) D Bird 131 on cholesterol twenty four weeks. Very heavy deposit of sudanophilic material in the intima and inner one-third media. (Frozen section  $\times 10$  sudan IV.)

more than a few millimeters in diameter. This progressed to increasing thickening of the intima in these regions and the appearance of more extensive, more deeply pigmented patches, which were striated or nodular in gross appearance. Progression led to severe involvement of almost the entire elastic aorta by either a confluent plaque or separate and extensive nodular or granular plaques. There was a clear line of demarcation at the junction of the elastic and muscular aorta. The aortic valves were frequently involved with heavy plaques of yellow material in the sinuses of Valsalva. The mitral valves showed pinpoint lipid deposits in their substance. We again noted<sup>6</sup> that there is a definite time lag in the involvement of the abdominal portion of the aorta. The interrenal area is preferentially involved. Involvement ranged from slight yellow streaking to almost complete occlusion of the lumen of the aorta by massive deep yellow plugs. Isolated nodular involvement of the proximal portion of the iliac vessels was a common phenomenon.

Microscopically, the least severe lesions consisted merely of some increased deposition of gray blue ground substance between the collagenous and reticular fibers of the intima. On frozen section and sudan staining these areas contained moderate amounts of sudanophile material and an increased number of fibroblasts (Fig 1, C). Sudanophile material could also be seen scattered lightly through the inner half of the media. Most of the early lesions however consisted of foam cell plaques of varying degrees of severity—from a single layer of cells to veritable foam cell cushions, several layers deep. The fat filled fibroblastic cells were arrayed along vertically disposed reticular fibers and their nuclei also were perpendicular to the intimal coat. Usually foam cells and an increased amount of intercellular ground substance could be seen infiltrating the inner half to one third of the medial coat (Fig 1, D). The coronary arteries were relatively uninvolved in these early lesions. As the period of cholesterol feeding was prolonged, more severe changes were seen in the thoracic aorta. The progression is not clear in all instances, i.e., some lesions were seen at 140 days which, comparatively speaking, were no more severe than those seen at 70 days. However, a number of very severe lesions were seen late in the feeding period. Hyaline and cartilaginous metaplasia associated with breakdown of the foam cell plaques, appears to be the first step. With time there is a disappearance of the well formed foam cells, although ghost cells can be seen in the areas undergoing hyaline metaplasia. Typical cartilage does appear in the mid depth of the plaque, which eventually becomes heavily basophilic and in some instances undergoes extensive calcification. In some sections there is actual breakdown of the centers of the foam cell plaques with the formation of "abscesses" containing necrotic debris, fragments of nuclei, free fat, cholesterol crystal clefts, and heavy deposits of calcium in granules or platelets. In the heavier foam cell plaques which remain intact, numerous fine vacuoles may be seen communicating with the lumen, and endothelialized spaces were found resembling vasa which are filled with foam cells, loose and in clumps (Fig 2, A).

The media is involved in all instances, particularly in its inner half, by infiltration of foam cells and free fat. Where the intimal lesions are very severe, there may be severe attenuation of the underlying media. Involvement of the coronary arteries is common in association with severe aortic atheromatosis. Foam cell plaques may be seen partially or completely occluding the lumina of small arterioles. Some of the lesions also show a scattered calcium granule deposition. Fig 2, C shows a coronary arteriole severely narrowed by foam cells with a heavy plaque of calcium almost completely replacing the underlying media.

The thoracic aorta therefore shows a spectrum of changes extending from minimal deposits of fat and cholesterol in the ground substance to extensive foam cell plaques, atheromatous abscesses, hyalinization, cartilaginous metaplasia, and calcification.

There appeared to be little or no correlation between the severity of the lesions in the thoracic aorta and those in the abdominal aorta. Early lesions in the abdominal aorta were of two types. One group was indistinguishable from those of the "spontaneous" type which

more than a few millimeters in diameter. This progressed to increasing thickening of the intima in these regions and the appearance of more extensive, more deeply pigmented patches, which were striated or nodular in gross appearance. Progression led to severe involvement of almost the entire elastic wall by either a confluent plaque or separate and extensive nodular or granular plaques. There was a clear line of demarcation at the junction of the elastic and muscular wall. The aortic valves were frequently involved with heavy plaques of yellow material in the sinuses of Valsalva. The mitral valves showed pin point lipid deposits in their subvalvular portion of the aorta. The interrenal area is preferentially involved. Involvement ranged from slight yellow streaking to almost complete occlusion of the lumen of the aorta by massive deep yellow plugs. Isolated nodular involvement of the proximal portion of the iliac vessels was a common phenomenon.

Microscopically, the least severe lesions consisted merely of some increased deposition of gray blue ground substance between the collagenous and reticular fibers of the intima. On frozen section and sudan staining these areas contained moderate amounts of sudanophile material and an increased number of fibroblasts (Fig 1, C). Sudanophile material could also be seen scattered lightly through the inner half of the media. Most of the early lesions, however, consisted of foam cell plaques of varying degrees of severity—from a single layer of cells to veritable foam cell cushions, several layers deep. The fat filled fibroblastic cells were arrayed along vertically disposed reticular fibers and their nuclei also were perpendicular to the intimal coat. Usually foam cells and an increased amount of intercellular ground substance could be seen infiltrating the inner half to one third of the medial coat (Fig 1, D). The coronary arteries were relatively uninvolved in these early lesions. As the period of cholesterol feeding was prolonged, more severe changes were seen in the thoracic aorta. The progression is not clear in all instances, i.e., some lesions were seen at 140 days which, comparatively speaking, were no more severe than those seen at 70 days. However, a number of very severe lesions were seen late in the feeding period. Hyaline and cartilaginous metaplasia associated with breakdown of the foam cell plaques, appears to be the first step. With time there is a disappearance of the well formed foam cells, although ghost cells can be seen in the areas undergoing hyaline metaplasia. Typical cartilage does appear in the mid part of the plaque, which eventually becomes heavily basophilic and in some instances undergoes extensive calcification. In some sections there is actual breakdown of the centers of the foam cell plaques with the formation of "abscesses" containing necrotic debris, fragments of nuclei, free fat, cholesterol crystal clefts, and heavy deposits of calcium in granules or platelets. In the heavier foam cell plaques which remain intact, numerous fine vessels may be seen communicating with the lumen, and endothelialized spaces were found resembling vasa which are filled with foam cells, loose and in clumps (Fig 2, A).

The media is involved in all instances, particularly in its inner half, by infiltration of foam cells and free fat. Where the intimal lesions are very severe, there may be severe attenuation of the underlying media. Involvement of the coronary arteries is common in association with severe aortic atheromatosis. Foam cell plaques may be seen partially or completely occluding the lumina of small arterioles. Some of the lesions also show associated calcium granule deposition. Fig 2, C shows a coronary arteriole severely narrowed by foam cells with a heavy plaque of calcium almost completely replacing the underlying media.

The thoracic aorta therefore shows a spectrum of changes extending from minimal deposits of fat and cholesterol in the ground substance to extensive foam cell plaques, atheromatous abscesses, hyalinization cartilaginous metaplasia, and calcification.

There appeared to be little or no correlation between the severity of the lesions in the thoracic aorta and those in the abdominal aorta. Early lesions in the abdominal aorta were of two types. One group was indistinguishable from those of the "spontaneous" type and

Fig 3—A Bird 488 on cholesterol for fifteen weeks. Very severe lesion of abdominal aorta. Surface of lesion is coated by a thin layer of connective tissue beneath which lies a deep layer of ground substance intersected by fine collagenous strands and containing cholesterol crystals, calcium granules and foam cell ghosts. (X10 hematoxylin and eosin.) B Bird 63 on cholesterol for ten weeks and then on ordinary mash for fourteen weeks. There is very minimal thickening of the intima of the thoracic aorta which is fibrocellular in character. (X10 hematoxylin and eosin.) C Bird 97, on cholesterol for ten weeks, then on ordinary mash for fourteen weeks. Note globular sudanophile masses immediately beneath endothelial lining of vessel. Also scattered sudanophile granules in the remainder of the intima. (Frozen section X480 sudan IV.) D, Bird 147 on cholesterol for ten weeks then on special low fat diet for five weeks. Note atheromatous abscess cavity surrounded by fibrocellular connective tissue. (Frozen section X120 sudan IV.)

and (2) more severe lesions showing heavy fibrosis but also severe residual deposits of sudanophile material and calcium. The latter probably represent the evolution of the second type of early abdominal lesion seen in the continuing cholesterol feeding. Fig 3, D is an illustration of one of these. It shows marked thickening of the intimal surface with fibrocellular connective tissue and partial obliteration by fibrous tissue of an atheromatous abscess. The cavities contain sudanophile material and heavy deposits of calcium. The underlying media shows some fibrosis.

In summary, cessation of cholesterol feeding and the institution of a low fat or normal mash diet were followed by fibrotic changes in lesions of both the thoracic and abdominal portions of the aorta, by the disappearance of foam cells, and by calcification of atheromatous abscesses. We also have noted the presence of scavenger-like cells in the intima.

*B Summary of Data on Degree of Atherosclerotic Lesions in Various Groups*—Table I summarizes the average gross gradings in the various groups for the entire duration of the experiment. The base line value of the severity of lesions at the end of ten weeks of feeding with cholesterol is based upon all chicks, both experimental and control, which either died or were sacrificed. Also included in this base line group are three birds from the low fat mash group and two from the plain mash group which died during the first week following division of the groups. The average gross grading for the eighteen chickens in this group was 2.5, which compares favorably with values reported by us in a previous experiment.<sup>6</sup>

TABLE I AVERAGE GROSS GRADING OF AORTIC ATHEROSCLEROSIS IN ALL GROUPS FOR ENTIRE DURATION OF EXPERIMENT

TIME FROM BEGINNING OF EXPERIMENT (WK)	ON 2% CHOLESTEROL DIET FOR 10 WEEKS AND THEN CONTINUED ON						CONTROLS ON PLAIN MASH	
	2% CHOLESTEROL		LOW FAT DIET		PLAIN MASH		NUMBER OF BIRDS	AVERAGE GRADE
	NUMBER OF BIRDS	AVERAGE GRADE	NUMBER OF BIRDS	AVERAGE GRADE	NUMBER OF BIRDS	AVERAGE GRADE		
9 to 11	18*	2.5					2	0
12 to 14	6	4.1	6	2.7	12	2.4	5	0.05
15 to 18	11	4.3	4	2.1	4	1.8	5	0.05
19 to 22	4	4.3	7	1.1	3	3.5	2	0
22 to 24	4	5.9	5	0.5	4	1.0	12	0.1
Total	43		22		23		28	

\*Includes seven chicks which died in the week prior to separation of the groups and three from the low fat and two from the plain mash groups which died during the first week after separation of the groups.

*Continued Cholesterol Feeding* This is best visualized in Fig 4. The average gross grade rose from 2.5 at the time of division (ten weeks) to 4.1 for the periods fifteen to twenty-two weeks, and then rose to 5.9 for the period twenty-three to twenty-four weeks. There was, therefore, an early rapid rise in severity of lesions, then a tendency to level off after fifteen weeks of cholesterol feeding, and finally a further rise after twenty-two weeks of cholesterol feeding.

*Normal Mash* Placing cholesterol-fed birds on a diet of normal mash resulted in a gradual decline in the extent and severity of the atherosclerosis.

This is best seen for the periods fifteen to eighteen weeks and twenty three to twenty four weeks where the average values obtained were 1.8 and 1 respectively. For the period eighteen to twenty two weeks a value of 3.5 was obtained. This average was constructed from data from three chicks one of which had very severe lesions. On the whole however the trend toward decreasing severity of the lesions was unmistakable.

Fig 4—Average gross grading of all groups from the time of division into groups to the conclusion of the experiment

*Low Fat* The group of cholesterol fed birds placed on a low fat cholesterol free diet gave values which closely resembled those obtained in the group of cholesterol fed birds placed on ordinary mash but the decline in the severity of the lesions was somewhat more marked and was consistent for all time periods. The decline first became evident at the fifteen to eighteen weeks period and was most noticeable during the eighteen to twenty two and twenty three to twenty four week periods where average gross values of 1.1 and 0.5 were recorded.

Combining the low fat and normal mash groups gave us a more adequate set of averages. Again a progressive decline in the severity of the lesions was apparent.

*Controls* The control group which received normal mash with no added cholesterol over the entire period was remarkable for the paucity of grossly

discernible atheromatous lesions of the so-called "spontaneous" variety. Only four of the twenty-six controls showed grossly visible atherosclerosis. Two were graded at  $\frac{1}{4}$ , one at  $\frac{1}{2}$ , and one at 1.

*C Blood Cholesterol Levels*—Fig 5 illustrates the blood cholesterol levels for the various groups throughout the course of the experiment. The first and second determinations were made at five and ten weeks after commencement of the experiment. Thereafter blood cholesterol determinations were

Fig 5—Average blood cholesterol levels before and after division of birds into the several groups

made at weekly or biweekly periods. The values for the 2 per cent cholesterol fed birds showed a good deal of variation from week to week, but the trend on the whole was toward increasing levels. The last three determinations were 2,629, 2,479, and 1,839 mg per cent respectively. During the same period the blood cholesterol level fell in the groups taken off the cholesterol diet. Within two weeks of cessation of cholesterol feeding, the blood cholesterol levels of the plain mash and low fat groups fell to 268 and 175 mg per cent respectively (control, 100 mg per cent). Within one more week the values for both groups were back in the normal range. The blood cholesterol levels of the controls showed no significant variation during this period.

In summary, continued cholesterol feeding after ten weeks results in the maintenance and further elevation of the blood cholesterol levels, while cess-

tion of cholesterol feeding leads to a very rapid fall of the blood cholesterol back to normal levels

#### DISCUSSION

The results obtained in the present study complement and extend our previous studies on cholesterol induced atherosclerosis in the chicken. It is now clear that continuing cholesterol feeding in the chick for periods up to six months results in progressive aggravation of the atherosclerosis. This is not in accord with previous data reported by us for a much shorter experimental period.<sup>6</sup> The progression is associated with a continued rise in the blood cholesterol levels. The spectrum of microscopic findings resulting from continued cholesterol feeding is wide indeed ranging from mere increases in amorphous ground substance to massive foam cell plaques, hyaline and cartilaginous metaplasia and heavy calcium deposits. We noted also the tendency for cholesterol induced lesions of the abdominal aorta to appear in an area usually involved in the 'spontaneous' variety of the disease and apparently to accelerate and/or aggravate the normally occurring lesion.

Cessation of cholesterol feeding after ten weeks resulted in a gradual decline in the severity of the lesions as judged by gross grading in both the plain mash and low fat groups. There was no essential difference between the two groups either from a gross or microscopic standpoint, and they have been combined for purposes of discussion (and in Table I). Blood cholesterol levels fell to normal within three weeks of cessation of cholesterol feeding. Microscopically the lesions were characterized by diminution and disappearance of foam cell deposits, increasing fibrotic changes in both the abdominal and thoracic portions of the aorta, diminution of grossly stainable lipid, and heavier calcification. Some of the chickens sacrificed at the very end of the experiment showed so little gross or microscopic evidence of atherosclerosis that it may be assumed that the lesions in these birds had undergone complete remission. In other birds severe fibrosis, remains of atheromatous abscesses, and heavy calcification tended to suggest that there is a limit to the degree of atherosclerotic damage which can be repaired.

Controls kept on ordinary mash showed only few gross lesions, but the incidence of microscopic lesions was much higher. This is in accord with previous experience in this laboratory.<sup>9</sup> In corroboration of Chaikoff and co workers,<sup>10</sup> we found lipid deposits in the thoracic aortas of cockerels, a phenomenon reported by Dauber<sup>9</sup> only in hens. These lesions of the thoracic aorta are never characterized by thickening of the intima or by foam cell deposits but consist of small focal deposits of lipid material in the ground substance of the intima and inner portion of the media. In the abdominal aorta, the spontaneous lesions are characteristically fibrotic with far less stainable lipid than in the cholesterol induced lesions. They are, however, very similar to some of the less severe lesions induced by cholesterol feeding particularly when the latter has been suspended for some time and the chicks have been returned to a normal diet.

Other investigators have made observations on the effect of suspending cholesterol feeding on the arterial lesions of the rabbit. Stuckey,<sup>1</sup> Kizlow, Wada,<sup>3</sup> and Scarff<sup>4</sup> were the first to report such observations, but then data is not very extensive. Anitschkow<sup>5</sup> was the first to study the problem extensively in the rabbit. He found that following three to four months of cholesterol feeding, and the resumption of a normal diet, there resulted a gradual loss of lipids from the plaques. The latter lost their yellowish color and no longer stained with sudan. They presented a whitish and fibrous appearance. He stressed, however, that this process was a slow one. The transformation of a large plaque rich in lipids into a plaque composed of fibrous tissue took two to three years, and even then small quantities of lipid could be discovered microscopically after sudan staining. Microscopically, Anitschkow noted the gradual disintegration and disappearance of the foam cell masses and their replacement by newly developing collagenous and elastic fibers and fibroblasts. He noted also the tendency for cholesterol crystals to persist long after the other lipids have been removed, and also the large quantities of calcium which were laid down in areas formerly occupied by atheromatous abscesses. He stated that if the development of the lipid deposits and the thickening of the intima had not reached a very considerable degree during the progressive period, all that was to be seen after resorption of the lipids had taken place was a slight fibrous thickening of the intima, sometimes containing a few cholesterol crystals, together with scattered lipid cells and globules of neutral fat. Anitschkow gave no data on the effect of cessation of cholesterol feeding on the blood cholesterol levels in the rabbit. Stemer,<sup>17</sup> among others, has observed that following the cessation of cholesterol feeding in rabbits the blood cholesterol levels fall very slowly over a period of months. It is of interest that the resorptive changes seen in the rabbit, and described by Anitschkow and others, so closely resemble the changes seen by us in the chicken. It is also of interest that the rate of regression of lesions in the chicken is much greater than in the rabbit. These two features may well be related in an etiologic and pathogenetic sense, as will be discussed.

The ability of the physiologic mechanisms to remove lipids from the arterial wall is not a feature common to the experimental animal alone. In man, Leary's<sup>13</sup> excellent studies have thrown considerable light on the problem of the bodily defenses against the development of atheromatous lesions. Leary believes that a defense mechanism exists which removes excess fat and cholesterol from the arteries of youth and from the ascending aorta even in old age. The cholesterol is transferred from wandering lipid cells (foam cells) to fixed fibroblasts in which the cholesterol esters are split, anisotropism is lost, and the cholesterol is brought into solution in an excess of fatty acids. Solution is followed by its disappearance from the lesions. With the removal of the excess cholesterol, the lesions stop progressing toward atherosclerosis and subside. In youth this mechanism is adequate to cope with lipid deposits in the intima. As man ages his ability to remove cholesterol appears to diminish, and atherosclerosis becomes severe. Increased deposition of collagen

and dense scar tissue with subjacent collection of fat is more common. In old age, cholesterol removal mechanisms appear to cease and foam cells accumulate in masses with inadequate nutrition and support and primary atheromatous abscess is the typical lesion. Further corroborative evidence on the resorbability of human lesions comes from two sources. Aschoff<sup>14</sup> observed that atherosclerotic lesions were rare in autopsy material during and after World War I in Germany—a period of severe famine and malnutrition, especially with respect to fats, cholesterol and proteins. More recently Wilens<sup>15</sup> has noted that at necropsy severe atherosclerosis is at least twice as common in obese as in undernourished persons 35 years of age or over. He found this relationship to be independent of sex or the presence or absence of diabetes or hypertension. Severe or even moderate atherosclerosis was seldom found in those with protracted undernutrition. Less severe atherosclerosis was observed in those with wasting disease than in those with terminal weight loss. He inferred from this data that resorption of atheromatous lesions may occur during periods of marked weight loss. Histologically the most conspicuous difference between the two groups lay in the amount of lipid in the intimal lesions—there were less lipids and fewer phagocytes in the intimal lesions of those with weight loss.

Thus far we have discussed only the spontaneous regression of lesions which takes place in the experimental animal on the cessation of cholesterol feeding, and in man following prolonged undernutrition. We have already noted that the provision of a low fat cholesterol free diet did not appreciably affect the rate of regression of lesions in the chick. Attempts have been made to influence the rate of regression of lesions in the rabbit through the use of various substances known to influence fat metabolism. Steiner<sup>12</sup> noted that the administration of choline to rabbits which had received cholesterol for 110 days resulted in a marked regression of the lesions. Examination of his data reveals that in the six rabbits in which choline appeared to have a positive effect, the blood cholesterol levels were never very high and rapidly fell to the normal range e.g.

DAYS	0	20	60
	476 mg %	149 mg %	96 mg %
	512	357	125

Where choline failed to influence the lesions the blood cholesterol was high at the start and tended to stay high e.g.

DAYS	0	60
	1265 mg %	1250 mg %
	900	544

In the group taken off cholesterol and maintained on a regular diet without choline the cholesterol values with one exception were over 300 mg per cent at the end of sixty days and the rate of fall was very slow. It would seem therefore that there is a strong correlation between the rate of fall of

the blood cholesterol levels and the efficacy of choline in affecting the regression of lesions. The failure of choline to act in four out of ten rabbits might well be accounted for on the basis of individual differences among rabbits, which are known to respond in varying fashion to cholesterol feeding. Steiner's results have been amply confirmed by Morrison and Rossi.<sup>16</sup>

By means of cholesterol tolerance tests<sup>17, 18</sup> we have been able to show that there is a marked difference in the response of different species to a standard load of their homologous cholesterol administered intravenously. We have found that in comparison with the chicken and the rat, the rabbit is much less capable of dealing with intravenously injected cholesterol and requires three to four times longer to dispose of an equivalent load of cholesterol. Kendall<sup>19</sup> and associates have published similar data using an artificially prepared emulsion of cholesterol. It appears therefore that the ability of any species to remove cholesterol from the arterial intima is related to its ability to metabolize cholesterol. Thus the chicken, which removes injected cholesterol from its blood stream about three times as fast as the rabbit, also shows a very rapid fall of blood cholesterol to normal after cessation of cholesterol feeding and a more rapid regression of lesions than does the rabbit. That this process may be accelerated by exogenous factors is well demonstrated by the effect of choline in the rabbit, and by undernutrition in man. The existence of a physiologic mechanism for the removal of fat and cholesterol from the vascular wall is well supported by the evidence cited and is clearly suggested by the results of the present investigation. We are therefore compelled to abandon our "static" concepts concerning the nature of atherosclerosis and to apply instead the dynamic principles of modern metabolic theory concerning the behavior of the lipids in other parts of the body. Body fat is now known to be in a constant state of flux, it is laid down in depots and is constantly moved and replaced, converted or destroyed as required.<sup>20</sup> It would appear from the present study that under certain circumstances the lipid content of atheromatous plaques is subject to similar metabolic forces. Further studies on this aspect of the problem with more refined metabolic tools are the *sine qua non* of therapeutic researches in this field.

#### SUMMARY

1 Prolonged feeding of a diet containing 2 per cent cholesterol in cotton seed oil for a period of twenty-four weeks resulted in progressive elevation of the blood cholesterol levels. There was increasing severity of the atherosclerosis for a period of fifteen weeks and then a levelling off, with a further increase in severity during the last two weeks of the experiment.

2 Cessation of cholesterol feeding after ten weeks is followed by a very rapid decline in the blood cholesterol levels to normal within three weeks. There was also a gradual regression in the severity of the lesions over a fourteen-week period. It appears that early lesions may be completely resorbed upon cessation of cholesterol feeding, while more severe lesions undergo regressive and reparative changes.

3 There appeared to be little difference in the rate of regression or disappearance of the aortic lesions in birds placed on a normal mash diet and those placed on a low fat, cholesterol free diet following cessation of cholesterol feeding

4 There is a wide spectrum of histologic changes resulting from prolonged cholesterol feeding, ranging from increase in the ground substance of the intima, with infiltration of sudanophile material, to very extensive foam cell plaques hyaline and cartilaginous metaplasia and heavy deposits of calcium in granules and plates

5 Cessation of cholesterol feeding is followed by fibrotic changes in lesions of both the thoracic and abdominal portions of the aorta by the disappearance and diminution of foam cells and fat, and by the calcification of atheromatous abscesses. We also noted the presence of scavenger like, fat filled cells in the intima

6 The controls showed few gross lesions but numerous microscopic ones. Scattered focal deposits of sudanophile material were seen in the intima and inner portions of the media of the thoracic aorta. In the abdominal aorta the spontaneous lesions were characterized by fibrosis of the intima, with sudanophile deposits and calcium granules at the intimal medial junction

7 The presence of a physiologic mechanism concerned with the regression of atheroma in animals and man is discussed and the application of modern dynamic principles of lipid metabolism to this mechanism is considered

We are indebted to Miss C Bolene (D V Dauber Memorial Research Assistant) Miss Lorraine Adams, Miss Eileen Arnold, Miss Marilyn Dudley and Mr William Foote for technical assistance in this study

## THE LACK OF EFFECT OF TWEEN 80 ON THE ABSORPTION OF ALUMINUM AND SODIUM PENICILLINS

LEON SCHWARTZ, M.D. AND WILLIAM P. BOGER, M.D.  
PHILADELPHIA, PA.

THE widespread use of oral penicillin despite the fact that only a fraction of an administered dose is absorbed from the gastrointestinal tract makes desirable the investigation of factors that may favor the absorption of penicillin from the gut. The present study reports the comparative plasma concentrations of penicillin that resulted from the oral administration of aluminum\* and sodium penicillins with and without orally administered Tween 80 (polyoxyethylene sorbitan monooleate).

The Tweens are a series of polyoxyethylene derivatives of the hexitols mannitol and sorbitol, and their anhydrides partially esterified that are classified as dispersing agents.<sup>1</sup> Such compounds might theoretically increase the absorption of substances from the gastrointestinal tract by lowering surface tension and increasing dispersion. It has been reported that one of these compounds, Tween 20, given by mouth and parenterally prolonged the penicillin plasma concentrations following oral and parenterally administered penicillin.<sup>2</sup> Tween 80 differing only in the fact that oleic acid is esterified with the hexitan in place of lauric acid, has been fed to human patients in amounts as large as 15 Gm per day without evidence of toxicity and furthermore has proved to be effective in increasing the absorption of fats and fat soluble substances in certain pathologic conditions marked by impaired gastrointestinal absorption.<sup>3</sup> Because of its nontoxicity and its proved efficacy in human beings Tween 80 was chosen for this study to determine whether it had any influence on the absorption of orally administered penicillin.

### MATERIALS AND METHODS

Twelve male subjects varying in age from 33 to 48 years afebrile and free of obvious renal, hepatic or gastrointestinal dysfunction were elected from the medical wards and divided into two groups of six each. One group was given aluminum penicillin with and without Tween 80 and the other was given sodium penicillin with and without Tween 80 each patient serving as his own control in determining the effect of the dispersing agent on penicillin plasma concentrations.

Penicillin was administered orally in a dose of 200,000 units every three hours for nine doses and blood samples were drawn into heparin wetted syringes at one-half, one, two, and three hours after the ninth dose. No medication was given for twenty-four hours and then 200,000 units of penicillin and 2 Gm of Tween 80 were given together every three hours for nine doses. After the ninth dose of the combination of drug, blood samples again were

From the Philadelphia General Hospital.

This study was made possible through grant in aid from the Research Fund for Infectious Disease of the University of Pennsylvania and from Sharp & Dohme, Inc.

Received for publication July 23, 1949.

Tween 80 was supplied through the courtesy of Atlas Powder Co., Wilmington, Del.; aluminum penicillin through the courtesy of Hynson, Westcott & Dunning, Inc., Baltimore, Md.; and sodium penicillin through the courtesy of Sharp & Dohme, Inc., Kenilworth, Pa.

drawn at one half, one, two, and three hours. The ninth dose of medication in each phase of the study was given at the same time of day and in the same relationship to the ingestion of food, so that the penicillin time dose response curves in the two phases of the study can be compared to determine the effect of Tween 80. The same lots of aluminum and sodium penicillins were employed throughout the study. Penicillin assays were done by the Kirby Rantz modification of the Rammelkamp serial dilution method,<sup>4</sup> employing as the test organism *Streptococcus* 98.

## RESULTS

In Table I are presented the data obtained following the use of sodium penicillin. It is apparent that in three patients (E U, B L, and P L) the penicillin plasma concentrations were actually lower when Tween 80 was administered, in two patients (G J and J M) the concentrations were higher, and in one patient (J M) the concentrations were equal to those obtained when penicillin was given alone. The average values from the six patients show the concentrations after penicillin alone to be slightly higher than those after penicillin and Tween 80.

\*Two 100,000 unit tablets each buffered with 0.35 Gm. calcium carbonate.

†10 Gm. per day administered as four 0.5 Gm. gelatin capsules every three hours.

Table II shows similar data after the use of aluminum penicillin. In two patients (H M and C B) the plasma concentrations of penicillin are lower after the use of Tween 80, in two patients (J W and R M), slightly higher, and in two patients (S B and E H), approximately equal to those observed after the use of aluminum penicillin alone. The average values from the six patients are practically identical.

## DISCUSSION

The Tweens are painful and irritating when injected intramuscularly, so even if effective in elevating penicillin plasma concentrations as claimed for Tween 20,<sup>2</sup> this route of administration would be impractical. Furthermore the amount of Tween 80 absorbed from the gut and excreted by the kidneys is

116 Gm per day administered as four 0.5 Gm gelatin capsules every three hours

so small<sup>5</sup> that a causamide like effect ascribed to Tween 20<sup>2</sup> seems unlikely. The sole anticipation of an effect of Tween 80 on the absorption of penicillin was predicated on its activity as a dispersing agent within the gut. The observations made in twelve patients under the conditions outlined indicate that Tween 80 exerted no effect on the absorption of penicillin from the gastrointestinal tract.

Aluminum and sodium penicillin were not compared in the same patients, but it is apparent that the penicillin plasma concentrations observed in similar groups of patients were approximately equal during the three hour period studied. A subsequent investigation will be directed toward comparing the maintenance of penicillin plasma concentrations for periods longer than three hours. It should be noted that the penicillin plasma concentrations were unexpectedly high, except initially, they exceeded those resulting from the intramuscular injection of 50,000 units of penicillin (crystalline penicillin in aqueous solution)<sup>6</sup>. The concentrations observed may be explained in part by the ages of the patients studied or by the possibility of penicillin accumulation in the circulation during the twenty four hours of medication prior to the time dose response values here recorded. Unfortunately there is no body of data in the literature with which to compare the results of this study but it would be unwarranted to assume that penicillin plasma concentrations of the magnitude herein reported obtain in all patients to whom 200,000 units of penicillin are orally administered every three hours.

#### CONCLUSIONS

Tween 80 (polyoxyethylene sorbitan monooleate) in oral doses of 16 Gm per day did not enhance the gastrointestinal absorption of penicillin as determined by the penicillin plasma concentrations resulting from the oral administration of the antibiotic with and without Tween 80.

The authors wish to acknowledge their indebtedness to the Chiefs of Medical Services at the Philadelphia General Hospital, Dr Russell Boles, Dr Harrison F Flippin, and Dr David N Kremer, for permission to study patients on their Services, and to Miss Mary Louise Cordes and Miss Elizabeth Fitz Gerald for technical assistance

## LABORATORY METHODS

### EVALUATION OF A MODIFIED SUMNER'S METHOD (DINITROSALICYLIC ACID) FOR DETERMINATION OF GLUCOSE IN URINE

ROLF BRODERSEN PH.D. AND HENRY T. RICKETTS M.D.  
CHICAGO, ILL.

SUMNER<sup>1, 2, 3</sup> has described methods for the determination of glucose in urine and blood, using dinitrosalicylic acid as an oxidizing agent. The reduced dinitrosalicylic acid is determined colorimetrically. This method has been employed extensively by Exton<sup>4</sup> for the determination of both urinary glucose and by modification, other sugars found in urine. Recently Leech and Woodford<sup>5</sup> have utilized this principle in a simple and rapid method for the approximate estimation of blood glucose.

The present paper deals with the employment and detailed evaluation of this method slightly modified for the determination of glucose in urines that do not contain other reducing sugars.

#### PROCEDURE

The following procedure was found to be satisfactory.

*Preparation of the Reagent*—Solution 1. 120 Gm. of sodium potassium tartrate and 6 Gm. of phenol (crystalline) are dissolved in 300 c.c. of water. A solution of 6 Gm. of sodium bisulfite in 60 c.c. of water is added.

Suspension 2. 20 Gm. of 3.5 dinitrosalicylic acid monosodium salt are suspended in 800 c.c. of water care being taken to avoid large lumps.

Solution 3. 40 Gm. of sodium hydroxide are dissolved in 400 c.c. of water and cooled.

Forty cubic centimeters of Solution 3 are added to Suspension 2 and the mixture is shaken until the salt has dissolved. This is completed in a very short time if there are no large lumps in the suspension. Now Solution 1 is added and mixed well with the solution of dinitrosalicylate. Finally 320 c.c. of Solution 3 are added in three or four portions. The mixture is shaken after the addition of each of these portions. If all of the sodium hydroxide is added at once, a precipitate may be formed which is very difficult to redissolve. The volume is made up to 2,000 c.c. with water.

This reagent is kept for two weeks at 25 to 30° C. before use.

*The Reduction and the Colorimetric Determination*—Ten cubic centimeters of reagent are pipetted into a 19 mm. test tube and 0.1 c.c. of urine is added from a blood capillary pipette. The pipette is rinsed in the reagent and the mixture is stirred with the pipette or a glass rod. To another 10 c.c. of reagent in a similar test tube is added 0.1 c.c. of water. The tubes are heated in boiling water for three minutes and cooled to room temperature.

The optical density is determined by spectrophotometry\* in a 19 mm. tube using the reagent blank as a standard. For glucose concentrations below 0.6

\*From the Department of Medicine, University of Chicago.

This work was performed as part of a project supported by the Division of Research Grants and Fellowships, National Institutes of Health, United States Public Health Service.

Received for publication June 1949.

Different type of colorimeter may be used. The described procedure is based upon the employment of a Coleman Junior Spectrophotometer which gives a very satisfactory result for this purpose. It may be operated rapidly and gives a reasonable degree of accuracy.

per cent the wave length  $540\text{ m}\mu$  is used, for concentrations above this value,  $700\text{ m}\mu$  is used. The glucose concentration is found from a standard curve or from Table III. Finally, the temperature of the solutions is measured and, if necessary, a correction made by means of Table IV.

#### RESULTS AND COMMENT

It was found that the results vary, depending on the method of preparing the reagent. The amount of color developed is further dependent upon the age of the batch of reagent used. From Fig. 1 it will be seen that the intensity of

Fig. 1—The density of color obtained after boiling, using the same batch of reagent at different periods of time after preparation. Constant glucose concentration.

the color, when the reagent is kept at  $27^{\circ}\text{C}$ , increases for the first twelve days or so and thereafter remains constant. It is thus necessary to leave the freshly prepared reagent for about two weeks at this temperature before use. At lower temperatures a longer time is required, while at  $37^{\circ}\text{C}$  the aging probably will be complete in one week. We have tried to age the reagent in five hours in boiling water. This procedure, although suitable for emergency use, is not recommended, since it results in a rather dark colored reagent which is unsuitable for exact work. As shown in Table I, the reagent, once it has been aged, is stable for at least three months at room temperature when kept in a brown bottle in the dark.

TABLE I DENSITIES FOUND, USING DIFFERENT BATCHES OF REAGENT  
All Glucose Concentrations Are 0.5% Each Value Is the Average of 5 Determinations

3/6	77	0.526
3/6	99	0.794
4/16	15	0.840
4/16	37	0.820
4/16	58	0.798
5/24	13	0.817
5/24	20	0.804

For pipetting the reagent an automatic 10 c.c. pipette\* is convenient

In these experiments 0.1 c.c. of urine† was used. The pipetting of this volume with a 0.1 c.c. capillary blood pipette is the largest single source of error in the method. The pipettes used in this work (Sargent Chicago), as received from the manufacturer, are said to measure  $0.1 \text{ c.c.} \pm 0.005$  cubic centimeter. All of thirty pipettes tried were found to be within these limits.

When working with pure glucose solutions or with urines containing much glucose and only small amounts of other reducing substances the mixture of urine and reagent may, if desired, be left at room temperature for an hour before boiling. Table II shows the values for optical density where different periods of time before boiling were employed‡. In the case of very concentrated solutions (10 per cent glucose) a certain amount of the brown color develops during the first hour at room temperature. This does not affect the final result.

TABLE II. VALUES FOR OPTICAL DENSITY FOUND WHEN A MIXTURE OF A PURE GLUCOSE SOLUTION AND THE REAGENT REMAINED AT ROOM TEMPERATURE FOR DIFFERENT PERIODS OF TIME BEFORE BOILING

If large amounts of creatinine are present reduction takes place at room temperature within a short time as indicated in Fig. 2. The amount of color developed by physiologic concentrations of creatinine is rather small and usually can be neglected. If one however is interested in determining concentrations of glucose in the range of 0.1 to 0.4 per cent the reduction by creatinine must be taken into consideration and the tubes should be put into the boiling water as soon as possible after mixing urine and reagent.

A boiling time of three minutes was found satisfactory. The variation of the color obtained by varying the boiling time from 2.5 to 4 minutes is seen in Fig. 3. One should make sure that there is proper contact between test tubes and boiling water. If many tubes are placed in the water bath without sufficient space between them, the tubes in the middle will remain at a lower temperature than the others and erroneous results will follow.

After boiling, the tubes are placed in cold water. It is convenient to have two vessels for this purpose. The tubes are first placed for a few minutes in one with running tap water and thereafter in the other containing water at room temperature. In this way rapid cooling is obtained and all the tubes will be at room temperature for the colorimetric determination. As will be shown later, this is essential since the intensity of the color depends upon temperature.

If mouth pipettes are used it must be remembered that the reagent is caustic and poisonous.

†It is usually unnecessary to filter the urine. Even urines containing large amounts of precipitates will usually give clear solutions on boiling in the strongly alkaline reagent.

‡The use of 19 mm test tubes for heating the mixture of reagent and urine in boiling water obviates any appreciable loss by evaporation.

Fig 2—Development of color expressed as density at 540  $m\mu$  by a solution of creatinine corresponding to 3.8 per cent in 0.1 cc of urine added to the reagent and standing at 25° C. Two samples were taken out and boiled and thereby the development of color was stopped at a lower density.

Fig 3—Twenty test tubes containing samples of the same mixture of glucose and reagent were boiled for different periods of time. The variation in density determined at 540  $m\mu$  after cooling reflects the statistical uncertainty of the determination. In addition there is possibly a slight increase in color from 2.5 minutes to 4 minutes.

For accurate work, the colorimetric determination should be carried out within one or two hours after boiling, since there is a small increase in the intensity of the color during the first twenty-four hours as shown in Fig 4. After twenty-four hours there is a decrease in color. The initial value is obtained again in a couple of days.

The method has the advantage that the entire range of glucose concentrations usually encountered (0.2 to 10 per cent) can be determined without the necessity of making different dilutions of urine. This not only saves time but

also eliminates an important source of mistakes in computation. Using the Coleman Junior Spectrophotometer and 19 mm test tubes it was found that the whole range could be covered by employing 0.1 cc of urine to 10 cc of the reagent and determining the developed colors at two different wave lengths

Fig 4—The density after boiling as a function of the time during which the tubes remained at room temperature. Each point is the average of five determinations

For lower concentrations up to 0.6 per cent glucose 540  $m\mu$  was found to be optimal, whereas for concentrations in the range 0.6 to 10 per cent 700  $m\mu$  was found to be optimal. For other types of colorimeter or for this colorimeter with a different sized tube a different wave length may be found to be better. To avoid mistakes it is preferable always to record the densities of all samples at both of the two wave lengths.

It is ordinarily recommended that wave lengths be employed for which the substance to be determined has a maximum or minimum of absorption. This could not be done in this instance since no such maximum or minimum is present.

Using other types of colorimeters it may be necessary to dilute the reaction mixture. If so dilution with water should be avoided since the color is unstable except in strong solutions of sodium hydroxide. Dilution may be made with 5 per cent sodium hydroxide which does not influence the stability of the color. In this case the reagent blank used as a standard must be diluted in the same proportion. It is easier, however, to dilute with the reagent itself in which case the reagent blank can be used unchanged.

The colors of the solutions were found to be dependent to a considerable degree upon temperature. Thus the density of the reagent increased 20 per cent with an increase in temperature from 20° to 30° C, whereas the density of the strongly colored solutions resulting from high sugar concentrations increases only 9 per cent with the same change in temperature. Therefore it is necessary first, to keep the reagent blank and the reaction mixture at the same temperature and, second, to take this temperature into consideration in the calculation. To be safe, it is always best to use one reagent blank with

each lot of tubes boiled. In this way one can be sure that there is no great temperature difference between reagent blank and reaction mixture. Table III is calculated for a temperature of 22° C. For other temperatures a correction\* must be made. Table IV shows the values for this correction. These are applicable, no matter what type of colorimeter is used.

For computation of the sugar concentration from the density a set of two curves can be used, one for each of the two wave lengths. For routine use, however, a table such as Table III is more convenient and is less subject to mistakes in application.

It should be pointed out that the relation between density and glucose concentration is not linear. It is especially remarkable that small amounts of glucose give no color at all. Thus a density reading of approximately zero means

\*For clinical work in which approximate values are satisfactory and in which laboratory temperatures vary only a few degrees this correction is unnecessary.

not that there is no glucose in the urine but that there is less than about 0.1 per cent. For clinical purposes glucose concentrations as low as this are usually of no significance.

For the purpose of rough estimations, where an error of  $\pm 20$  per cent is unimportant, the standard curve may be determined by applying the previously described procedure to known solutions of glucose. If limits of error of about  $\pm 10$  per cent are required, great care must be taken to make the standard curve exact enough. In this work the following procedure was employed.

The glucose content of a commercial dextrose preparation was determined by polarimetry. From this preparation a solution was made up, containing a known amount of glucose per gram. A portion of this solution was weighed out, water added to make a total volume of 1 cc., and 100 cc. of reagent were added. After thorough mixing, the solution was divided into ten portions in each of ten test tubes and heated in boiling water for three minutes. After cooling, the color was determined in the usual manner using ten different tubes of reagent blank. The average of the ten readings makes up one point of the curve. The figures in Table III are read from this standard curve.

A number of calibrated colorimeter tubes were used for determination of the density of the same solution. They were found to vary slightly, the standard deviation being  $\pm 0.5$  per cent. Other colorimeter errors were found to cause a standard deviation of  $\pm 1$  per cent. The errors in determining the points on the standard curve, made in the previously described manner, were found to cause a standard deviation in the apparent glucose concentration of  $\pm 0.4$  per cent for values higher than 0.3 per cent glucose.

The upper and lower limits of error, given in Table III, were calculated from these figures together with the previously mentioned pipette errors. These limits are determined in such a way that the probability is about 99 per cent that the true value is to be found within them.

The method described is sufficiently accurate for clinical work. The Benedict titration, in the form in which it is carried out in many clinical laboratories that is, without any precautions to prevent the oxidizing influence of the air, is much less accurate. Titrations of eleven portions of a single sample of urine from a diabetic patient showed the following percentages of glucose: 13, 14, 0.9, 1.3, 1.2, 0.8, 1.0, 1.1, 1.9, 1.9. The proportion between the highest and the lowest of these values is more than 2:1.

*Interference by Substances Other Than Glucose*—In the present work, it was assumed that no sugars other than glucose were present. The fact that different sugars give different reduction rates with the dimethylglyoxime reagent has been utilized by Epton<sup>6</sup> for the identification of these substances in urines. We have found, however, that the relative rates of reduction depend not alone upon which sugar is present but also to some extent upon the concentration. Thus, further investigations must be carried out before the method can be adapted to routine use for the differentiation of melliturias.

Other reducing substances present in urine, such as creatinine, uric acid, phenols, and amino acids, may interfere with the determination of glucose by

most of the methods in common use. In order to test their effect on the present method, the following substances were added to the reagent in amounts corresponding to very high concentrations in the urine: 11 per cent phenol, 22 per cent salicylic acid, 10 per cent acetone, 30 per cent urea, 10 per cent oxalic acid and 3 per cent nitric acid. None of these substances gave any measurable color. The color produced by creatinine has been mentioned previously, 0.16 per cent creatinine in the urine was found to give a density of 0.03 after standing at room temperature for an hour. For most clinical purposes reduction by creatinine can be neglected.

A number of urines from dogs were determined both by this method and by the Benedict titration (Table V). In about half of the "normal" urines the Benedict method yielded considerable amounts of reducing substances, the maximum being 0.9 per cent expressed as glucose equivalent and values of about 0.6 per cent being very common. In one such urine no fermentation occurred with yeast, whereas a nonreducing urine to which was added 0.6 per cent glucose gave a slight fermentation. In contrast by the dinitrosalicylic acid method much lower reducing values were found in the same urines, usually about half as much as by the Benedict titration, indicating a higher degree of specificity of the present method.

TABLE V REDUCING POWER OF DIFFERENT SAMPLES OF DOG URINES AS DETERMINED BY THE BENEDICT METHOD AND BY THE DINITROSALICYLIC ACID METHOD  
Values Are Expressed as Per Cent Glucose Equivalent

0.56	0.30
0.40	0.36
0.51	0.23

#### SUMMARY

A modification of Sumner's method has proved very satisfactory as a routine method for the determination of glucose in urine. The procedure has the advantage that the entire range of glucose concentrations from 0.2 to 10 per cent is covered without using different dilutions of the urine. The limits of error are within  $\pm 10$  per cent for concentrations higher than 0.3 per cent glucose. For such concentrations the influence of nonsugar reducing substances can be largely neglected. This method is thus more specific than other routine methods. If sugars other than glucose are present, however, erroneous results will be obtained.

# A SIMPLE METHOD FOR DETERMINING SULFONAMIDE SENSITIVITY IN VITRO AND ITS CLINICAL APPLICATION

FRITZ B SCHWEINBURG, M D AND ALEXANDER M RUTENBURG, M D  
BOSTON, MASS

THIS communication describes a simple method for the determination of the relative sensitivity of a given bacterial strain to different sulfonamides. A method for this purpose has not heretofore come into clinical use in part because various substances contained in the usual culture media, particularly peptone,<sup>1</sup> prevent a determination of the absolute antibacterial effect of sulfonamides. Special media which do not contain such inhibitors have been prepared,<sup>2</sup> but the techniques involved are too laborious for practical clinical application. Peptone containing media however, if properly prepared, can be used for determining the relative antibacterial potency of various sulfonamides against a given bacterial strain. The method described below enables one not only to determine the sensitivity of a given bacterial strain to a series of sulfonamides but also to choose the most potent one.

## METHOD

Nutrient broth (Difco) containing 0.5 per cent peptone was adjusted to a pH of 8.2 in order to obtain maximum solubility of the sulfonamides. The amount prepared was sufficient to serve for all procedures of the entire study. For growth of the more fastidious bacteria the pH was lowered (pH 7.6) and horse serum (5 per cent) and glucose (1 per cent) were added. Serial dilutions of each of a 1000 mg per cent stock solution of the various sulfonamides were prepared in concentrations of 750, 500, 200, 100, 50, 25, and 10 mg per cent respectively. One cubic centimeter of each of the eight dilutions was placed in Wassermann tubes. To each tube was added 0.1 cc of a bacterial suspension prepared by diluting an eighteen to twenty four hour culture so that 0.1 cc contained 1000 to 20,000 bacteria. A control tube containing broth and no sulfonamide was inoculated with 0.1 cc of the same bacterial suspension.

Such small inocula were used because for some strains large inocula are said to depress the activity of the sulfonamides.<sup>3</sup> The broth prepared as described was used to prepare all stock solutions, all the dilutions of the sulfonamides, and the bacterial cultures and dilutions. The tubes were incubated for twenty four hours at 37° C. The lowest concentration of each sulfonamide which completely inhibited macroscopically visible growth was taken to be the bactericidal titer. The concentration of each sulfonamide which produced a recognizably lesser degree of turbidity than the control tube was considered to be the bacteriostatic titer.

We are aware of the fact that this method of reading an *in vitro* test is somewhat inaccurate. The last clear tube may contain a small number of viable bacteria, which may be destroyed within another twenty four hours or may start to multiply after twenty four hours have elapsed. Also a tube macroscopically just as cloudy as the control tube might well contain fewer organisms than the latter. However for practical purposes these possibilities can be neglected, as will be shown in the discussion of the results.

Received for publication July 11, 1949

## RESULTS

Two hundred bacterial strains were studied. Markedly different action was observed by various sulfonamides on many strains of *Escherichia coli*, *Aerobacter aerogenes*, *Klebsiella pneumoniae*, *Eberthella typhi*, *Salmonella schottmulleri*, *Salmonella enteritidis*, *Bacillus proteus vulgaris*, and *Pseudomonas aeruginosa* and among some strains of *Staphylococcus aureus hemolyticus*, but only rarely on various strains of hemolytic streptococci and pneumococci. Some bacterial strains of each of these species were equally resistant while others were equally sensitive to all sulfonamides studied. Gram-negative cocci and gram positive bacilli were not examined. Table I provides a few significant examples.

## CLINICAL OBSERVATIONS

The clinical importance of such tests for selecting the most effective sulfonamide is emphasized by the following representative case histories.

CASE 1—A 25 year old man with pneumonia of the right upper lobe was treated with large doses of sulfadiazine for three days without effect. At this time, the process extended to the right middle lobe. A pneumococcus Type 1, isolated from blood and sputum, was completely resistant in vitro to penicillin, sulfadiazine, sulfamerazine, and sulfamethazine. The bactericidal titer with sulfathiazole was 100 mg per cent. Administration of sulfathiazole in adequate dosage led to recovery within thirty six hours.

CASE 2—A sequestrectomy was performed in a girl of 10 with osteomyelitis of the right tibia of four to five weeks' duration. Penicillin and sulfadiazine were administered without effect. Temperature remained high. A hemolytic, coagulase positive *Staph aureus*, isolated from the draining sinus in pure culture, was completely resistant in vitro to penicillin, sulfadiazine, sulfamerazine, and sulfamethazine. The bactericidal titer with sulfathiazole was 250 mg per cent. Following sulfathiazole therapy, fever rapidly declined, drainage subsided, and the patient recovered.

CASE 3—A 70 year old woman with acute postoperative cystitis due to *Esch coli* was treated for five days with full doses of sulfadiazine without effect. The strain was completely resistant in vitro to sulfadiazine, sulfathiazole, sulfamethazine, and streptomycin. The bactericidal titer with Nu 445 (3,4 dimethyl 5 sulfanilamido isovazole) was 100 mg per cent. There was complete clinical and bacteriologic cure after three days of treatment with Nu 445.

CASE 4—A 40 year old woman with acute pyelonephritis and cystitis due to *Esch coli* was treated for six days with full doses of sulfadiazine without improvement. The bactericidal titer with sulfadiazine, sulfathiazole, and sulfamethazine was 500 mg per cent, but with Nu 445 it was 250 mg per cent. Clinical and bacteriologic cure was achieved within six days with Nu 445.

CASE 5—Following prostatectomy a 59 year old man developed acute cystitis and bilateral pyelonephritis due to *A. aerogenes* and *Ps. aeruginosa*. Prolonged therapy with sulfadiazine and later with sulfamerazine was ineffective. Both strains were resistant in vitro to sulfadiazine, sulfamerazine, and sulfathiazole. The bactericidal titer of the *A. aerogenes* with sulfamethazine was 100 mg per cent, of the *Ps. aeruginosa*, 250 mg per cent. Treatment with this drug rapidly cured the infection.

CASE 6—A 66 year old woman following perineorrhaphy developed acute cystitis due to *Ps. aeruginosa* and *B. faecalis alcaligenes*. Penicillin in large doses was without effect. In vitro tests showed a bactericidal titer for the *B. alcaligenes* of 100 mg per cent with sulfadiazine, sulfathiazole, and sulfamethazine. The *Ps. aeruginosa* was completely resistant to

c Bactericidal titer st Bacteriostatic titer

All strains were freshly isolated from human infections Only those showing marked difference in sensitivity against various sulfonamides are listed

Titers of 50 mg per cent or less are likely to be therapeutically effective

sulfadiazine and sulfathiazole The bactericidal titer with sulfamethazine was 100 mg per cent Sulfamethazine administration led to complete clinical and bacteriologic cure within three days

### DISCUSSION

The method described is based on the assumption that the inhibitors contained in the broth do not affect the relative potency of the sulfonamides used in these tests, even if they do substantially lower the absolute potency From the available evidence<sup>3, 7, 8</sup> it appears that the same amount of inhibitor affects sulfadiazine, sulfathiazole, and sulfapyridine equally While such data are not available for sulfamethazine or Nu 445, our experience suggests that this is probably also the case for them

Although the action of a sulfonamide on a given strain is stronger the simpler the composition of the medium,<sup>3, 7</sup> we observed that the marked differences in relative potency of the various sulfonamides on a given bacterial strain were exactly the same whether a simple synthetic medium or a broth was used (Table II) The difference in potency is of the order of one to two tubes This observation indicates that the foregoing method is sufficiently accurate for routine laboratory work

TABLE II COMPARISON OF BACTERICIDAL TITERS IN MG PER CENT OF STRAINS OF ESCH COLI IN NUTRIENT BROTH AND IN THE SYNTHETIC MEDIUM OF KOHN AND HARPIS<sup>7</sup> IN VARIOUS SULFONAMIDES

		Synthetic med	250	250	50	100	250	500

SD sulfadiazine SM sulfamerazine SMT sulfamethazine ST sulfathiazole, PST sulfathiazidine Nu 445 3,4-dimethyl-5-sulfanilamido-isoxazole

Similar comparative tests done with strains of *A. aerogenes*, *B. proteus vulgaris* and *P. aeruginosa* gave similar results

From the close correlation between results of the *in vitro* test and the therapeutic effect, two further conclusions may be drawn (1) The choice of the sulfonamide should be made on the basis of the bactericidal and not the bacteriostatic titer The gap between the two titers varies with nearly every strain While they are occasionally identical, the bacteriostatic titer is often from one tube to three to four tubes removed from the bactericidal titer (2) A sulfonamide exerting bactericidal action on a given strain in a concentration of 250 mg per cent or lower is very likely to be therapeutically effective If the bactericidal titer is 500 mg per cent, the clinical action of the drug is questionable but the drug should be tried if a more effective agent is not available Sulfonamides with a bactericidal titer of 750 mg per cent or higher are not therapeutically effective

This study emphasizes the fact<sup>a</sup> that the sensitivity of different strains of a given species of bacteria is extremely variable. Some strains may be very sensitive and others completely resistant to the same sulfonamide.

#### SUMMARY

A simple method for determining the *in vitro* effect of various sulfonamides on a given bacterial strain is described. Clinical experiences are given showing the importance of the correct choice of sulfonamide.

The fact that a majority of the strains of a given species are usually sensitive to a sulfonamide does not assure a therapeutic effect in a given instance. Hence it is frequently necessary to determine the relative sensitivity of the strain responsible for the infection to a series of sulfonamides.

# A MODIFIED ULTRAVIOLET SPECTROPHOTOMETRIC METHOD FOR QUANTITATIVE DETERMINATION OF BARBITURATES

T C GOULD, M A, AND C H HINE, M D, P H D  
SAN FRANCISCO, CALIF

## INTRODUCTION

THE three drug depressions most commonly encountered in clinical medicine are due to the excessive absorption of alcohol, bromides, or barbiturates.

The first two of these agents may be determined readily, both qualitatively and quantitatively, by well-established clinical laboratory techniques. The qualitative detection of barbiturates also can be carried out with a fair degree of success by the Koppanyi method providing sufficient blood or urine samples are available. However, until recently, quantification of the barbiturate levels in sera was not feasible since large quantities of blood were necessary.

Recently, spectrophotometric techniques for quantitative barbiturate determinations in sera have been proposed by others.<sup>1,2</sup> These techniques are extremely sensitive, so that an accurate barbiturate determination can be made on as little as 1 ml of blood. The method developed in this laboratory has a distinct advantage over previous methods in that it can be applied directly to serum extracts with the elimination of interference due to serum and reagent blanks. We have used this procedure as a diagnostic aid in over fifty cases of barbiturate intoxication during the past year and have followed the blood levels of a number of these patients during their course of recovery in the hospital.

Determination of barbiturate sera levels aids the clinician in evaluating the relative effectiveness of various therapeutic measures he employs in his treatment of barbiturate intoxication.

## EXPERIMENTAL

*General Description of the Method*—The barbiturate is extracted directly from serum in a semimicro continuous extractor using diethyl ether. The ether is evaporated and the barbiturate residue is brought into solution as the sodium salt using a borate buffer of pH 9.5. Optical density of the solution is determined by means of a Beckman spectrophotometer, and the amount of drug present is calculated using a standard curve prepared by a method which eliminates blank serum interference.

*Importance of the Influence of pH on the Absorption Spectra*—The influence of pH on the absorption spectra of barbital and the 5,5-disubstituted barbiturates was reported by Elvidge,<sup>3</sup> Stuckey,<sup>4</sup> and more recently by Walker and co-workers.<sup>5</sup> We have confirmed these studies by measuring the absorption curves of six barbiturates in aqueous solution at various pH values between 7.0 and 12.0. The barbiturates studied were Amytal, barbital, cyclobarbital, Cyclopal, pentobarbital, and phenobarbital. The absorption curves for Amytal, which are similar to those of the other barbiturates tested, are shown in Fig. 1.

From the Division of Pharmacology and Experimental Therapeutics, University of California Medical School.

Supported in part by the Research Committee, University of California Medical School.

Received for publication July 11, 1949.

The observation, as reported by Goldbaum that each barbiturate gives a characteristic absorption curve at pH 11 or greater suggested the possibility that the ratios of the optical densities at specific wave lengths could be used as criteria for the differentiation of the various barbiturate derivatives. The use of this means of identification is of little practical significance in clinical analysis however since the marked absorption due to blood or serum

Fig 1—Absorption curves of Amytal in aqueous solution at varying pH values

usually obscures not only the characteristic maximum but the other critical portions of the curve. The greatest amount of absorption per unit concentration is obtained between the pH values 9.0 and 10.0. Within this range of alkalinity all 5,5-disubstituted barbiturates develop peak absorption in the wave length range from 239 to 240 millimicrons. Although it is not possible to differentiate any one of the barbiturates by the shape of its absorption spectra in this pH range, the type of curve obtained with its steep slope is least likely to be obliterated by interfering serum blanks.

Thus the optimum pH range for measurement of the absorption spectra of barbiturates was found to lie between 9.0 and 10.0. In the determination of drug levels in serum unless the solution is carefully maintained in this range of alkalinity variations may appear in the absorption curve which give erratic results. With reference to Fig. 1, it is evident that measurement of optical density at a pH of 11, rather than from 9 to 10 would result in only about 85 per cent recovery. For this reason we have used a borate buffer of pH 9.5 as the solvent in the determination of barbiturate absorption.

**Interference by Serum Blanks**—Interfering absorption by ether or chloroform extracts of serum proved to be a problem of considerable difficulty. In experimental work

a blank serum specimen can be determined prior to the administration of the drug, and, provided no change occurs in the blank, a correction factor may be applied for the subsequent barbiturate determination. In clinical and forensic medicine, however, these blank samples are rarely available. Thus, the amount of absorption due to serum itself is unknown, and the accuracy of the quantitative determination of the drug is subject to a variable degree of error.

Fig 2—Absorption curves of ether extracts of normal human serum in borate buffer (pH 9.5). The absorption curve of pentobarbital (8γ per milliliter in borate buffer of pH 9.5) is superimposed to illustrate the importance of serum interference.

Goldbaum<sup>2</sup> has suggested an optical density value of 0.030 to be applied as a control blank in toxicologic analyses where no barbiturate free samples of normal blood are available. This value was reported as the average for chloroform extracts of all normal blood samples measured at 255 mμ in 0.5N sodium hydroxide. Determinations were made in this laboratory of the optical densities of both ether and chloroform extracts of a series of 150 sera obtained from patients having had no history of recent drug ingestion. The optical densities of these "normal" sera were found to vary between 0.040 and 0.250 at wave length 240 millimicrons. Serum absorption measured at 255 mμ was only slightly less. The absorption curves of a few typical specimens of normal human serum are shown in Fig 2, with an absorption curve of pentobarbital superimposed to illustrate the importance of blank serum interference. It is evident that no average blank value of any significance can be derived from these results.

Walker and associates have reported a method for the elimination of blank interference due to blood in which they employ an acid alkaline shift.<sup>1</sup> The procedure is not applicable to direct extracts of blood or serum, as stated by Walker and confirmed by our experiments, and must be carried out on the filtrate of a tungstate sulfuric acid protein precipitation. In so doing approximately 25 to 35 per cent of the barbiturate is accounted for, a factor which limits the accuracy of the method.

A satisfactory method of correcting for the interference of absorption due to serum and reagent blanks was developed in this laboratory by adapting a procedure described by Tunnichiff. The correction can be applied to extracts made directly from serum without preliminary protein precipitation. Fig 3 illustrates an actual problem demonstrating that the curve obtained from any clinical specimen (pentobarbital in serum)

Fig 3—Absorption curves of ether extracts of serum and pentobarbital in serum and standard pentobarbital curve. All absorption curves were determined in borate buffer at pH 9%. The pentobarbital concentration was 8γ per milliliter.

is the additive effect of the blank serum curve plus the actual barbiturate curve. It is evident that the peak absorption D cannot be used as a measurement of drug concentration since an unknown fraction of its magnitude is due to serum absorption. The method we have adopted is based on the observation that the absorption curves of normal blank sera conform approximately to a straight line in the range of wave lengths from 225 to 265 mμ (Fig 2). Thus with reference to Fig 3 if a base line is drawn between the optical density values  $d_1$  and  $d_3$  a value  $d$  is obtained which serves as an adequate index for the amount of barbiturate present since it is directly proportional to drug concentration, and it is not significantly altered by serum blanks. This  $d$  value may be obtained either graphically

by plotting the three values,  $d_3$ ,  $D$ , and  $d_1$ , and drawing the base line  $d_3d_1$ , or by simple algebraic calculation using the equations

$$d = D - d_1 \quad (A)$$

$$\text{where } d_1 = \frac{5}{8}d_3 + \frac{3}{8}d_1 \quad (B)$$

The derivation of (B) is as follows

$$\frac{d_3 - d_1}{d - d_1} = \frac{\lambda_3 - \lambda_1}{\lambda_2 - \lambda_1} \quad (C)$$

$$d = d_3 \frac{(\lambda - \lambda_1)}{(\lambda_3 - \lambda_1)} - \frac{d_1 (\lambda - \lambda_3)}{(\lambda_3 - \lambda_1)} \quad (D)$$

Substituting wave length values in Equation (D) and solving

$$d_1 = d_3 \frac{(240 - 265)}{(225 - 265)} - \frac{d_1 (240 - 225)}{(225 - 265)} \quad (E)$$

which results in (B)

$$d = \frac{5}{8}d_3 + \frac{3}{8}d_1 \quad (B)$$

A practical example will be cited to illustrate how the calculation may be applied (Table I). Following the regular extraction procedure the optical density was determined on I, a blank sample of human serum, and III, the same serum to which had been added a known quantity of pentobarbital. II represents the standard absorption curve of the concentration of pentobarbital present in the serum. Table I includes the data as calculated algebraically using Equations (A) and (B). Fig. 3 illustrates the example graphically.

TABLE I ILLUSTRATION OF ACCURACY OF CALCULATION OF BARBITURATE CONCENTRATION BY THE BASE LINE METHOD

WAVE LENGTH	SYMBOL	OPTICAL DENSITY		
		BLANK SERUM I	PENTOBARBITAL II	PENTOBARBITAL IN SERUM III
225 mμ	$d_3$	0.295	0.137	0.432
240 mμ	$D$	0.235	0.320	0.555
265 mμ	$d_1$	0.150	0.023	0.173
	$d_2$	—	0.094	0.335
	$d$	—	0.226	0.220
/ per ml		—	5.0	7.8

By the use of this method the interference due to serum blanks is almost completely eliminated. In the foregoing example, the calculated value of barbiturate level is 97.5 per cent of the actual level. In practice, the accuracy of the method depends in part upon the nature of the blank serum absorption curve. The curve as a whole, from 225 to 265 mμ, does not always coincide exactly with the base line  $d_3d_1$ . This is not of great importance, however, since it is the amount of deviation in optical density between the serum curve and the base line at 240 mμ which is significant. This deviation is rarely more than shown in the example given, 0.006 optical density. The dependability of this correction for blank interference is reflected in the data contained in Table II.

#### PROCEDURE

1. One milliliter of serum is placed in the extractor, and from 5 to 10 ml of distilled water are added, depending upon the volume of the extractor. Larger volumes of water are

be used when available. Approximately 30 ml of diethyl ether are placed in the receiving flask.\* The apparatus is assembled as shown in Fig 4 the ether being evaporated in a water bath regulated between 50 and 55 C. In the event that emulsions are formed at the interface, they are readily removed by addition of a few crystals of anhydrous sodium sulfate. When

Fig 4—Diagram of semimicro extraction apparatus

extraction is complete (fifteen to sixty minutes) the ether may be evaporated into a clean extractor and saved for redistillation. The receiving flasks containing the barbiturate residue must be completely dry before addition of the borate buffer. This is best accomplished by placing them in a drying oven for a few minutes.

**Reagents** Diethyl ether technical grade. Washed with distilled water, treated with ferrous sulfate, dried with anhydrous calcium chloride and redistilled, preferably over metallic sodium.

**Borate buffer** 0.2M boric acid C.P.  
0.1M potassium chloride C.I.—Solution A  
0.2M sodium hydroxide C.P.—Solution B

prepared according to Peters and Van Slyke to pH 9.  
**Apparatus** Semimicro continuous extractor with condenser and receiving flask (Fig 4).  
Water bath with thermoelectric control ranging from 40 to 55 C. Beckman Model DU Ultra violet spectrophotometer with 1 cm quartz absorption cell.

TABLE II RECOVERIES OF BARBITURATES ADDED TO BLANK SERUM  
(LEVELS WERE CALCULATED BY THE BASE LINE METHOD)

NUMBER OF DETERMINATIONS	MICROGRAMS ADDED	AVERAGE RECOVERY* (PER CENT)
11	14.4	92.2 ± 2.75
14	20.0	98.5 ± 1.95
12	75.0	101.2 ± 1.28
10	100.0	93.7 ± 1.81

\*This includes one standard error of the mean

2 When dry, the barbiturate residue is brought into solution with an accurately measured quantity of borate buffer (pH 9.5). A volume of 2 ml or more may be used, depending upon the concentration of drug present.

Fig 5—Standard concentration curves of a few representative barbiturates. The optical density is measured in  $d$  units calculated from Equations A and B.

3 With the barbiturate present in the alkaline form in the pH range from 9.0 to 10.0, absorption is determined at three wave lengths, 225, 240, and 265  $m\mu$  ( $d$ ,  $D$ , and  $d$ , respectively), and the  $d$  value is calculated by using Equations (A) and (B).

4 Barbiturate concentration in the borate buffer is determined by reference to a standard curve (Fig 5).

The value may be expressed as milligrams per cent in the serum according to the equation

$$\text{Mg per cent of barbiturate} = \frac{\gamma B}{10 S}$$

where  $\gamma$  = micrograms of barbiturate read from the standard curve

$B$  = milliliters of borate buffer

$S$  = milliliters of sample

**Accuracy of the Method**—Table II includes data from a series of experiments to determine the accuracy of the method. Known amounts of barbiturates were added to normal sera (beef, horse, and human) of unknown optical density levels. The samples were determined according to the procedure outlined in the preceding section with 1 ml serum and in all instances the base line method was used to determine the drug level. Amobarbital, barbitol,

pentobarbital, phenobarbital and Seconal were the representative barbiturates included in the study. No significant difference between the recovery of the five barbiturates was noticed.

#### DISCUSSION

*Base Line Method of Calculation*—The three wave lengths, 225, 240, and 265  $m\mu$ , were empirically chosen since this combination of wave lengths resulted in the greatest  $d$  value per unit concentration. For the actual barbiturate curve (Fig 3), the farther removed the values  $d_3$  and  $d_1$  are from  $d$  the greater the  $d$  index. There are, however, certain limiting factors. At wave lengths less than 225  $m\mu$  there is a sudden steep rise in serum absorption as barbiturate absorption falls off. Beyond 265  $m\mu$ , although serum absorption is gradually becoming less, the drug absorption also decreases. The wave length 240  $m\mu$  is the logical place for the  $D$  absorption since peak absorption occurs here.

*Interfering Substances*—There are three types of compounds of clinical importance which might cause interference in the barbiturate determination.

*1 Sulfonamides* Although alkaline solutions of sulfonamides elicit absorption in the critical range of the barbiturate spectrum they may be almost completely eliminated when present in serum by the process of extraction. By carrying out the extraction procedure at the pH of serum, only negligible interference by sulfonamides was obtained with levels as high as 10 mg per cent in serum. The absorption curve of the small amount of sulfonamide which is extracted is such that at 240  $m\mu$  there is no deviation of the curve from the  $d_3d_1$  base line. The following sulfonamides were tested at concentrations of 10 mg per cent and were not found to interfere with the determination: sulfanilamide, sulfadiazine, sulfaguanidine, sulfapyridine, sulfamerazine, sulfathiazole.

*2 Salicylates* The salicylates give absorption curves with two maxima, one in the critical range of barbiturate absorption and the other beyond the limit where absorption of the non-thio type of barbiturate occurs. Salicylates can be identified easily by their characteristic absorption curves and consequently should not be mistaken for barbiturates. There is at present no satisfactory method of eliminating their interference.

*3 Products of Barbiturate Metabolism* In the metabolism of the nonsulfur containing barbiturates the splitting of the malonyl urea ring yields a compound which does not produce interfering absorption in the ultraviolet range. It is possible that alterations of the barbiturate other than breakdown to a ureide could yield metabolic products which would contribute to the absorption spectrum. Whether or not these compounds would be extracted by our method and whether or not their absorption curves could be differentiated from those of the parent compound are problems which are in need of further investigation.

In cases of barbiturate intoxication where the identity of the barbiturate is not known, there is an inherent error in all spectrophotometric methods, since barbiturates differ to some degree in their molecular extinction coefficients. From a practical standpoint this difference is not of great importance. It has been our practice when the ingested barbiturate was not

known or could not be qualitatively identified to express the sera level in terms of pentobarbital, since the  $d$  values for this compound are closest to the mean of the commonly encountered barbiturates

#### SUMMARY

A method for quantitative barbiturate analysis has been developed which has the following advantages

1 The interference due to absorption of reagent and serum blanks is eliminated by means of a graphic solution or a simple algebraic calculation

2 Careful regulation of pH in determining ultraviolet absorption increases the accuracy of the determination

3 Samples as small as 1 ml of serum may be extracted directly without preliminary protein precipitation

4 There is a considerable economy of glassware and reagents involved as well as ease of extraction

## FAT DETERMINATION IN FECES USING MOJONNIER EXTRACTION FLASKS

ULLA SODERHJELM, M.D. LIC. AND LARS SODERHJELM, M.D. LIC.  
GALVESTON, TEXAS

IN FAT balance studies the methods commonly employed for the determination of the fat in feces have not been particularly satisfactory. The procedure of drying the fecal specimens is cumbersome and time consuming and an error is introduced because during the drying and grinding process part of the feces sticks to the walls of the receptacles. Extraction of fat with the Soxhlet apparatus is difficult where the water pressure is not constant and the water is not sufficiently cold to condense the ether vapors. This latter feature is particularly significant in warm climates. Extraction methods employing wet feces are simple and efficient but it is difficult to avoid emulsification in extraction with alcohol and ethyl ether, hence centrifugation is often necessary.

### METHOD

An adaptation of the Roesse Gottlieb fat extraction method applied to wet feces and using Mojonnier extraction flasks was suggested by Hilda F. Wiese of the Department of Pediatrics.

The feces are washed with distilled water into a tared jar or a Waring Blendor for mixing. Water is added to make the sample sufficiently fluid to be drawn into a pipette. The total weight of feces and water is taken. After thorough mixing either in the Waring Blendor or with an electric stirrer which can be inserted directly into the weighed jar, 3 to 8 ml. aliquots are withdrawn and transferred directly into the bottom chamber of the weighed Mojonnier fat extraction flasks. The extraction flasks are weighed directly on an analytic balance. If the total fat excreted is to be reported on the dry basis separate aliquots are measured out for the determination of total solids.

For the extraction a few drops of concentrated HCl are added, then 12 to 15 ml. 95 per cent alcohol. The flasks are tightly stoppered and shaken for thirty seconds. Then 10 ml. ethyl ether are added, the flasks are stoppered and shaken vigorously for sixty seconds. This is followed with 25 ml. petroleum ether and the shaking is continued for sixty seconds. The flasks are then allowed to stand ten to fifteen minutes for complete separation of the ether layer. The Mojonnier fat extraction flasks are constructed that the ether layer can be poured off directly into weighed containers for evaporation of the solvents without danger of contamination from the aqueous layer (See Fig. 1). The extraction procedure is repeated using 5 ml. 95 per cent alcohol, 15 ml. ethyl ether and 15 ml. petroleum ether. If the fat content of the feces is very high it may be necessary to make a fourth extraction. Just before the last ether layer is poured off sufficient water is added to fill the bottom chamber so the ether layer can be removed completely. The ether extracts are evaporated on the water bath, the flasks are dried in a desiccator and weighed. With the given proportions of alcohol and ether emulsions rarely occur.

From the Department of Pediatrics, University of Texas Medical Branch.  
Research Assistant and Visiting Lecturer respectively, University of Texas Child Health Program. Present address: Akademiska Sjukhuset, Uppsala, Sweden.

Received for publication July 11, 1949.

The Mojonnier fat extraction flasks are manufactured by Mojonnier Brothers Company, 4601 West Ohio Street, Chicago 44, Ill.

However, if emulsification results, this can usually be broken by the addition of a small amount of alcohol. Also, it is sometimes desirable to re-extract the fat residues with petroleum ether alone. These can be filtered readily through fat free cotton inserted into a small funnel.

Fig 1 —Mojonnier flask used for fecal fat extraction

#### RESULTS

In fifty consecutive duplicate determinations, forty-three showed a difference of less than 2.5 per cent. Two of the samples contained less than 1 per cent fat and the differences here were higher (3.3 and 6.1 per cent). These specimens were obtained from infants who were maintained on a skimmed milk mixture. In the other five instances, differences of 3.3 to 5.1 per cent were obtained. These latter determinations were made at the beginning of the study, and the maximum variation of 5 per cent in duplicate samples seemed satisfactory, hence they were not repeated.

The method described offers several advantages. There is little loss of feces in the preparation and transfer of the material. The extraction can be completed in a very short time and emulsification rarely occurs. Duplicate samples agreed within narrow limits, except in two instances where the fat content was less than 1 per cent of the sample.

## THE SIGNIFICANCE OF CHOLESTEROL VARIATIONS IN HUMAN BLOOD SERUM

LESTER M MORRISON M D , WILLIAM T GONZALES, M D , AND  
LILLIAN HALL, M D  
LOS ANGELES, CALIF

IT HAS been pointed out that the literature dealing with serum concentrations of lipids and cholesterol is filled with conflict<sup>1 2</sup> These inconsistencies appear to be accounted for by differences in technique and the unreliability of certain methods now widely used This subject has been reviewed adequately elsewhere<sup>3 4</sup> Accordingly, a modification of the Sperry Schoenheimer method<sup>4</sup> has been employed for cholesterol, as developed by Chaney and Lovell<sup>5</sup> This modification has been checked against the original Sperry Schoenheimer method and also against other procedures in wide use The results again emphasize the need for adhering to the fundamental principles of the Sperry Schoenheimer procedure and demonstrate that wide variations in results are likely to occur in other methods which do not adequately control the Liebermann Burchard color reaction The modification of Chaney and Lovell appreciably curtails the time required for the procedure and reduces the complexities of the original Sperry Schoenheimer method while maintaining its accuracy

The need for standardization and perfection of such technique has been even more emphasized by the recent renewal of interest in and investigations into the role of fat metabolism in the production of arteriosclerosis and in particular coronary thrombosis Recent studies suggested that serum cholesterol levels are subject to variations under certain conditions in the same subject at different time periods We therefore undertook an investigation into these circumstances of variation and present the following results

The additional value of such an inquiry would be in supplying further criteria on which to evaluate the role of certain lipotropic agents, such as choline, inositol, etc These have been recently employed both experimentally and clinically as "decholesterizing" agents in arteriosclerosis<sup>6 7</sup> Changes in serum cholesterol values were reported<sup>8</sup> following the use of these agents

### CLINICAL MATERIAL

Two or more fasting serum cholesterol tests were made at intervals in 161 subjects who were divided into four groups Group A consisted of thirty-two normal individuals who were free of any clinical symptoms or demonstrable evidence of any illness These subjects served as the normal controls Group B was selected as a control group comprising thirty-one patients who had varied illnesses such as chronic peptic ulcer, chronic

nephritis, chronic nonspecific ulcerative colitis, cirrhosis of the liver, chronic, rheumatoid arthritis, and essential hypertension. No patient in this group had known evidence of coronary occlusion or angina pectoris. Group C consisted of fifty patients who had had recent coronary occlusions (within a six month period of time) but who received no specific medication or lipotropic agents, except in a few instances where maintenance doses of digitalis or Mercuhydrin had been prescribed. Group D comprised forty-eight patients who had been on 6 Gm daily doses of choline bicarbonate for variable periods of time and who had suffered a recent coronary occlusion within six months of the institution of choline therapy. As in Group C, several patients were on maintenance doses of digitalis or Mercuhydrin.

#### RESULTS

*Group A*—Thirty-two normal subjects were studied whose ages ranged from 13 years to 72 years, the average age being 35 years. Twenty were male subjects, twelve were female. The time interval between the first cholesterol determination and the second (which was the last in most instances) ranged from eight weeks to sixty-four weeks, the average time interval being thirty-six weeks. As shown in Fig 1, the average initial serum cholesterol was 202 mg and the average final serum cholesterol was 200 milligrams. The variations between these two ranged from 0 to 38 mg, with an average variation of 11 milligrams. The normal serum cholesterol values are from 140 to 220 milligrams. Thus Fig 1 illustrates the constancy of cholesterol levels in normal controls, when two or more determinations separated by a considerable period of time (one to sixty-four weeks) are made on the same individual. It will be noted that the increase or decrease in level is slight, less than 20 mg per cent (or about 10 per cent of the total) in nearly all instances.

*Group B*—This group consisted of thirty-one patients with various diseases as noted, excluding known illness due to coronary artery disease. The ages ranged from 24 years to 62 years, the average being 46 years. Twenty patients were men, eleven were women. As shown in Fig 2, miscellaneous patient controls, the average initial cholesterol was 279 mg and the average final cholesterol was 280 milligrams. The intervals of observation ranged from one week to twenty-six weeks, the average being nine weeks. In this group were twelve patients whose serum cholesterol varied less than 10 per cent between the first and last determinations, the average amount of cholesterol variation being 23 milligrams. There also were ten patients whose serum cholesterol values showed substantial decreases, on an average of 83 mg between the first and last determinations. There were an additional nine patients whose serum cholesterol increased on an average of 73 mg between the first and last determinations. In Fig 2, describing this miscellaneous series of conditions, some involving elevated cholesterol values, but in which coronary artery disease was absent, the tendency for greater fluctuations to occur is evident from the graph, and increases or decreases up to 100 mg or more occur as frequently as lesser deviations.

*Group C*—Group C consisted of fifty patients who had had recent coronary artery occlusions (coronary occlusion controls), Fig 3, within six months prior to the study. Their ages ranged from 38 years to 80 years, the average being 62 years. Forty patients were men, ten patients were women. The interval

Fig 1

Fig

range between initial and final cholesterol determinations was from one week to sixty weeks, the average being fourteen weeks. In this group there were three further subgroups. Ten patients had less than 10 per cent variations in serum cholesterol from first to last determinations, the average variation being 26 milligrams. Nineteen patients showed substantial interval cholesterol decreases with an average decrease of 69 milligrams. Twenty one revealed interval

Fig 3

cholesterol increases with an average of 83 mg increase. Fig 3 (coronary occlusion controls) reveals that the average initial serum cholesterol was 266 mg and the average final serum cholesterol was 242 milligrams. In acute coronary occlusion, which condition is frequently associated with elevated blood cholesterol, as has been shown previously,<sup>2</sup> there is a more marked tendency to fluctuate. Here it is noted that the majority of cases show a marked difference in level from an initial determination to a succeeding one and that this difference may as frequently be an increase as a decrease.

*Group D*—This group consisted of forty-eight patients who had had recent coronary artery occlusion within six months prior to testing and treating, most of whom had received 6 Gm of choline bicarbonate daily. This was given in three divided daily doses, each containing 2 Gm (coronary occlusion—choline therapy, Fig 4). The ages ranged from 29 years to 80 years, with an average age of 59 years. Forty-two patients were men and six patients were women. The interval range between the first and last cholesterol while on choline therapy was from one week to sixty-seven weeks, the average being twelve weeks. This

group had three further subgroups. One consisted of thirteen patients who showed less than 10 per cent interval variation in serum cholesterol values. The average variation was 5 milligrams. Eighteen patients revealed an average interval decrease of 72 mg while on choline therapy. Seventeen patients showed an average interval increase of 98 mg on choline therapy. Fig 4 further shows how these fluctuations render more difficult the interpretation of the effect of

Fig 4

choline feeding on cholesterol levels. However, by graphing the results on this series (Fig 4) in the same manner, it is apparent that no significant change can be attributed to the choline which is not already accounted for by the fluctuations inherent in the disease.

#### DISCUSSION

Confirmation is again made of Sperry's observation that in normal health the blood serum cholesterol is maintained at a constitutional level characteristic for the individual and from which significant alterations are not prone to take place. It is of interest to note here that in two of the normal control subjects wider variations in serum cholesterol were found than in the other subjects. Upon careful interrogation, it was elicited that one subject aged 41 had had a severe attack of infectious hepatitis eighteen years previously. Liver function tests in this individual had shown moderate impairment up to five years following recovery but had not been repeated since the subject felt himself to be in good health. After the serum cholesterol determinations had been made and were found to be more variable than in the other normal subjects (a variation of 29 mg), liver function tests were repeated and showed a again low grade impairment of liver function tests.

The other normal control subject, age 42, who revealed a 38 mg variation, was closely questioned and was found to have a brother who had died recently of an acute coronary occlusion with hypercholesterolemia, one sister who had had a coronary artery occlusion, and parents who had died of coronary occlusions. A familial susceptibility or hereditary cholesterol metabolism disorder associated with coronary artery disease may be a possibility in this case.<sup>13</sup> Our control series of fifty cases of coronary thrombosis (Group C) confirms the findings of Steiner and Domanski<sup>11</sup> who also found that the serum cholesterol level in patients with coronary arteriosclerosis is variable and subject to wide fluctuations. Our finding of wide serum cholesterol fluctuations in miscellaneous diseases is in agreement with the report just published by Astup.<sup>12</sup> The Group D patients with coronary artery occlusions who were under choline therapy revealed the same type of fluctuations of serum cholesterol observed in the control group of noncholine-treated coronary artery occlusion cases. That is to say, there were three similar subgroups, one showing 10 per cent fluctuation in serum cholesterol values on choline treatment, another showing significant increases in serum cholesterol values on choline treatment, and the other showing significant decrease under therapy.

It has been demonstrated that the liver exerts the chief control over cholesterol metabolism, as well as fat metabolism.<sup>1</sup> It also has been established that the liver plays the main role in the synthesis, distribution, and regulation of cholesterol in the blood stream. It is therefore possible that abnormal variations or instability in the serum cholesterol levels encountered in Groups B and C, comprising coronary thrombosis and certain other diseases, indicate an impairment in the function of the liver regulating cholesterol metabolism in these diseases.

#### SUMMARY AND CONCLUSIONS

- 1 In a series of thirty-two normal subjects, the constancy of blood serum cholesterol levels was reaffirmed over prolonged test periods using a modification of the Speiry-Schoenheimer serum cholesterol procedure.

- 2 Wide variations in serum cholesterol values were found in a group of thirty-one patients with miscellaneous diseases.

- 3 Marked fluctuations in serum cholesterol values were observed in a series of fifty patients who had recently experienced a coronary artery thrombosis.

- 4 Analogous wide fluctuations in serum cholesterol values were found in a series of forty-eight patients who had recently experienced a coronary artery thrombosis and ingested 6 Gm of choline daily. These fluctuations rendered it impracticable to determine whether choline effected a reduction or increase in serum cholesterol levels.

- 5 It is suggested that variations or instability in serum cholesterol exceeding 15 per cent when determined by the Speiry-Schoenheimer procedure or a proved modification thereof in an individual presumed to be normal may possibly indicate a systemic disorder or latent illness.

6 It is suggested that if the Sperry Schoenheimer procedure or a proved modification thereof shows abnormal variations in serum cholesterol, these may be due to a disturbance in the function of the liver regulating cholesterol metabolism

# IRON METABOLISM

## ERYTHROCYTE IRON TURNOVER

C A FINCH, M.D.,\* J A WOLFF, M.D.,† AND C E RATH, M.D.,‡ BOSTON, MASS., AND R G FLUHARTY, PH.D.,§ CAMBRIDGE, MASS

THE hemoglobin cycle in man is particularly accessible to studies employing radioactive isotopes of iron. The incorporation of radioiron into circulating hemoglobin or the disappearance of tagged cells from circulation may be measured. Such studies have necessarily been of short duration. In the turnover of the red cell mass, iron liberated from hemoglobin is passed on to other tissue and serum proteins (Fig 1) and rapidly rerouted to the bone marrow. Once the radioiron reaches a state of equilibrium in the circulating red cell mass, the level of radioactivity may remain relatively constant for months or years. In the present study it has been possible to isolate the erythrocyte portion of the hemoglobin cycle, so that the survival of a population of red cells of approximately the same age might be determined.

The assumption has been made on the basis of *in vitro* studies<sup>1, 2</sup> that circulating red cells neither take up nor give off iron. The reticulocyte, however, has recently been shown to take up iron and synthesize heme.<sup>3</sup> These studies have allowed further observations *in vivo* and over a long period of time regarding the question of iron exchange between red cell and plasma.

Certain observations have previously been made regarding the breakdown and reutilization of hemoglobin iron. In studies on blood preservation, donors were prepared by injecting radioiron and obtaining blood after the iron had been incorporated in the red cell mass. The disappearance rate of these tagged erythrocytes from the blood stream of the recipient was measured over a period of twenty-four to forty-eight hours.<sup>4, 7</sup> Thereafter, the radioiron was rapidly incorporated into new red cells so that in the ensuing days the level of radioactivity approximated that originally present. If red cell destruction occurred more gradually, no drop in the circulating radioactivity level was observed. This efficient reutilization of broken down hemoglobin iron has been commented on by several investigators as indicating that iron so liberated from hemoglobin falls into a small labile reserve which is rapidly recruited through the hemoglobin cycle.<sup>8, 9, 10</sup> It has been shown that this utilization of radioiron for hemoglobin production may be largely prevented under two circumstances.<sup>11</sup>

first, when the bone marrow is producing little or no blood and second when the iron stores are greatly enlarged. Advantage was taken of this in the choice of recipients for our studies. Subjects were selected who for one of these reasons should be unable to reutilize the radioiron liberated from tagged erythrocytes. It would then be possible to follow the intracellular radioiron through the period of time that the red cell remained in the circulation provided no free exchange of iron occurred.

## PROTEIN-IRON COMPLEXES OF THE HEMOGLOBIN CYCLE

Fig 1—In the serum iron is bound to a beta globulin which transports iron from one tissue to another within the body. In the marrow the iron is stripped from the beta<sub>1</sub> globulin by the developing red cell and synthesized along with pyrrole pigment and globin into hemoglobin. As hemoglobin the red cell iron would appear to remain within the erythrocytes until the stroma is broken down. At this time the pigment is degraded into its component parts and the iron may reappear in the serum bound to the transport globulin or may remain in the tissues incorporated in one of the iron storage proteins ferritin or hemosiderin.

### MATERIALS AND METHODS

Single isotopes of  $\text{Fe}^{55}$  and  $\text{Fe}^{59}$  obtained by cyclotron bombardment at the Massachusetts Institute of Technology were employed in both human and animal studies. Radioactive iron containing both isotopes  $\text{Fe}^{55}$  and  $\text{Fe}^{59}$  with a specific activity of 20 and 80 microcuries per milligram of iron obtained from Oak Ridge was used in some animal experiments. Radioactive donors were prepared as previously described.<sup>2</sup> Tagged blood for transfusion was drawn into acid citrate dextrose preservative and given immediately to the recipient except in one instance in which the effect of storage was under study. The circulating level of radioactivity approximately twenty minutes after blood was given to the recipient was determined and taken to represent 100 per cent of the transfused cells. In two instances, however, where subsequent levels were significantly higher, the latter values were assumed to represent 100 per cent. The blood volume as determined by T1824 dye was compared with the cell volume as determined by dilution of the transfused tagged cells. Subsequent blood samples were taken into calibrated centrifuge tubes over a period of 150 days. Hematocrits were determined on an aliquot by the Wintrobe method. The subsequent wet ashing of samples, addition of carrier iron, precipitation, electroplating and counting have been described previously.<sup>12</sup>

### EXPERIMENTAL DATA

*I Animals*—Dog SFD90 was given 0.2 m.  $\text{Fe}^{55}$  ( $1 \times 10^6$  counts per minute) intravenously and the subsequent incorporation of the iron into the circulating red cell mass was determined (Fig 2). At fifteen days 75 per cent

of the injected iron was found in the peripheral blood\*. On the twenty seventh day and until the 108th day injections of nonradioactive iron in the form of ferrous-ascorbate gelatin† totalling 4,170 mg were given intravenously. Throughout the period of observation the dog remained in good condition

Fig 2—The initial utilization of  $\text{Fe}^{55}$  in a normal dog is shown. Circulating radio levels were followed during a period of 100 days while nonradioactive iron was injected intravenously. A subsequent utilization curve with  $\text{Fe}^{59}$  is shown. The ordinate is expressed in days.

There was a gradual drop in hemoglobin from 18 to 15 grams but no change in cell indices, reticulocytes, or in the leucocyte picture. In Fig 2 is shown the level of circulating radioactivity. At 120 days 0.5 mg of  $\text{Fe}^{59}$  ( $1 \times 10^6$  counts per minute) was injected intravenously. Sixteen per cent of this iron appeared in the red blood cell mass at the end of two and a half weeks.

In two further experiments dogs were placed on corn grit and iron diets which had previously been shown to produce large iron stores in animals<sup>13</sup>. These dogs received red cells prepared by injecting radionon in a single donor dog one week previously. A similar rapid decline in circulating radioactive levels was observed in these dogs, in the neighborhood of 100 days. The red cell life was calculated from the time 50 per cent of the tagged cells had appeared in the blood of the donor dog to the time 50 per cent of the circulating radioactivity had been lost from the blood of the recipient dogs. In Dog J-FD219 the erythrocyte life span was 106 days and the average survival in Dog C-FD218 was 109 days. These dogs showed no significant hematologic

\*The dog's blood volume was determined by T1824 dye and the per cent circulating radioactivity calculated as previously described<sup>14</sup> according to the formula:  $\frac{\text{per cent activity}}{\text{counts per cubic centimeter red cells} \times \text{cubic centimeter circulating red cells}} \div \text{the counts injected}$

†This iron preparation was obtained through the courtesy of the Knox Gelatin Products, Inc., Camden, N. J.

change through the period of experimentation. The pathologic examination of both dogs revealed extensive deposits of hemosiderin and greatly increased tissue iron by analysis.

### LIFE SPAN OF ERYTHROCYTES TAGGED BY RADIOIRON

Fig 3—The solid line represents the actual radioactivity levels in the circulating blood of the recipients. The dotted line in *A*, *D*, and *E* allows for the added period of red cell life in the donor. In *E* the third line represents the additional period of blood storage.

*A* Sixty day old normal cells to patient with aplastic anemia.

*B* Pernicious anemia reticulocytes to patient with aplastic anemia.

*C* Iron deficient reticulocytes to patient with aplastic anemia.

*D* Iron deficient erythrocytes to a patient with hemochromatosis.

*E* Twenty-one-day old blood stored for twenty four days transfused to a patient with Cooley's anemia.

*F* Iron deficient reticulocytes transfused to a patient with Cooley's anemia.

**II Human Subjects**—Six populations of radioactively tagged erythrocytes were followed in recipients chosen because of their large iron stores and/or impaired bone marrow function. There follows in each instance a characterization of the blood given, the age of the red cells given, the hematologic status of the recipient, and the radioactive survival curves as determined by measuring levels of radioactivity in the recipient blood. The data are plotted in Fig 3.

**1** Five hundred cubic centimeters of blood were drawn from a young man who had been given radionon ( $\text{Fe}^{59}$ ) sixty five days previously. The donor's red cells were normal in appearance and measurements showed a mean

corpuscular volume (MCV) of 85, a mean corpuscular hemoglobin (MCH) of 32, and a mean corpuscular hemoglobin concentration (MCHC) of 35. The recipient W-FD129 was a girl of 6 years with aplastic anemia who had been transfused every six to eight weeks since the age of 2 months. Preceding the transfusion her blood showed a hemoglobin of 5 grams, red count 1.8 million, and hematocrit 16 (MCV 108, MCHC 28, MCH 31) and no reticulocytes in 1,000 red blood cells. The subsequent decline in circulating radioactivity levels is shown in Fig 3, *A*. The projected life span of the red cells, allowing for the time they had circulated in the donor, is shown by the dotted line.

*B* The same recipient, W-FD129, was transfused one month later with 250 cc of blood tagged with  $\text{Fe}^{59}$ . The donor in this case, G-FD131, had classical pernicious anemia and had received liver six days previously and radionon four days before the blood was drawn. The transfused blood had a MCV of 130, MCH 37, and MCHC 35. There were 31.9 reticulocytes. In the blood fractionated by albumin flotation<sup>14</sup> the distribution of radioactivity corresponds to the distribution of reticulocytes (Table I). These data would indicate that the isotope is found almost exclusively in the reticulocyte fraction and that, in effect, tagged reticulocytes are being transfused. Subsequent survival of this blood is shown in Fig 3, *B*.

*C* Recipient W-FD129 was used for a third study after all previously administered radioactivity had disappeared from her circulating blood. Donor SL-FD262 had typical untreated polycythemia vera. The donor's blood showed a hemoglobin of 20.1 grams with slight microcytosis and hypochromia (MCV 75, MCH 23, MCHC 31). Five hundred cubic centimeters of blood were drawn on the third day after injection of radionon. Evidence that these tagged cells were comprised chiefly of reticulocytes is shown in Table I. The determinations of circulating radioiron levels in the recipient are shown in Fig 3, *C*.

*D* Five hundred cubic centimeters of blood were drawn from the same donor, SL-FD262, on the tenth day following injection of radionon. This blood was transfused to recipient R-FD108 who had hemochromatosis confirmed by

TABLE I

IRON DEFICIENT BLOOD	COUNTS/UNIT CELLS	RETICS (%)
Top fraction	2,900	10.8
Middle fraction	920	2.9
Bottom fraction	500	1
PERNICIOUS ANEMIA BLOOD		
Top fraction	5,660	39.1
Bottom fraction	187	0.1

liver biopsy. The recipient had a saturated non binding protein, a serum iron of 250  $\mu\text{g}$  per 100 cc, and a slightly macrocytic anemia (hematocrit 40, MCV 102). Radioactivity was expressed as counts per cubic centimeter of red cells since it was felt that the red cell mass should be relatively constant through the period of observation. This is in contrast to the other cell viability experiments in which activity is related to cubic centimeters of whole blood. There is no evident explanation for the initial lower level of radioactivity unless it is

related to the temporary red cell mass increase due to the transfusion. It is to be noticed (Fig 3, *D*) that there is a reutilization in this patient of 25 per cent of the erythrocyte non similar to that seen in previous animal experiments.

*E* A third phlebotomy was performed on the donor on the twenty first day after iron injection. This blood was preserved in acid citrate dextrose for twenty five days at 4° to 6° C and then transfused. The recipient JS FD265, was a 4 year-old child who had Cooley's anemia and had received approximately twenty transfusions before the present study. On the day of transfusion his hemoglobin was 10 grams. The survival time of these red cells and the projected survival allowing for their time in the donor and preservative are shown in Fig 3, *E*.

*F* Donor LK FD244 was a patient with polycythemia vera who had been controlled by phlebotomy for two years. He showed a high grade iron deficiency at the time of phlebotomy (MCV 70 MCH 22 MCHC 30). Six days after injection of  $\text{Fe}^{59}$  500 cc of blood were removed and transfused immediately to recipient L FD263. The subsequent levels of circulating radio iron per cubic centimeter of whole blood are shown in Fig 3 *F*. The recipient in this transfusion was a 4 year old girl who had been anemic since birth with typical findings of Cooley's anemia. She had had more than eight transfusions before the present study and a hematocrit of 18.2 prior to transfusion.

In another series of observations, normal male subjects were given  $\text{Fe}^{59}$  intravenously and beginning twenty one days later iron was taken for four to six months by mouth immediately after meals. Subjects F and R consumed 200 Gm of ferrous sulfate and Subject M 400 grams. It would appear that enough iron was absorbed in this fashion to interfere somewhat with reutilization and to allow one to approximate the life span of the erythrocyte in each case (Fig 4). Mean cell age was calculated as 125 days (Subject F) 125 days (Subject R) and 114 days (Subject M).

#### DISCUSSION

The sensitivity of the counters used reach 3 per cent efficiency in the case of  $\text{Fe}^{59}$  and 20 per cent in the case of  $\text{Fe}^{50}$ . The counting levels obtained from blood samples were sufficient to allow accurate measurement of samples containing less than 5 per cent of the initial circulating radioactivity except for experiment B (Fig 3 *B*). Here accurate counting that is counts more than twice background, was attained only in values showing over 30 per cent erythrocyte survival.

In the dogs and in the patient with hemochromatosis (Figs 2 and 3 *D*) there was appreciable reutilization of the erythrocyte non in the neighborhood of 25 per cent. Since these new base lines are stable over a period of several weeks it seems justifiable to assume 100 per cent destruction of transfused erythrocytes when this level has been attained. In the remaining transfusions there was no significant reutilization. Normal subjects fed iron however showed so great a reutilization (approximately 75 per cent) that interpretation of the data is difficult.

In these studies a population of red cells of approximately one age has been followed throughout their survival period in the circulating blood. The entrance of these cells into the circulation in the donor is shown by the utilization of the injected non for hemoglobin production. In Fig 5 is a composite curve of such utilization of radioiron obtained previously in normal subjects. This

Fig 4—The initial utilization of radioiron in three normal subjects is shown and the subsequent circulating radioactive levels during the period of iron intake by mouth. The subsequent utilization curve with Fe<sup>59</sup> is also shown. It will be observed that between 100 and 150 days there is a significant decline in circulating radioactivity levels in each subject.

indicates that normally the fourth day will represent the mean age of tagged cells and that some 75 per cent of the total number of tagged cells appear in circulation between the second and seventh days.<sup>11</sup> In non deficient and pernicious anemia patients responding to treatment, the utilization may be even more rapid. For purposes of calculation in Fig 3, corrections are made by a dotted line for the mean age of the cells, according to when they would be expected to appear in the donor's circulation.

It might be questioned whether the sample taken immediately after transfusion is representative of the initial red cell level or whether during the process of transfusion which took between one-half and two hours some red cell-

might already be lost from the blood stream. It has been previously demonstrated that nonviable erythrocytes may disappear very rapidly from circulation, that is, within minutes of transfusion.<sup>4-15</sup> For this reason it appeared necessary to have some check on the initial level. Highly quantitative measurements were not possible since the blood given was only roughly measured and

### UTILIZATION OF RADIOIRON FOR HEMOGLOBIN PRODUCTION

Fig. 5—On the basis of data previously reported a composite utilization curve is shown. This has been normalized from the 4 per cent which appears in the blood to 100 per cent so that the daily increment of radioiron incorporated in erythrocytes may be shown.

since the transfusion set was not always completely emptied of blood. In patient FW FD129 three transfusions were given (I, 3, 1 B and C). The calculated blood volume on the basis of the radioactivity administered and the initial post transfusion level were respectively in observations A, B and C 1340 cc, 1400 cc and 1280 cubic centimeters. Since A represents fresh normal cells which have been shown previously to be a reliable measure of the circulating mass,<sup>16</sup> the immediate survival of the other two populations of red cells may be assumed to be reasonably good. In D the calculated radioactive cell volume was 2160 cc while the Evans blue dye determination gave a cell mass of 1975 cubic centimeters. In E a blood volume employing T1824 immediately after transfusion gave a determination of 1030 cc whereas the radioactive blood volume was 950 cubic centimeters. In patient L FD263 (F) an Evans blue blood volume performed six months after the initial study was 1500 cc as compared with the post transfusion radioactive measurement of 1200 cc in the same patient. In no instance therefore was there an indication of an abnormally large blood volume by radioactive measurement using the twenty minute samples. This would appear to exclude any appreciable cell destruction during the time of transfusion since such an event would result in a greatly enlarged cell volume determination by the radioactive method.<sup>15</sup>

Previous work has shown that very little radionon injected intravenously appears in the circulating red cell mass when bone marrow synthesis is severely impaired, suggesting that only as a result of hemoglobin synthesis by the developing red cell can radionon gain access to the erythrocyte<sup>10, 11</sup>. In the present studies, reutilization of iron is largely or completely blocked. Should there be an exchange of hemoglobin iron with plasma iron, the level of circulating activity would rapidly fall. The radioactivity in the recipients' circulation, however, followed a survival curve similar to that obtained when the pyridol pigment<sup>17</sup> or globin of the hemoglobin molecule is isotopically tagged. It would then appear to be a safe assumption that the mature red cell throughout its life span has no appreciable exchange of iron with its surrounding environment.

In three dogs the average turnover of iron from the time of appearance in circulation to disappearance is from 95 to 109 days. In patients transfused with various populations of erythrocytes, 50 per cent of the erythrocytes had disappeared from circulation between 77 and 110 days after their appearance in circulation. The one normal cell population (Fig 3, A) showed a mean cell survival of 110 days. This is consistent with other data of the life of the human red cell<sup>18</sup> and would indicate that normally there is approximately a 1 per cent daily turnover of iron through the red cell mass as a result of erythropoiesis and erythrocyte breakdown.

In contrast to differential agglutination studies in which the red cell population measured is a mixed one, in these studies red cells of a single age could be followed throughout their life period. By drawing blood shortly after injection of radionon it was possible to obtain young cells as shown in Fig 3, B and C. That these young cells represent reticulocytes is indicated by Table I and by other studies,<sup>19</sup> demonstrating that in fractionated blood the reticulocyte level and radioactive level show a high degree of correlation. Other studies<sup>3, 20</sup> have demonstrated that reticulocytes are capable of synthesizing heme and maturing, and that their disappearance from circulation is associated with an increase in mature red cells. The present observations would indicate that they not only mature but have a reasonably normal life span.

It is of interest that in pernicious anemia the reticulocytes after liver therapy have a normal life expectancy, since other observations on mixed populations of untreated pernicious anemia macrocytes have indicated a considerably shorter life span. Iron deficiency reticulocytes as shown in Fig 3, C and F survive a somewhat shorter than normal period, whereas the same cells in a subject with a relatively normal blood picture show a relatively normal survival. This suggests an influence of anemia per se on the life span although the varied nature of the recipients is such that no conclusions can be drawn. The different survival curves obtained with red cells from the same donor in different recipients (Fig 3, C and D) emphasize the importance of such factors. It is of interest that storage of blood before transfusion seemed to result in an immediate loss of approximately 20 per cent of the transfused red cells, while the remaining erythrocyte population survived what would appear to be a relatively normal life span.

In subjects fed non the erythrocytes remained in their normal environment and were subjected to no manipulation. Although the great reutilization obscures the erythrocyte breakdown the mean cell age estimated at 122 days is quite similar to the figure of 127 days obtained by Shemin and Rittenberg<sup>1</sup> using  $N^{15}$  in the same type of study.

#### CONCLUSIONS

The reutilization of radioactive iron from broken down red cells is effectively blocked by the presence of enlarged iron stores and/or bone marrow dysfunction in animals and in human subjects. By using recipients with these characteristics, the erythrocyte unit of iron metabolism may be isolated.

Under these experimental conditions it was possible to measure the life span of a red cell population of a single age. Observations were made of tagged macrocytes, microcytes and normal red cells in normal and anemic recipients. The reticulocytes from a patient with pernicious anemia responding to therapy and from a patient with iron deficiency have been shown to have a relatively normal life span.

The erythrocyte iron turnover measured directly is approximately 1 per cent a day in dog and in man.

There is no discernible exchange of iron between the red cell and its surroundings throughout the life span of the erythrocyte.

## TYROSINE METABOLISM IN HUMAN SCURVY

WALTER F. ROGERS, M.D. \* SYRACUSE N. Y. AND  
FRANK H. GARDNER, M.D. † BOSTON MASS.

### INTRODUCTION

It has been shown that vitamin C is intimately connected with the metabolism of tyrosine and phenylalanine. Sealock and Silberstein<sup>1</sup> reported that when tyrosine was fed to scorbutic guinea pigs homogentisic acid was excreted, a phenomenon that could be prevented by the administration of ascorbic acid. They also demonstrated<sup>2</sup> that tyrosine, fed to guinea pigs on a diet deficient in vitamin C, resulted in the excretion of homogentisic, *p*-hydroxyphenylpyruvic, and *p*-hydroxyphenyl lactic acids, and that the administration of ascorbic acid prevented the abnormal excretion of these metabolites. Painter and Silva<sup>3</sup> fed large doses of tyrosine to scorbutic guinea pigs but found no excretion of homogentisic acid in the urine but did observe excessive excretion of the intermediary metabolites of tyrosine. In addition, Levine and co-workers<sup>4</sup> noted that premature infants fed diets of vitamin C free cows milk containing 5 Gm. or more of protein per kilogram of body weight excreted *p*-hydroxyphenyl lactic and *p*-hydroxyphenylpyruvic acids the excretion of which was eradicated by the administration of ascorbic acid.

The purpose of this communication is to report the effects in normal and scorbutic human beings of feeding large amounts of tyrosine and the rapid effect of ascorbic acid in correcting the abnormal tyrosine metabolism found in the individuals with scurvy.

### MATERIALS AND METHODS

The patients observed in this study were four scorbutic men aged 62, 64, 66, and 71 years, two normal men aged 22 and 29, and one normal woman aged 75 ‡.

During the course of the studies the scorbutic patients were maintained on a vitamin C free diet consisting of two quarts of boiled skimmed milk, 40 grams of boiled rice and thirty six soda crackers daily. Sugar coffee and vitamin C free purified jellies were allowed ad libitum. The two normal male subjects were allowed their usual diets. The normal female subject was maintained on the same vitamin C free diet as the scorbutic patients but received large supplements of crystalline ascorbic acid. Twenty four hour samples of urine were collected daily from the patients and after suitable control periods of at least six days, all except one scorbutic patient were given 20 Gm. of powdered L-tyrosine per day orally divided into four doses of 5 Gm. each.

¶This 5 year-old patient was thought to have scurvy because of purpura. The purpura was of senile type only and he was then studied as a normal patient after receiving large supplements of ascorbic acid.

‡Kindly supplied by Merck & Co., Inc., Rahway, N. J.

After a period of tyrosine administration, four of the scorbutic patients received large doses of ascorbic acid in addition to the tyrosine. When possible, a control period was included after the discontinuance of tyrosine.

The ascorbic acid content of the white blood cell platelet layer was determined by the method of Butler and Cushman.<sup>6</sup> The addition of 100 mg of human fibrinogen (Fraction I of human plasma [Cohn]<sup>7</sup>) to 10 ml of oxalated blood produced better separation of the white cell platelet layer for assay. The whole blood ascorbic acid levels were determined by the method of Keuthner.<sup>8</sup>

The total excretion of hydroxyphenyl compounds in the urine, expressed as tyrosine equivalents, was measured by the method of Medes.<sup>9</sup> The compounds measured by this method include tyrosine, *p* hydroxyphenyl lactic, and *p* hydroxyphenylpyruvic acids, and are designated "tyrosyl derivatives."

The reduction of phosphomolybdic acid by the urine as outlined by Medes<sup>9</sup> also was determined. This method, for the most part, measures the excretion of *p* hydroxyphenyl pyruvic acid, but is not specific and will react with homogentisic acid and other reducing substances. Since the reducing substances excreted by the scorbutic patients, while receiving tyrosine, were not chemically identified, their reducing power was calculated as equivalents of a standard solution of hydroquinone. The presence of homogentisic acid was tested for qualitatively by adding ferric chloride to urine that was made alkaline with sodium hydroxide. Calibration curves with hydroquinone standards for the phosphomolybdic reducing power and *l* tyrosine for the "tyrosyl" derivatives were prepared using the Evelyn photoelectric cell colorimeter. The tyrosyl derivatives were read in the colorimeter exactly one minute after color formation to obtain maximum values. If they were read after allowing the color reaction to proceed for twenty minutes, as outlined by Levine and associates,<sup>4</sup> there was a marked drop in color intensity. The phosphomolybdic reaction was allowed to proceed for three hours before readings were made in the colorimeter.

## RESULTS

**Scorbutic Patients—Case 1** (Fig 1), a 62 year old man, was admitted to the Boston City Hospital because of pain in the right thigh. He had classical signs of scurvy: a positive tourniquet test, purpura on the legs, ecchymoses of the right thigh, and hematomas around carious teeth. There was no detectable ascorbic acid present in the white blood cell platelet layer of the blood. In a control period of six days on a vitamin C free diet, this patient's total "tyrosyl" excretion averaged 195 mg of tyrosine equivalents per day with a range of from 128 mg to 248 mg per day. In this same control period, the excretion of reducing substances as measured by the reduction of phosphomolybdic acid was equivalent to an average of 84 mg of hydroquinone per day and ranged from 37 mg to 146 mg per day.

When the patient was given 20 Gm of tyrosine daily, for six days, the excretion of "tyrosyl" compounds immediately increased, and on the sixth day of administration reached a level of 6,300 milligrams. The reducing substances of the urine remained unchanged from the control values for three days, but then steadily increased until on the sixth day of tyrosine administration the concentration was equivalent to 6,300 mg of hydroquinone per day.

The patient was then given the daily addition of 1 Gm of *l* ascorbic acid orally as well as 20 Gm of tyrosine per day for five days. The ascorbic acid was then reduced to 0.5 Gm per day for the remainder of the study. With ascorbic acid therapy, the excretion of "tyrosyl" compounds immediately decreased and on the second day of therapy was 533 mg and fluctuated between 453 and 1,073 mg per day for the next seven days. The study ended. The reducing substances of the urine showed no decrease on the first day of ascorbic acid therapy and, in fact, increased to 6,620 mg of hydroquinone equivalents. However, on the second day of ascorbic acid therapy, the concentration of reducing substances dropped to slightly above control levels, averaged 152 mg per day, and remained

it that value for four days. At this time the reducing power increased to a daily average of 252 mg of hydroquinone equivalents and is interpreted as an increased excretion of ascorbic acid since this compound will reduce phosphomolybdic acid under the conditions used.

During the period of tyrosine administration, the capillary fragility increased as measured by the tourniquet test, and there was some bleeding from the gingival hematomas. All signs of capillary fragility disappeared promptly after administration of ascorbic acid.

Fig. 1—Case 1 (scurvy). Twenty-four hour excretion levels before and after treatment.

Case 2 (Figs. 2 and 3) was a 64-year-old man with the clinical picture of scurvy and with no detectable ascorbic acid in the white cell platelet layer. He was maintained on the same vitamin C free diet as provided for the first patient. In a nine-day control period he excreted a daily average of 109 mg of tyrosyl compounds. The reducing substance of the urine in this same control period was equivalent to a daily average of 74 mg of hydroquinone.

The patient was then given 20 Gm of tyrosine daily orally with a large immediate rise in excretion of "tyrosyl" derivatives. On the second day he excreted 7,700 mg and on the fifth day 16,120 milligrams. On the seventh day of tyrosine administration, he was given 2 Gm of ascorbic acid orally per day. This dose was continued for five days and then decreased to 1 Gm. per day for the remainder of the observation period. Following the administration of ascorbic acid the excretion of tyrosyl compounds rapidly fell and, although the patient received tyrosine for twenty-five days after institution of antiscorbutic therapy, his excretion of tyrosyl derivatives after the initial drop became evident averaged only 336 mg per day with a daily range of from 200 to 1,400 milligrams. Tyrosine was stopped for a period of one week during which time the average excretion dropped to 30 mg per day. In order that the patient should act as his own control he was given tyrosine for another eight-day period during which time the average excretion of tyrosyl derivatives was 312 mg per day with the daily maximum being 400 mg on the fourth day. In a final control period of ten days without tyrosine he excreted an average of 110 mg per day.

Fig 2—Case 2 (scurvy) Daily 'tyrosyl' excretion

Fig 3—Case 2 (scurvy) Reducing substance in the urine measured as hydroquinone equivalents

The reducing substances in this patient's urine, during the administration of tyrosine increased rapidly to 3,480 mg of hydroquinone equivalents on the second day and ranged above 2500 mg per day throughout this period except for one value of 1,340 mg which may be in part an incomplete sample. There was a marked fall concomitant with the administration of 2 Gm of ascorbic acid per day to an average level of 471 mg of hydroquinone per day. Again it is believed that this higher level of excretion than in the original control period was caused by the excretion of ascorbic acid and was not due to the administration of tyrosine. This contention is borne out by the fact that when tyrosine administration was discontinued for seven days the daily average remained essentially the same (446 mg of hydroquinone equivalents per day) and that on reinstitution of tyrosine administration the level tended to fall slightly averaging 392 mg of hydroquinone per day.

During the period of tyrosine administration, there was a marked increase in capillary fragility. For the first time, the tourniquet test produced numerous small hematomas over the forearm as well as petechial hemorrhages. The patient became weak and developed nausea and diarrhea, all symptoms disappeared when ascorbic acid was given.

Case 3 (Table I) was a 71 year old man who entered the hospital with hematomas of both calves and marked capillary fragility. There was no detectable ascorbic acid in the white blood cell platelet layer. Throughout the study the patient was on a vitamin C free diet and received no additional tyrosine.

In a six day control period before the administration of ascorbic acid the patient excreted an average of 201 mg of hydroxyphenyl compounds per day and the reducing substance of the urine was equivalent to 64 mg of hydroquinone per twenty four hours. After this control period the patient was given 1 Gm of ascorbic acid a day orally for five days and then 0.5 Gm for the remainder of the study. With ascorbic acid therapy there was no significant change in excretion of tyrosyl derivatives which averaged 196 mg per day. The reducing substances in the urine remained low (averaging 92 mg hydroquinone equivalents per day) for four days and then rose to an average excretion of 192 mg per day which undoubtedly reflected the increased amounts of ascorbic acid being excreted in the urine.

TABLE I CASE 3 (SCURVY) EXCRETION LEVELS BEFORE AND AFTER ADMINISTRATION OF ASCORBIC ACID

TREATMENT	DAYS	AVERAGE TYROSYL DERIVATIVES (MG/24 HR.)	AVERAGE HYDRO QUINONE EQUIVALENTS (MG/24 HR.)
0	6	201	64
Ascorbic acid			
10 Gm. 5 days	10	196	192
0.5 Gm. 5 days			

Case 4 (Fig 4) The patient entered the hospital complaining of weakness and inability to walk. He had large hematomas in the right popliteal fossa extending to the groin. There was no measurable vitamin C in the white blood cell platelet layer of the blood. Throughout the observations the patient was maintained on the vitamin C free diet. During a five day control period the patient excreted a daily average of 219 mg of 'tyrosyl' derivatives. The average daily excretion of reducing substances in the urine was 20 mg hydroquinone equivalents.

The patient was then given 20 Gm of tyrosine daily. By the third day the 'tyrosyl' excretion had increased to 11300 mg and the reducing substances to 3,005 milligrams.

During the period of tyrosine administration the patient developed nausea, diarrhea, angulitis and marked lassitude. The diet intake was not maintained and urine collections could not be made. Tyrosine was discontinued and the patient received 15 Gm of ascorbic acid parenterally and 25 Gm orally daily. Despite the large doses of ascorbic acid and parenteral dextrose solution the patient did not respond. He died five days after the onset of ascorbic acid therapy in an episode of pulmonary edema and shock. Post mortem examination revealed only pulmonary congestion and no hemorrhagic phenomena.

FIG 4—Case 4 (scurvy) Excretion levels during tyrosine administration

TABLE II RESPONSE OF THREE NORMAL SUBJECTS TO 20 GM PER DAY OF L TYROSINE ORALLY

\*500 mg ascorbic acid given orally during control and administration of tyrosine

†These values are markedly elevated because of ascorbic acid administration throughout this period

*Normal Patients—Normal Subject 1* (Fig 5) in a control period of fourteen days excreted an average of 242 mg of tyrosyl compounds per day. The reducing substances in the urine in this same period were 184 mg hydroquinone equivalents per day. He then received 20 Gm of tyrosine daily for eleven days which resulted in a gradually increased excretion of tyrosyl compounds until the fifth day when it was 1270 milligrams. Thereafter for the next five days a moderate fall in the excretion of tyrosyl derivatives occurred, followed by a second peak reaching 1018 mg on the last day of tyrosine administra-

Fig 5.—Normal Subject 1. Excretion levels of normal subject during tyrosine administration.

tion. The average excretion of tyrosyl derivatives during the entire period of tyrosine administration was 755 mg per day. In a subsequent control period without tyrosine the excretion dropped to preadministration levels.

The reducing substances in this individual's urine did not change appreciably during any portion of the experiment. During the administration of tyrosine they were 167 mg hydroquinone equivalents per day which was slightly lower than in the previous control period. Whole blood ascorbic acid levels were within normal limits and showed no significant change during the control periods or when the patient was receiving tyrosine.

In order to determine if added ascorbic acid would change the response to 20 Gm of tyrosine per day, the same observations were repeated on this patient with the exception that he was given 500 mg of ascorbic acid daily starting three days before the administration of tyrosine and continuing through the entire period of tyrosine administration (Table II, Period 2). The addition of ascorbic acid in this instance did not change the response to tyrosine as evidenced by the fact that on one day the patient excreted 1134 mg of 'tyrosyl' derivatives and the average excretion during tyrosine administration was 734 mg per day as compared with the value of 755 mg per day when he was not receiving ascorbic acid. The reducing substances in the urine immediately increased when he took ascorbic acid, but were not augmented further on addition of tyrosine to his diet.

*Normal Subject 2* The response to 20 Gm of tyrosine daily for eight days in another normal male, aged 22, is shown in Table II. It is similar to that of the previously described normal person, although this patient excreted slightly less hydroxyphenyl compounds, averaging 614 mg per day during the period of tyrosine administration. As in the first normal subject, after an initial rise, there was a decreased excretion for three to four days followed by a second rise.

*Normal Subject 3*, a 75 year old woman, was given the same vitamin C free diet as described for the scorbutic patients. In addition, she received 1 Gm of ascorbic acid orally for the first eleven days of control observation and 2 Gm daily throughout the remainder of the study. During a control period of nine days she averaged 218 mg per day of "tyrosyl" derivatives. She was then given 20 Gm of tyrosine daily for a five day period and the "tyrosyl" excretion averaged 582 mg per day. During another five day control period the excretion averaged 230 mg per day.

During a nine day control period while receiving 2 Gm of ascorbic acid daily, the patient's average excretion of reducing substances was 683 mg hydroquinone equivalent. During the period of tyrosine administration it rose to a daily average of 887 milligram. In the second five-day control period the daily average was 636 milligrams. Again it is believed that the high values in the control period are associated with the reducing power of ascorbic acid. This normal subject showed a rise in reducing power of the urine during tyrosine administration. Although no complete explanation is available, the large dosage of this amino acid may have materially aided in the excretion of ascorbic acid.

#### DISCUSSION

From the foregoing results, it would seem safe to assume that the relationship between ascorbic acid and the metabolism of tyrosine in the adult human being is similar to that which had previously been demonstrated in the guinea pig<sup>1, 2</sup> and the premature infant.<sup>5</sup> Sealock<sup>1</sup> has reported that normal human beings on a "diet practically free of ascorbic acid" excrete significant amounts of homogentisic acid when ingesting tyrosine, which was prevented by "reasonably large doses of crystalline ascorbic acid." However, no quantitative data are presented as to the amount of tyrosine ingested, the excretion of homogentisic acid, or the amount of ascorbic acid given.

In the present observations, the ingestion of tyrosine orally by scorbutic patients resulted in a markedly increased excretion of "tyrosyl" derivatives. The method used for the detection of the "tyrosyl" compounds theoretically measures tyrosine, *p*-hydroxyphenylpyruvic acid, and *p*-hydroxyphenyl lactic acid. As the urines were not fractionated or the compounds isolated, it is impossible to say which ones were proportionally responsible for the increased excretion of hydroxyphenyl compounds. Evidence that a large proportion was due to *p*-hydroxyphenylpyruvic acid is found in the marked increase of the reducing power of the urine. However, this reaction is not specific since another intermediary of tyrosine metabolism, namely homogentisic acid, will cause the reduction of phosphomolybdic acid. Although qualitative tests for homogentisic acid in these urines were negative, it conceivably could have been present and could have affected the quantitative reduction of phosphomolybdic acid, but could not be detected qualitatively. The absence of homogentisic acid is more in keeping with the animal studies of Painter and Silva.<sup>3</sup>

In the scorbutic patients, the increased power of the urine to reduce phosphomolybdic acid lagged behind the increased excretion of tyrosyl derivatives, the latter increasing immediately after the ingestion of tyrosine. Likewise, the response of the reducing substances to ascorbic acid in one patient (Case 1) was slower than that of the total hydroxyphenyl compounds. Despite the nonspecificity of the methods used the changes noted in the scorbutic patients would seem to be the result of the tyrosine and ascorbic acid administration since the regimes were constant except for these two variables.

The excretion of tyrosyl derivatives by scorbutic patients who were maintained on a vitamin C free diet did not differ appreciably from that of normal subjects when they were not receiving tyrosine. The metabolic abnormality was noted only when they were given exogenous tyrosine. Furthermore the scorbutic patient (Case 3) who received only ascorbic acid and no tyrosine showed no statistically significant change in excretion of "tyrosyl derivatives" after the administration of ascorbic acid. Normal Subject 3 demonstrated that the dietary regime had no significant role in tyrosyl excretion.

The scorbutic patients demonstrated a progressive increase in capillary fragility while receiving tyrosine. While the death of the patient (Case 4) cannot be ascribed to a hemorrhagic lesion as a result of scurvy, nevertheless all the vitamin C deficient patients showed progression of the scorbutic skin lesions associated with increased weakness and lassitude during administration of L tyrosine. Presumably the administration of amino acid in these large amounts placed an increased demand on the unmeasured body stores of vitamin C. In the original work of Scaloek<sup>1</sup> it is implied that the feeding of tyrosine results in a depletion or excess utilization of the ascorbic acid of the body. This phenomenon was apparently demonstrated clinically under the conditions used in the present study by the progressive intensity of the signs and symptoms of scurvy. However in the normal individual there was no significant decrease in the ascorbic acid content of the whole blood during the administration of tyrosine and when these same individuals were given added ascorbic acid before and during administration of tyrosine it did not change their response to this amino acid.

That the abnormality of the metabolism of hydroxyphenyl compounds has wider implications than in scurvy alone has support in the effect that liver extract and pteroylglutamic acid have on the metabolism of hydroxyphenyl compounds. Swendseid and co-workers<sup>10, 11</sup> have reported that patients with pernicious anemia excrete abnormally large amounts of hydroxyphenyl compounds and that the excretion of these compounds decreases to normal levels when liver extract is given. Scaloek and Lepow<sup>12</sup> also have shown that antipermeicous marmoset extracts partially improved the tyrosine metabolism of scorbutic guinea pigs. Likewise pteroylglutamic acid has been shown to have an effect on the metabolism of hydroxyphenyl compounds in scorbutic guinea pigs both in vivo<sup>13</sup> and in vitro experiments<sup>14</sup>. In addition the administration of ascorbic acid to animals deficient in pteroylglutamic acid has altered the course of this deficiency.<sup>15</sup>

## SUMMARY

The metabolism of tyrosine was studied in four patients with scurvy and in three normal individuals. In six of these individuals, 20 Gm of tyrosine per day was given by mouth for periods varying from five to thirty one days.

The patients with scurvy, while on a vitamin C-free diet and oral administration of tyrosine, excreted large amounts of "tyrosyl" derivatives, and the ability of their urine to reduce phosphomolybdic acid increased markedly presumably due in part to the presence of *p*-hydroxyphenylpyruvic acid. The addition of ascorbic acid to this regime in the scorbutic patients resulted in a rapid decrease in the excretion of "tyrosyl" derivatives and the disappearance of the abnormal reducing material in the urine.

The excretion of "tyrosyl" derivatives in normal individuals on tyrosine was comparable with that of scorbutic subjects during the period when they were receiving ascorbic acid. At no time did the reducing substance of the urine of normal individuals rise significantly while they were receiving tyrosine. The addition of ascorbic acid to a normal individual's diet did not change the response to the administration of tyrosine.

It is concluded that individuals with scurvy have a marked defect in the metabolism of tyrosine and hydroxyphenyl compounds and that previous experiments with scorbutic animals and premature infants are in general agreement with the findings reported here.

It seems unlikely that this defective metabolism of tyrosine plays a significant role in the clinical picture of scurvy since the excretion of "tyrosyl" derivatives was not remarkable unless added tyrosine was given.

The clinical status of scurvy is made more severe during tyrosine therapy with increase in capillary fragility. These manifestations are completely controlled when ascorbic acid is added to the diet despite continued administration of tyrosine.

# OBSERVATIONS ON THE ETIOLOGIC RELATIONSHIP OF ACHYLIA GASTRICA TO PERNICIOUS ANEMIA

## XI HEMATOPOIETIC ACTIVITY IN PERNICIOUS ANEMIA OF A BEEF MUSCLE EXTRACT CONTAINING FOOD (EXTRINSIC) FACTOR UPON INTRAVENOUS INJECTION WITHOUT CONTACT WITH GASTRIC (INTRINSIC) FACTOR

FRANK H GARDNER, M D,\* JOHN W HARRIS, M D,  
ROBERT F SCHILLING, M D,† AND  
WILLIAM B CASTLE, M D  
BOSTON, MASS

PREVIOUS observations<sup>1, 2</sup> have shown that 200 Gm of beef muscle are hematopoietically active in addisonian pernicious anemia when 150 ml of normal human gastric juice also are given by mouth within six hours, or preferably simultaneously, as a daily regime for a period of ten days. If an acid mixture of beef muscle and gastric juice is incubated for twelve hours for the purpose of effecting peptic digestion of the beef muscle and is then neutralized, it also is active.<sup>3</sup> On the other hand, if the incubated mixture is heated to 100° C for five minutes, its hematopoietic activity as determined by oral administration is destroyed,<sup>3</sup> whereas that of whole liver or liver extract is not detectably affected by such a procedure. From this it was assumed that the thermostable antipernicious anemia principle of liver was *not* formed by the incubation procedure *in vitro* and that the effect of heat was merely to destroy a thermolabile factor in the gastric juice.

If a beef muscle and gastric juice mixture is given at an acid pH (1.8 to 3.5) subsequent to the twelve-hour acid incubation period, no hematopoietic effect appears.<sup>3</sup> It, however, this acid incubated mixture is treated with alkali to give a pH of 5 to 7 just prior to oral administration, it is active. This suggested that a preliminary chemical interaction occurred between the so called extrinsic factor of beef muscle and the intrinsic factor of normal human gastric juice at or about neutrality within the intestinal tract. Such a reaction was conceived as necessary for the eventual formation of the antipernicious anemia principle in the body. It seemed probable, therefore, that the extrinsic factor was chemically different from the antipernicious anemia principle of liver.

Because of this evidence, the increased hematopoietic activity in pernicious anemia of liver<sup>4</sup> and of relatively crude liver extracts<sup>5</sup> when given orally together with normal human gastric juice was originally assumed to indicate the presence of extrinsic factor as well as of the antipernicious anemia principle.<sup>6</sup> However, it was later shown<sup>7</sup> that even refined liver extracts when given by

mouth were potentiated in their hematopoietic effect by gastric juice and that destruction of the antipernicious anemia principle of such extracts by hydrolysis with 5 per cent sulfuric acid resulted likewise in the loss of extrinsic factor activity. Recently it was found that the hematopoietic activity of orally administered pure vitamin  $B_{12}$  derived from liver (presumably the antipernicious anemia principle) also was enhanced by the simultaneous administration of normal human gastric juice—but that the activity of the combination when given orally was not so great as that of the vitamin  $B_{12}$  when administered alone parenterally.

The observations reported here concern questions obviously raised by these findings: (1) Can extrinsic factor *alone* (beef muscle) act directly as the antipernicious anemia principle—that is, is a suitable preparation of beef muscle, like vitamin  $B_{12}$ , hematopoietically effective in pernicious anemia upon parental administration without contact with gastric juice? (2) Is the hematopoietic potentiating action of intrinsic factor in pernicious anemia *specific* only for vitamin  $B_{12}$  and chemically similar substances in beef muscle and in other foods, or does intrinsic factor also facilitate the nonspecific absorption or otherwise enhance the hematopoietic action of other substances?

#### METHODS

All patients studied had Addisonian pernicious anemia either in relapse or without previous treatment. The diagnosis was established by the characteristic blood and bone marrow morphology and by the presence of histamine fast achlorhydria. It was confirmed in each patient by one or more reticulocyte responses to specific therapy and eventually by a return to normal blood values as a result of liver extract therapy. During the observations the basal diet of the patients contained no meat, fish, or eggs and little milk. The administration of the test substances, including the normal human gastric juice, was made at 8 P.M. The last meal of the day, consisting of tea and white toast, was at 4 P.M. This separated the test substance by at least four hours from any food constituent considered likely to contain extrinsic factor.

The attempted plan of the observations was to administer to the patients during three consecutive periods of ten or more days each a uniform daily dose of extrinsic factor derived from 400 Gm of beef muscle first orally, then orally with 150 ml of normal human gastric juice, and finally intravenously *without* gastric juice. In evaluating the hematopoietic activity of the various preparations used, the method of serial reticulocyte responses<sup>3</sup> was employed.

Formigne<sup>3</sup> has shown that a 70 per cent alcohol extract of beef muscle possesses extrinsic factor activity in pernicious anemia. Consequently the preparation of such an extract was undertaken, starting with a concentrated aqueous extract of lean beef muscle,\* of which 1 Gm was derived from 14 to 16 Gm of beef muscle. Following dilution of the aqueous extract with an equal volume of distilled water, a 70 per cent alcohol concentration by volume was made by the addition of suitable amounts of 95 per cent ethyl alcohol. The

flocculent precipitate resulting was allowed to settle overnight at 5° C. The supernatant liquid was then filtered through a fluted paper filter and the precipitate washed on the paper with one-fifth the initial volume of 70 per cent alcohol. The precipitate was then discarded. Thereafter, the alcoholic filtrate was concentrated by free evaporation on electric hot plates. At the final point of concentration, the boiling point reached 108° ± 4° C. The volume of the concentrated filtrate was then so adjusted with distilled water that 1 ml was derived from 40 Gm of the original beef muscle. The filtrate was then bottled and autoclaved for twenty minutes. Throughout the preparation of the alcoholic extract, precautions were maintained to employ pyrogen-free fluids and apparatus.

When the preparation was given orally, 10 ml were diluted in either 150 ml of physiologic saline or in 150 ml of neutralized normal human gastric juice secreted after the injection of histamine. When given intravenously, 10 ml of the extract were mixed with 500 ml of 5 per cent sterile dextrose and water. The slow intravenous administration of the meat extract was followed in a few instances by moderate or mild febrile reactions. These reactions

usually developed with the first two or three injections and did not thereafter recur. No signs of subsequent sensitization to the extract or to beef appeared in any of the patients.

## OBSERVATIONS

*Is Extrinsic Factor Hematopoietically Effective Upon Parenteral Administration Without Intrinsic Factor?* The results of the observations upon the hematopoietic effect of the 70 per cent alcohol extract of beef muscle in seven patients with pernicious anemia are shown in Table I. Although the individual reticulocyte peaks are small, the trend of their values and the time of their maxima and of the clinical improvement exhibited by the patients convinced the observers of the validity of the conclusions drawn under the usual carefully controlled conditions of the tests. In one patient, Case 105, the extract derived from 600 Gm of beef muscle given orally daily together with 150 ml of normal human gastric juice was hematopoietically active. In two patients, Cases 109 and 111, the extract derived from 400 Gm of beef muscle was inert upon daily oral administration, was slightly active upon daily oral administration with 150 ml of normal human gastric juice, and was still more active upon daily intravenous administration without gastric juice. In one patient, Case 110, the preparation of extrinsic factor was weakly active upon

daily oral administration, was slightly more active when given with normal human gastric juice, and was still more active upon intravenous administration without gastric juice. Three patients, Cases 106, 107, and 108, received the extract without gastric juice by intravenous injection only. A definite reticulocyte response appeared in each instance. In Case 107 the red blood cell count

Fig. 1—Hematopoietic effects in Case 111 of the uniform daily administration of various substances in successive periods as shown. (I) refers to 10 ml. of 70 per cent alcohol soluble beef extract derived from 400 Gm. of beef muscle. Note the three successive reticulocyte peaks indicating respectively activation of the extract upon oral administration with normal human gastric juice, its greater activity upon intravenous administration without gastric juice and finally the still greater activity of vitamin B<sub>12</sub> when given in a dose of 1  $\mu$ g daily.

increased in twenty days from 2.07 to 3.09 millions per cubic millimeter. In two patients, Cases 108 and 111, the daily intramuscular administration of 1  $\mu$ g of crystalline vitamin B<sub>12</sub>\* following the period of intravenous administration of the beef muscle extract resulted in another definite reticulocyte peak. From this it was inferred that the hematopoietic activity of the extrinsic factor preparation upon parenteral administration was distinctly less than that of 1  $\mu$ g of vitamin B<sub>12</sub>. The results in Case 111 are shown in Fig. 1.

*Is the Hematopoietic Potentiating Action of Intrinsic Factor Specific?*  
In order to determine whether or not normal human gastric juice possesses a nonspecific effect in enhancing absorption from the alimentary tract in pernicious anemia, the blood levels of test substances presumably unrelated to vitamin B<sub>12</sub> were followed after oral administration to seven patients with pernicious anemia. Most of the observations were made before treatment, but a few were conducted subsequently during remission after specific therapy. Thus, blood glucose and blood tyrosine levels were determined following the

\*Kindly supplied by Dr. Augustus Gibson of Merck & Co. Inc., Rahway, N. J.

oral administration of single doses of 50 and 10 Gm respectively of those substances to fasting patients. The test substances were mixed together and given simultaneously with either 150 ml of normal human gastric juice or with an equal amount of physiologic salt solution upon alternate days. Blood alpha amino nitrogen and nonprotein nitrogen levels were similarly followed after the ingestion of 50 Gm of vitamin free casein (Labeo) (previously shown to contain no extrinsic factor)<sup>10</sup> with either physiologic saline or normal human gastric juice upon different days. Glucose determinations were made according to the method of Folin and Wu<sup>11</sup> and of Folin,<sup>12</sup> tyrosine by the method of Bernhart and Schneider<sup>13</sup> alpha amino nitrogen by the method of Krauel<sup>14</sup> and nonprotein nitrogen by the method of Folin and Wu.<sup>1</sup> As shown in Table II, no consistently enhanced absorptive effects upon glucose, tyrosine, or casein were observed that could be attributed to the gastric juice in any of the patients with pernicious anemia so tested before effective therapy. Not shown are the similar negative results obtained in a few patients after treatment.

The possible hematopoietic potentiating effect of normal human gastric juice upon synthetic pteroylglutamic acid<sup>8</sup> either by increasing its absorption or by other action was also assayed in two patients. Cases 112 and 113, not included in the tables. To each 0.5 mg of pteroylglutamic acid was given orally daily during a first period of ten or more days together with 150 ml of physiologic saline, and during a second period of ten days the same amount of pteroylglutamic acid was given orally daily together with 150 ml of normal human gastric juice. In the first period of Case 112 a reticulocyte peak of 9.3 per cent was reached on the eighth day following an initial red blood cell count of 1.63 million per cubic millimeter. In Case 113 the corresponding value was 8.1 per cent reticulocytes on the eleventh day following an initial red blood cell level of 1.86 million per cubic millimeter. When gastric juice replaced the physiologic saline in the second periods no detectable reticulocyte peaks appeared in either patient. Thus no hematopoietic potentiating effect of normal human gastric juice upon pteroylglutamic acid was observed.

#### DISCUSSION

In 1938 Dock<sup>15</sup> wrote: "It seems probable that beef muscle contains the same material as liver but in quantities too small to be effective unless absorption is increased by gastric or enteric ferment. For some reason parenteral administration of muscle extract seems not to have been tried, but extract of muscle which had been incubated with gastric juice was potent in Wilkinson's experiments."

The potentiation of the hematopoietic activity of vitamin B<sub>12</sub> with gastric juice upon oral administration<sup>7, 1</sup> and the present confirmation of our preliminary observation<sup>7</sup> that the extrinsic factor of beef muscle is hematopoietically active upon parenteral administration *without gastric juice* go far to support Dock's surmise. It is of interest that Wilkinson<sup>16</sup> employed by daily intramuscular injection an extract derived from about the same amount of

<sup>15</sup> Foliole kindly supplied by Dr Guy W. Clark of Lederle Laboratories Inc. Pearl River, N. Y.

†Normal human gastric juice

beef muscle as we used. Although it was administered subsequent to incubation with an extract of hog mucosa it seems probable that this was the first demonstration, though not then so interpreted of the hematopoietic activity of a beef muscle extract upon parenteral administration.

The potentiating effect of normal human gastric juice upon orally administered vitamin  $B_{12}$  has been demonstrated.<sup>17</sup> The present observations fail to show any enhanced absorption by gastric juice of l tyrosine, glucose, or of the digestive products of orally administered casein. Pteroylglutamic acid was not demonstrably more active in producing a reticulocyte response when given with gastric juice than with an equal amount of physiologic salt solution. On the basis of the present evidence then the action of intrinsic factor appears to be a specific one—presumably a hematopoietic potentiating effect on substances possessing identity with or chemical similarity to vitamin  $B_{12}$ .

There is suggestive evidence however, that vitamin  $B_{12}$  may exist in nature, not necessarily in the pure form employed in these observations, but rather as protein 'conjugates' or analogues. Thus Smith and Parker<sup>18</sup> noted the "dramatic" increase in concentration effected by hydrolysis with trypsin of liver fractions containing vitamin  $B_{12}$ . According to Cohn and associates,<sup>20</sup> the antipernicious anemia activity of liver may remain largely with the proteins if their denaturation is avoided during the chemical fractionation of the liver. A synthetic modification of vitamin  $B_{12}$  known as vitamin  $B_{12a}$ <sup>1</sup> with definite though reduced hematopoietic activity has recently been made by hydrogenation of vitamin  $B_{12}$ . By chromatography a second crystalline variant, designated as vitamin  $B_{12b}$  has been prepared from liver and appears to possess biologic activity in both chick and microbial assays.<sup>2</sup>

Finally, from the comparative degrees of potentiation of pure vitamin  $B_{12}$  and of the present beef muscle extract by normal human gastric juice, at least an impression of a discrepancy is conveyed. Thus in our previously reported observations,<sup>7</sup> with the exception of Case 102 the potentiation of the activity of 5  $\mu$ g of pure vitamin  $B_{12}$  by gastric juice though definite, was not remarkable in terms of reticulocyte responses. Yet in the present observations upon Cases 108 and 111, the daily dose 10 ml of the beef muscle extract employed, although possessing upon intravenous injection distinctly less than the hematopoietic activity of 1  $\mu$ g of pure vitamin  $B_{12}$  was nevertheless capable of detectable increase in hematopoietic effect when given orally in the same dosage with gastric juice. According to microbial assays using the organism *Lactobacillus lactis* Dorner,\* the vitamin  $B_{12}$  content of 10 ml of this beef muscle extract was 0.9 microgram. Assay of the same extract using the organism *Lactobacillus leichmannii*<sup>22†</sup> demonstrated 0.37  $\mu$ g of vitamin  $B_{12}$  per 10 milliliters. In the latter method the effect of bacterial growth promoting substances other than vitamin  $B_{12}$  is stated to be determined by difference following destruction of the vitamin  $B_{12}$  in an aliquot portion of the sample by alkaline hydrolysis. This procedure completely destroyed the microbial activity for

\* These assays were kindly performed by the laboratories of Merck & Co. Inc., Rahway, N. J.

† The assays were kindly performed by Dr. Thomas H. Jukes of Lederle Laboratories Inc., Pearl River, N. Y.

*L. leuckmanni*, and so presumably indicates the absence of significant quantities of thymidine or of other desoxyribosides. The results obtained upon microbial assay are seemingly in reasonably close agreement with each other and with the clinical effects upon intravenous injection in Cases 108 and 111. However, as indicated, the potentiating effect of gastric juice upon the beef muscle extract when orally administered is perhaps greater than would be expected from less than 1  $\mu\text{g}$  of vitamin  $\text{B}_{12}$ . Thus, it is possible that substances in the beef muscle extract other than microbially active vitamin  $\text{B}_{12}$  may be effective as food (extrinsic) factor in pernicious anemia. Yet, so far as can be inferred from the negative results of the studies with glucose, *L*-tyrosine, casein, and pteroylglutamic acid, the function of the gastric (intrinsic) factor is a specific one.

#### SUMMARY AND CONCLUSIONS

1 Observations were made during successive periods of ten or more days in seven patients with addisonian pernicious anemia employing a 70 per cent alcohol extract of beef muscle as a source of food (extrinsic) factor.

2 When 10 ml of the extract derived from 400 Gm of beef muscle were given daily by mouth to these patients, a detectable reticulocyte response appeared in only one instance. When the extract was given together with 150 ml of normal human gastric juice to four patients, reticulocyte responses appeared in all instances, and when the material was subsequently given intravenously without gastric juice to three of these patients, another reticulocyte response appeared, thus indicating greater hematopoietic activity.

3 In two patients it was shown that the hematopoietic effect of 10 ml of the beef muscle extract upon daily intravenous injection was less than that of the daily intramuscular injection of 1  $\mu\text{g}$  of crystalline vitamin  $\text{B}_{12}$ . Microbial assays indicated that 10 ml of the beef muscle extract contained from 0.37 to 0.9  $\mu\text{g}$  of vitamin  $\text{B}_{12}$  activity.

4 However, judging from our previous observations upon the potentiation of 5  $\mu\text{g}$  of crystalline vitamin  $\text{B}_{12}$  by normal human gastric juice, the hematopoietic activity of the beef muscle extract when given orally with gastric juice appeared to be surprisingly great.

5 Only this fact suggests that substances in the meat extract other than vitamin  $\text{B}_{12}$  are susceptible of potentiation by normal human gastric juice upon oral administration in pernicious anemia.

6 No evidence was obtained for a nonspecific effect of gastric (intrinsic) factor in increasing the hematopoietic action of pteroylglutamic acid or in promoting the intestinal absorption of glucose, *L*-tyrosine, or the digestion products of casein.

We desire to express our indebtedness to the late Dr. Lionel Berk, whose death we happily interrupted the preliminary work that led to the present observations. We have received much valuable advice from Dr. Arnold B. Welch and Dr. Robert W. Henle of the School of Medicine of Western Reserve University. Finally, we are grateful to Miss Phyllis Gordon, Mrs. Katharine Bingham, and Miss Angela Pasquariello for the performance of the blood examinations.

# FURTHER OBSERVATIONS ON THE USE OF THE URINARY PIGMENT-CREATININE RATIO FOR THE MEASUREMENT OF BASAL METABOLIC RATE

JEFFERSON J VORZIMER, MD, F A C P, AND IRA B COHEN, MD  
NEW YORK, N Y

**I**N A previous communication,\* it was found that an accurate correlation existed between the basal metabolic rates as determined by the respiratory calorimeter and the urinary pigment-creatinine ratio (P/C) † On the basis of statistically valid results obtained in 156 adult female subjects and 57 adult male subjects, regression equations were derived which permit the calculation of the basal metabolic rate from the urinary pigment-creatinine ratio These equations are

Male  
Female

$$\begin{aligned} \text{BMR} &= 57.0 + 0.25 \text{ P/C} \\ \text{BMR} &= 54.7 + 0.22 \text{ P/C} \end{aligned}$$

This present study is an analysis of the results obtained in comparing the basal metabolic rates determined by the respiratory calorimeter and the pigment-creatinine ratio in 740 observations made on 424 adult patients Of the 740 observations, 457 (61.7 per cent) were on euthyroid patients, 168 (22.8 per cent) were on hyperthyroid patients, and 115 (15.5 per cent) were on hypothyroid patients The clinical material consisted of hospital, private, and out-patient department patients

## RESULTS

We have previously reported\* that the determination of the pigment creatinine ratio is unreliable in the presence of increased bilirubinemia, azotemia, and in the presence of hemoglobinuria and drugs and foods which impart an abnormal color to the urine (e.g., riboflavin, aureomycin, beets, and rhubarb) There were 32 such cases in our series The pigment creatinine determination is also deficient in measuring hypometabolism, rarely indicating metabolic rates of less than -15 per cent There were 115 observations on cases of this type in our series Thus, there were 147 instances in which the pigment-creatinine determination would not be expected to be of diagnostic value

Of the remaining 593 observations, the BMR as determined by the respiratory calorimeter and the pigment-creatinine ratio agreed with each other and with the clinical findings in 508 cases (85.6 per cent) Of these 508 observations, 380 (64.0 per cent) were on euthyroid patients and 128 (21.6 per cent) were on hyperthyroid patients In 58 cases (9.8 per cent) the BMR as determined by the pigment-creatinine ratio was more consistent with the clinical findings than the BMR determined on the basis of oxygen con

†The chemical determinations involved in this test can be done in about twenty five minutes and can be performed easily in any routine chemical laboratory

TABLE I RESULTS OF TESTS—EXCLUDING OBSERVATIONS IN WHICH P/C WOULD NOT BE USED FOR DIAGNOSTIC PURPOSES

RESULT	NUMBER OF OBSERVATIONS	PER CENT OF TOTAL
B M R and P/C agree with each other and with the clinical findings		
a Euthyroids	380	64.0
b Hyperthyroids	128	21.6
	508	85.6
P/C more accurate than B M R		
a Euthyroids	48	8.1
b Hyperthyroids	10	1.7
	58	9.8
B M R more accurate than P/C		
a Euthyroids	14	2.4
b Hyperthyroids	13	2.2
	27	4.6
Total	593	100.0

The P/C determination is not reliable in cases of jaundice, azotemia, and in the presence of hemoglobinuria or drugs that color the urine (3 cases) or in hypothyroidism—metabolism below -15 per cent (115 cases)

sumption. Of these 58 cases 48 (81 per cent) were euthyroid patients and 10 (17 per cent) were hyperthyroid patients. In 27 cases (4.6 per cent) the B M R determined by the pigment creatinine ratio was less in agreement with the clinical findings than was the B M R as determined by the respiratory calorimeter. Of these 27 cases, 14 (2.4 per cent) were euthyroid patients and 13 (2.2 per cent) were hyperthyroid patients. Thus in 566 observations (95.4 per cent), the B M R as determined by the pigment creatinine ratio in normal and hyperthyroid patients was of diagnostic value. In the remaining 27 cases (4.6 per cent) the pigment creatinine metabolic rate was inaccurate.

#### DISCUSSION

The observation that the B M R as calculated from the urinary pigment creatinine ratio is at least as accurate as that calculated from the respiratory calorimeter in 95.4 per cent of instances when cases in which the pigment creatinine ratio would not be expected to be accurate are eliminated indicates that the pigment creatinine B M R should be used to check the oxygen consumption B M R when the latter does not seem to agree with the clinical picture. In addition, there is a group (58 cases or 9.8 per cent of patients having metabolism tests) in which the B M R calculated by the pigment creatinine ratio should be used in preference to the B M R determined by oxygen consumption. We were able to break down this group into five types:

1. Cases of hyperthyroidism under prolonged therapy in which the B M R remains elevated in spite of clinical improvement—10 cases

*Example A.* A 48-year-old white man was seen in the Outpatient department for the first time in December 1945, complaining of weakness, nervousness, palpitations, and weight loss for one year. Physical examination revealed an enlarged firm thyroid gland, warm moist skin, and a tachycardia. B M R was +30. He was given thiouracil and later changed to propylthiouracil in adequate dosage. The patient showed gain in weight and disappearance of all signs of thyrotoxicosis except that repeated B M R determinations remained between +30 and +48. The patient volunteered this information. When taking

a BMR I'm always nervous and feel as if I'm choking'' In July, 1948, it was decided to stop all antithyroid medication as the patient was asymptomatic although the BMR was +30 In November, 1948, while the patient was still clinically euthyroid, the oxygen consumption BMR was +32 while the BMR calculated on the basis of urinary pigment creatinine ratio was successively -4 and +2 In January, 1949, while still asymptomatic, the oxygen consumption BMR was +36 while the BMR calculated from the P/C was -8

## 2 Cases in which an anxiety state or neurocirculatory asthenia causes an abnormally elevated BMR inconsistent with the clinical findings—32 cases

*Example A* S C, a 47 year old white woman, was admitted to the hospital March 3, 1949 She gave a three year history of nervousness, hypertension, palpitations, heat intolerance, and sweating In December, 1946, her BMR was +50 and a subtotal thyroidectomy was performed Her symptoms persisted for eighteen months postoperatively In July, 1948, she had a BMR of +7 with all the symptoms of thyrotoxicosis still present Her present admission was due to the appearance of a small nodule on the left side of the thyroid gland She showed no evidence of weight loss, there was no tremor, the pulse rate was 100 She was quite apprehensive about the prospect of further surgery On March 9, 1949, the oxygen consumption BMR was +24 whereas the P/C BMR was -11 On March 15, the oxygen consumption BMR was +21 while the P/C BMR was -13 On March 16, the patient was reassured that no surgery would be necessary She slept well that night and on the following day the oxygen consumption BMR was +7 and the P/C BMR was -8 The patient was discharged from the hospital with the diagnosis of menopause, essential hypertension, and anxiety state This patient had received no specific therapy at any time during her hospital stay

*Example B* G A, a 27 year old white woman, was admitted to the hospital in January, 1949, for an evaluation of an asymptomatic hypertension known to be present for two months The only significant finding on physical examination was a blood pressure of 200/140 On January 19, a BMR was reported as +34, the P/C BMR calculation was -7 On January 25, a repeat oxygen consumption BMR was -1, the P/C BMR at this time was -2 There was no specific therapy given during the hospital stay The patient was discharged with a diagnosis of essential hypertension

*Example C* E W, a 30 year old white woman, was referred to the private office of one of the authors (J J V) for the first time in April, 1949, because she had been found to have a BMR of +60 two weeks previously She complained of palpitations and a 22 lb weight loss in the past twenty months following a pregnancy Physical examination revealed a warm moist skin, thyroid moderately enlarged, pulse rate 128 per minute, and slight prominence of the eyes A BMR at this time was +47 The patient was started on cyclohexylmethylthiouacil, 300 mg per day With the institution of therapy, the patient began to feel better and gain weight, and the pulse rate fell although the BMR remained elevated Five weeks after she was first seen, she had no complaints, had gained 14½ lb, and the pulse rate was 72 per minute A BMR at this time was +33 Because of the discrepancy between the clinical condition of the patient and the oxygen consumption BMR, a P/C BMR was determined and found to be -3

## 3 Cases in which it is not technically possible to obtain an accurate BMR (e.g. edentulous patients, patients with punctured eardrums, an swallowers)—5 cases

*Example* G S, a 67 year old white woman, complained of nervousness There was no evidence of hyperthyroidism clinically, but because the patient was edentulous, numerous attempts to do a basal metabolism test were unsuccessful In October, 1948, two successive P/C BMR determinations were +3 and -2

## 4 Cases in which a basal metabolism test is done on a patient for the first time as part of a routine work-up and yields a high result where there is no evidence of hyperthyroidism—10 cases

*Example S F*, a 36 year old white woman came to the Outpatient department complaining of pains in the knees which were diagnosed as due to osteoarthritis. She was 58 inches tall and weighed 20½ pound. Aside from the obesity and arthritis the physical examination was negative. A routine oxygen consumption B M R was +0. The P/C B M R was +8.

5 Cases in which the patient refuses to undergo a metabolism determination—1 case

*Example I C*, a 22 year old white woman was known to be a diabetic for four years. She had had numerous hypoglycemic reaction. She was hospitalized because of frequent episodes of nervousness and sweating which her physician attributed to an anxiety state. She became very upset at the prospect of undergoing a basal metabolism test and refused it. A B M R calculated on the urinary pigment creatinine ratio was -3. This result confirmed her physician's impression.

#### SUMMARY

The results of the comparison of the basal metabolic rate as determined by the oxygen consumption method and by the urinary pigment creatinine ratio method (P/C) in 740 observations made on 424 patients are reported. Of the 740 observations 457 (61.7 per cent) were on euthyroid patients, 168 (22.8 per cent) were on hyperthyroid patients and 115 (15.5 per cent) were on hypothyroid patients. The clinical material consisted of hospital private and out patient department patients.

The B M R as determined by the pigment creatinine ratio (P/C) is unreliable in cases of hypothyroidism, hyperbilirubinemia, azotemia, and in cases in which the urine is discolored by drugs or foods. There were 147 such cases in this series. If these observations are eliminated then the P/C B M R is at least as accurate as the oxygen consumption B M R in 95.4 per cent of the remaining cases.

The P/C B M R should be used to check all cases in which the oxygen consumption B M R does not agree with the clinical findings in euthyroid and hyperthyroid patients.

The P/C B M R determination should be used in preference to the oxygen consumption B M R for the following groups of patients (9.8 per cent of our series):

- 1 Cases of hyperthyroidism under prolonged therapy in which the B M R remains elevated in spite of clinical improvement.
- 2 Cases in which anxiety state or neurocirculatory asthenia causes an abnormally elevated B M R inconsistent with the clinical diagnosis.
- 3 Cases in which it is technically impossible to obtain an accurate B M R.
- 4 Cases in which a basal metabolism test is done on a patient for the first time and yields a high result where there is no evidence of hyperthyroidism.
- 5 Cases in which the patient refuses to undergo a metabolism determination.

The authors appreciate the technical assistance rendered by Mrs. Jennie Shatton, Miss Edna Arzt, and Miss Virginia Rehnitzer, and are grateful to Mr. Jules Joskow, Department of Economics, The City College of New York, for his statistical analysis of the results.

## EFFECT OF RETAINED BRONCHIAL LIPIODOL ON BLOOD IODINE

LEROY HYDE, M D, VAN NUYS, CALIF, AND BERNARD  
HYDE, M D, LOS ANGELES, CALIF

NUMEROUS studies have been made on the metabolism of iodine and blood iodine levels in normal people and in various pathologic conditions. Normal standards for protein-bound blood iodine have been established,<sup>1, 2</sup> 30 to 85  $\mu\text{g}$  per 100 ml of blood being the quoted normal range. In our laboratory, 5 to 7  $\mu\text{g}$  per 100 ml is considered normal. Patients with pulmonary tuberculosis have normal protein-bound blood iodine values.<sup>4</sup> Normal blood iodine values have been secured in numerous other pathologic conditions. Most observers agree that hyperthyroidism produces an elevation of the protein-bound blood iodine.<sup>1, 2, 3</sup> Turner<sup>2</sup> found elevated blood iodine levels, up to 18  $\mu\text{g}$  per 100 ml of blood, in lymphatic leucemia. Several observers<sup>1, 6</sup> have found increased protein-bound blood iodine values in patients with liver and gall bladder disease. The effects of previously administered iodine containing compounds such as gall bladder dyes must be always borne in mind in these latter patients. It is known that the liver takes up iodine and excretes it into the bile. Cohn and Feldman<sup>5</sup> quote Greene and Bruger as finding normal blood iodine values in liver and gall bladder disease, if no iodine containing compounds had been taken previously. Cohn and Feldman<sup>5</sup> found experimentally that common bile duct ligation in cats failed to produce an elevation of blood iodine. The administration of gall bladder dyes, however, elevates the protein-bound blood iodine for several weeks. A group of patients with advanced liver disease was compared with a group of normal subjects, and blood iodine levels were found to be similar. Rabbits had no elevation of blood iodine following carbon tetrachloride poisoning to produce liver cell necrosis and extensive liver damage.<sup>5</sup>

It is quite clear that an elevated blood iodine may be due to hyperthyroidism and previous administration of iodine containing compounds, among other things.<sup>7, 8</sup> Chemical laboratories doing blood iodine determinations usually recommend that patients do not receive any iodine containing compounds for from ten to thirty days prior to the determination of this test.

No information can be found in the literature concerning the quantitative effect on the protein-bound blood iodine of retained Lipiodol in the bronchi and alveoli of the lung as a result of previous bronchograms. Means<sup>9</sup> has noted "the prolonged 'spurious' elevation of protein-bound iodine which follows the administration of such organic iodine containing compounds as

Fig 1

Fig

Iodeikon or Lipiodol used in roentgenography" Salter<sup>10</sup> has stated that "the intrathecal injection of Lipiodol may form a localized reservoir of iodine which will slowly feed small amounts of iodine into the general circulation over the course of many weeks" Communication with several chemical laboratories and with the manufacturers of Lipiodol indicates that the quantitative effect

Fig 3

of retained Lipiodol is unknown and no studies have been published. The purpose of the present work is to determine the effect of retained Lipiodol upon the blood iodine.

Forty-one determinations of protein-bound blood iodine were secured on thirty patients at varying known intervals following the instillation of Lipiodol for a bronchogram. Four patients had normal protein bound blood iodine determinations before Lipiodol instillation (6, 6, 7, and 8  $\mu\text{g}$  per cent). It soon became apparent that retained Lipiodol causes an elevation of the blood iodine† for prolonged periods of time. Values of over 400  $\mu\text{g}$  per 100 ml of blood were secured one week following the instillation of Lipiodol. The

\*Lipiodol 40 per cent containing 540 mg of iodine by weight per milliliter was used. Varying amounts from 5 to 20 ml were instilled for visualization of the bronchi.

† Blood iodine refers to protein bound blood iodine as determined by the method of Barker<sup>11</sup> modified by M. E. Morton using 10 per cent trichloroacetic acid to precipitate plasma protein.

protein bound blood iodine level dropped rather rapidly to average approximately 200  $\mu\text{g}$  per 100 ml of blood one month after instillation of Lipiodol (still greatly elevated) and then gradually dropped further for some time. It is important to note that the curve drawn of the various values of blood iodine plotted against the time since the last bronchogram did not reach the normal range (4 to 8  $\mu\text{g}$  per 100 ml blood) until seventeen months after the patient's last bronchogram (Figs 1, 2 and 3).

#### SUMMARY AND CONCLUSIONS

1 Instillation of Lipiodol for a bronchogram produces extremely high levels of protein bound blood iodine for prolonged periods (months).

2 It requires approximately seventeen months for the blood iodine level to reach normal in patients who have received bronchograms with Lipiodol. Individual patients may have elevated blood iodine values for three and four years.

3 Blood iodine cannot be used as a diagnostic agent (e.g. in suspected cases of hyperthyroidism) in patients who have had Lipiodol bronchograms within the previous two years and possibly longer.

Grateful acknowledgment is made to Ellen M. Bahr for the blood iodine determinations.

# THE EFFECT OF THYROID SECRETORY ACTIVITY ON THE DISTRIBUTION OF RADIOIODINE IN PLASMA

ALBERT M. POTTS, M.D., PH.D., REGINALD A. SHIPLEY, M.D.,  
JOHN P. STORAASLI, M.D., AND HAMER L. FRIEDEL, M.D., PH.D.  
CLEVELAND, OHIO

WHEN labelled inorganic iodide is administered by mouth, 90 per cent or more is absorbed in ninety minutes<sup>1</sup>. During this interval, and for several hours thereafter, a portion of the administered dose diffuses into the extracellular fluid. While absorption and diffusion are occurring and during the ensuing twenty-four to forty-eight hours almost all of the iodide ion is competitively removed from the blood and body fluid by the thyroid gland and the kidneys. That which is trapped by the thyroid is soon synthesized into hormone. A variable portion of the latter is stored in the gland while the remainder is secreted into the blood. Once thyroid hormone is released into the blood it apparently undergoes a slow degradation at the rate of about 5 per cent of the existing level per day<sup>2</sup>. Both the rate at which the thyroid gland removes iodine from the blood and the total amount ultimately retained by the gland are characteristically influenced by the state of thyroid activity provided the gland has not been previously saturated with iodine. Each has been measured repeatedly in human subjects by direct and indirect techniques<sup>3,4</sup>. However, a more positive measurement of thyroid function would necessitate an estimation of the actual rate of hormone secretion. This present study is, therefore, chiefly concerned with the problem of the rate of release of hormone and is based upon serial determinations of radioiodine in the organic fraction of plasma at successive intervals after the administration of a tracer dose of  $I^{131}$ .

## METHODS

Subjects selected for study included patients with either hyperthyroidism or myxedema, along with a group of euthyroid subjects to serve as controls. In none of the patients was the diagnosis equivocal because of grossly atypical clinical findings or inconsistent laboratory data. No subject had received iodine therapy within six weeks or antithyroid drugs within two weeks before the experiments were started.

The tracer dose of  $I^{131}$  was given orally and varied from 0.1 to 0.2 mc except for occasional patients with hyperthyroidism who received 0.4 millicurie. No normal subjects received more than 0.1 millicurie. The material was either carrier free or contained not more than 0.5 mg of NaI. Blood samples were drawn at intervals of two, eight, and twenty-four hours after ingestion of the tracer dose. These were oxalated and a 5 cc portion of plasma precipitated with 45 cc of Somogyi's zinc sulfate sodium hydroxide reagent (45 cc) as described by Man and associates<sup>5</sup>. After centrifugation, a 20 cc aliquot of supernatant was removed and evaporated to dryness in a 2 oz ointment tin (29 sq cm area) by the aid of an infrared lamp. The activity of this fraction was considered to represent that of inorganic iodine.

From the Departments of Medicine and Radiology, University Hospitals of Cleveland and Western Reserve University School of Medicine.

A preliminary report of this work was presented at the meeting of the Cleveland Section, Society for Experimental Biology and Medicine on April 9, 1948.

Received for publication July 29, 1949

Nodular glands (all others are diffuse)

†Standard error of mean

The protein precipitate which contained organic hormonal iodine was washed three times with 50 cc portions of water. Assays of the washings on six different blood samples indicated that any additional washing would not remove more activity than 0.5 per cent of that in the total supernatant fraction from which the precipitate was removed. The washed precipitate was quantitatively transferred to a weighed ointment tin and dried under the heat lamp. It was then distributed evenly over the bottom of the tin with the help of a stirring rod and a small quantity of acetone. The half density of the precipitate in the containers averaged only 10 mg per square centimeter.

Counts were made under a Geiger Muller tube with a 6 mg per square centimeter mica window, 6.2 cm in diameter and connected with a scale of 8 counter. An appropriately sized aliquot of the original material was counted at the same time so that decay calculations were unnecessary. Aliquots of the standard and inorganic fraction were combined with 1 cc of a solution recommended by the Oak Ridge National Laboratory to prevent loss of volatile iodine.\*

## RESULTS

Individual values are recorded in Table I, and composite curves of the inorganic and organic fractions are depicted in Fig 1. The value of the inorganic fraction at two hours was arbitrarily set at 100 per cent as reference for the remaining determinations. Since total blood or body iodine content was not known, there was no advantage in employing the original dose as a standard for comparison.

The inorganic fraction is seen to decline much more rapidly in hyperthyroid patients than in normals. This is presumed to be due to the more rapid rate of removal by the thyroid gland, provided there is no significant increase in the rate of renal removal. It is of interest that the decrease of plasma iodine with time in the three curves does not give a straight line of constant slope on a semilogarithmic plot. Without more points on the curve it is impossible to come to any exact conclusions, but it may well be that this reflects the sequential operation of several biologic processes, each in itself expressed by a true exponential function.

A more rapid decline is present between the second and eighth hour than between the eighth and twenty-fourth. The initial rapid fall could be due to two factors: (1) The passage of iodine into the extracellular fluid in addition to the thyroid and the urine. (2) An exaggerated peak of the blood concentration if the rate of absorption should materially exceed the rate of diffusion into the extracellular fluid. The slope of the three curves between the second and eighth hour when inorganic iodine is being disposed of most rapidly may be seen in the table and in Fig 1. The difference between hyperthyroid and normal subjects is very real. However, the five patients with myxedema, although showing a flatter average curve, do not differ from the normals to a statistically significant degree.

The behavior of the organic fraction likewise is not the same in hyperthyroid subjects as in normals. Between the eighth and twenty-fourth hour the patients with hyperthyroidism show a distinct rising trend, while the curve of the normal subjects tends to decline. This difference in behavior of the two curves is a real one, as an analysis of the slopes of the two groups

\*NaHSO<sub>3</sub> 500 mg    NaI 250 mg    NaOH 750 mg    water to 1 000 cc

will reveal (Table I) The trend of the organic fraction in myxedematous patients is not significantly different from that of the normal group An observation to be discussed later is the high activity which was encountered in the organic fraction at the two hour period

#### MEAN PLASMA RADIOACTIVE IODINE LEVELS

Fig 1

In four of the hyperthyroid patients and four normals additional measurements were made after forty eight hours The trend of the organic and inorganic curves during this interval was similar to that observed between the eighth and twenty fourth hour

#### DISCUSSION

McConahey, Keating, and Power have recently reported their results of blood fractionation studies in a small series of patients and normal subjects who were given doses of  $I^{131}$  ranging from 1 to 100 millicuries<sup>8</sup> Our own findings are similar in some respects to those reported by this group of workers The chief point of difference is that the organic fraction in their three normal patients and also in the one hypothyroid patient showed a progressive rise albeit with a more gradual slope than in the series of hyperthyroid cases The curves for both normal and hypothyroid patients presented here show a slight progressive fall in activity of this fraction The reason for

this decline cannot be determined with any degree of precision, however, certain general principles should be noted. There is a slow process of disintegration of thyroid hormone in the body fluids which should proceed at approximately equivalent rates in all subjects. In hyperthyroidism, with relatively little hormone stored in the gland and a relative high uptake of radioiodine, it is to be expected that the material secreted after a tracer dose would be proportionately rich in radioactive iodine. On the other hand, with a normal gland, the comparatively large amount of preformed, nonradioactive hormone would force the gland to deliver to the blood a product relatively poor in the newly acquired radioactive component. Thus it is conceivable that in its normal state of activity the quota of radioactive hormone delivered to the blood would be insufficient to result in a steadily mounting activity within the organic fraction. The rate of change of organic iodine in the blood, therefore, does not offer a direct measure of true secretory activity. That the behavior of the organic fraction is quantitatively influenced by thyroid hyperactivity is nevertheless clearly demonstrated by the difference in slope of the curves as shown here.

The finding of small but unmistakably real quantities of active material in the organic fraction of patients with myxedema in the present study, and in that of McConahey and co-workers, is of interest. Moreover, our own finding of a relatively high value as soon as two hours after ingestion with a decline during the next six hours even in the presence of hyperthyroidism should also be commented upon. An explanation of the presence of active material in myxedematous patients, along with the temporarily high level in all patients, might suggest an extrathyroidal synthesis of an organic iodine complex. Incubation of serum with inorganic iodine under physiologic conditions has not been found to promote such a synthesis.<sup>6</sup> Morton and co-workers, on the other hand, have demonstrated the *in vivo* production of thyroxine and diiodothyroxine in thyroidectomized rats as early as two hours after the administration of labelled inorganic iodide.<sup>7</sup> It is difficult to believe, however, that the high level of serum activity here encountered at two hours could be achieved so rapidly by extrathyroidal synthesis. Moreover, the initial drop in the curve (between two and eight hours) is too rapid to be attributed to simple thyroxine decay. There is a possibility that a portion of the protein-bound material is not actually a hormonal compound but that it is fixed to protein fully as firmly and resists removal by washing.

The usefulness of a determination of blood radioiodine as a diagnostic test cannot be determined on the basis of the present observations. Significant differences between mean values can easily be demonstrated, but an overlap exists. The steepest slope for the curves of inorganic iodine (two to eight hours) in the normal group was -11 (Table I). However, two hyperthyroid patients (E N and E F1) showed slopes which were less steep. Both patients suffered from a relatively chronic type of disease of only moderate severity and each had a rather large nodular gland. In the case of the organic fraction, if one arbitrarily divides hyperthyroid patients from normals on the basis

of a positive or negative slope between eight and twenty four hours, the overlap consists of one normal patient with a positive slope and two hyperthyroid patients with slightly negative slopes

Thus the large majority of our cases show definite differences between normal and hyperthyroid blood values. Just how much overlap actually exists can be shown only by a large series. It may well be that this type of determination will prove a useful adjunct to already existing tests for hyperthyroidism.

Freedberg and co-workers have recently reported that protein bound radioiodine twenty four hours after a tracer dose was consistently higher in hyperthyroid patients than in normal controls.<sup>8</sup> In the present study the rate of change between eight and twenty four hours correlated with clinical status more consistently than did the final twenty four hour level.

The behavior of the inorganic fraction in myxedema was not greatly different from normal and the rate of change of the organic component was not distinguishable from that in the normal group. In our own experience the best diagnostic criterion for myxedema when one employs radioiodine techniques is the failure to demonstrate any local uptake of activity by direct measurement over the gland with a counter.

#### SUMMARY

After a tracer dose of radioiodine the activity of the inorganic fraction of the blood in hyperthyroidism declines more rapidly than normal while in myxedema the decline tends to be somewhat slower than normal. The activity of the organic fraction is distinctly elevated in all types of cases at the end of two hours, and then tends to decline between the second and eighth hour. This decline is progressive for the ensuing sixteen hours in both normal subjects and patients with myxedema; however, in patients suffering from hyperthyroidism there is characteristically a progressive rise in this fraction between the eighth and twenty fourth hour.

We are indebted to Ethel Buchwald Chudack for technical assistance.

## INHIBITION OF THE GROWTH OF STAPHYLOCOCCUS AUREUS BY HUMAN SEMEN

R. ROZANSKY, M.D., J. GURFVITCH, M.D., A. BRZEZINSKY, M.D., AND  
B. ECKIRLING, M.D.  
JERUSALEM, ISRAEL

THE presence of penicillin in blister fluid of human skin following parenteral and topical application was determined by Dostrovsky, Gurevitch, and Rozansky.<sup>1</sup> In another study the concentration of penicillin in human milk was determined by Rozansky and Brzezinsky.<sup>2</sup> In pursuing these studies further we attempted to determine whether penicillin is excreted in the human semen. It was first necessary to find out whether semen in itself has any inhibitory effect on the growth of bacteria. Preliminary examinations revealed inhibition of the growth of *Staphylococcus aureus* by human semen. The following is a detailed report on a study of the inhibition of the growth of *Staph aureus* by human semen.

### MATERIALS AND METHODS

Twenty-eight specimens of semen obtained from twenty-four men between the ages of 27 and 47 years were examined. The semen of four patients was examined twice. Five of the examined specimens were azoospermic, ten were oligospermic (spermatozoa count lower than 60,000,000 per cubic centimeter), and thirteen were normospermic. The patients applied to the clinic for consultation in connection with sterile marriage. Only one patient (Specimen 21) had received 60 mg. testosterone propionate (six injections of 10 mg.) before examination. All the others had received no previous treatment. In most instances the semen was obtained under as sterile conditions as possible by masturbation in the outpatient clinic, but in four instances specimens were brought to the clinic from outside. Each specimen was tested for bacterial contamination before examination. One specimen was discarded because of contamination by *Esch. coli*. In five other ejaculates a few colonies of *Staphylococcus albus* were found.

The inhibitory effect of human semen on bacterial growth was examined by the cup method used in studies on the concentration of antibiotics.<sup>3</sup> The first test strain was *Staph. aureus*, Heatley, in use in antibiotic studies in this laboratory for a period of four years. In the course of later experiments two additional strains of *Staph. aureus* freshly isolated in the laboratory were used: strain 924 isolated from the urine of a patient with cystopyelitis, and strain 598 isolated from the pus in a case of furunculosis. All three strains had the usual properties of pathogenic strains of *Staph. aureus*: coagulase positive, marmite positive, actively hemolytic.

From the Department of Bacteriology and Serology, and the Department of Obstetrics and Gynecology of the Rothschild-Hadassah University Hospital.  
Received for publication Aug. 3, 1949.

Examinations were conducted as follows. One cubic centimeter of a 1:1,000 dilution of a twenty four hour broth culture of the test strain was added to 20 c.c. of nutrient agar (Difco) and plates were poured. The plates were left at room temperature for four hours after which five cups 8 mm. in diameter (external) were placed on each plate. Four cups each received 3 drops of the tested ejaculates and the fifth received 3 drops of a penicillin solution containing 0.1 unit per cubic centimeter. The cup containing penicillin served as a control of the area of inhibition of growth of the staphylococcus. The results were read after twenty four hours of incubation at 37° C. In most examinations two plates were prepared for each specimen examined. The specimens were left at room temperature for four hours before examination to permit the ejaculates to liquify and to become homogenous. When sufficient material was available residues were stored at 8° C. after the first examination and were re-examined twenty four hours to seventy two hours later.

#### RESULTS

The results of the examinations are summarized in Tables I, II, and III, comprising studies in the Heatley strain strain 924 and strain 598 respectively.

As may be seen in Table I twenty three of the twenty eight specimens studied with the Heatley strain inhibited the growth of the staphylococcus over an area from 10 to 20 mm. in diameter while five gave negative results. The positive results include examinations repeated after twenty four and seventy two hours. In three instances no inhibition was found at the first examination but the same specimens were positive when examined twenty four and seventy two hours later. Of the twenty three positive specimens fourteen yielded similar areas of inhibition in both plates and nine specimens yielded positive results in one plate (four of these specimens were examined with one plate only). Specimen 17 was examined in three plates and areas of inhibition 16 mm. in diameter were observed in all of them. In six instances the semen was re-examined following twenty four hours of storage at 8° C. Five of these specimens were positive and one was negative. Three of the positive specimens were particularly interesting because they were negative on first examination but yielded a distinct area of inhibition twenty four and seventy two hours later. Following two weeks of storage at 8° C. Specimen 14 yielded an area of inhibition similar to that of its first examination. Specimen 21 was negative following one week's storage at 8° C.

The inhibitory effects of eighteen specimens of human sperm on *Staph aureus* strain 924 isolated from urine are summarized in Table II.

Fourteen of the eighteen specimens were positive five in two plates and nine in one plate. Four specimens in this series were negative.

The inhibition of *Staph aureus* strain 598 isolated from a furuncle, by eight specimens of human sperm is summarized in Table III. Of the eight examinations five were positive each of them in two plates and three were negative when examined in one plate only.

## COMMENT

Human semen has been found capable of inhibiting growth of several strains of *Staph aureus*. Inhibition was observed in 80 per cent of the examinations done with three strains of *Staph aureus*. The active principle of the semen was not associated with the spermatozoa, since only the supernatant fluid of the semen was used in the experiments. This is supported by the fact that four of the azoospermic specimens showed inhibitory activity. At this stage of the investigation little can be said as to the nature of the active principle. The factor is stable when stored for days at 8° C. Specimen 14 remained active even after fourteen days. The active principle is thermostable. Specimen 18 remained positive after heating for half an hour at 56° C. Specimens 24 and 25 retained their activity after exposure to 75° C for fifteen minutes.

Three specimens were negative in the first examination but found to be positive in examinations repeated after twenty four and seventy two hours. It may be of interest that these three specimens were not kept at room temperature as is usual in these experiments, but were placed mistakenly in the refrigerator when brought from the outpatient clinic. It may be assumed that the homogenization of these specimens, which takes place at room temperature was interfered with by refrigeration.

Six specimens of sperm which inhibited *Staph aureus* had no effect on the growth of *Fsch coli*.

## SUMMARY

Twenty eight specimens of human semen were tested for their inhibitory effects on the growth of *Staph aureus*. Eighty per cent of the specimens inhibited the growth of this organism. Preliminary studies indicate that the active principle is associated with the liquid part of the semen. Some properties of the active principle in the semen are discussed.

IOWA CITY, IOWA

## INTRODUCTION

THIS is a preliminary report on a clinical study of the analgesic properties of Nu 2206\* (3-hydroxy-N-methylmorphinan-hydrobromide) which includes observations on a series of normal subjects, on a series of patients with postoperative pain, and on a series of patients with intractable pain due to cancer. In instances abstracted in this report it was possible to observe the effect of this drug during and after prolonged use.

## CHEMISTRY

Nu 2206 (3-hydroxy-N-methylmorphinan-hydrobromide) has the following structural formula:

Nu 2206 occurs in the form of colorless crystals melting at 193° to 195° C. The substance is rather soluble in water at 20° C. It is easily soluble in water at 100° C. and in alcohol, but it is insoluble in ether. It has analgesic properties similar to those of morphine and some of the other morphine-like compounds developed recently.<sup>2,3</sup>

## ADMINISTRATION TO NORMAL SUBJECTS

The effect on the pain threshold in six normal volunteer student subjects was determined by the Hardy-Wolff-Goodell technique. Doses used were 0.5, 1.0, 2.0, and 3.0 milligrams. Each student received two subcutaneous doses of each of the four graded doses. No subject received more than two doses each week. These doses were compared with doses of 5.0, 10.0, and 15.0 mg of morphine sulfate given in similar manner and under similar conditions. The results indicated that Nu-2206 was about four times as potent as morphine on a per milligram basis. Peak threshold effects were reached at about the same time as with morphine but there was a somewhat greater duration of effect. The blood pressure changes were no greater than could be accounted for by sedation and rest of the subject.

From the Departments of General Surgery, Urology, Pharmacology, and Obstetrics and Gynecology, the State University of Iowa College of Medicine.

Received for publication Aug 3 1949

\*Supplied by Dr M J Schiffrin, Hoffmann-La Roche Inc, Nutley, N J

Doses of 0.5 to 1.0 m<sub>g</sub> apparently produced no symptoms in any of the volunteers other than awareness of some vague gastrointestinal distress. Slight sedation may have occurred in some instances. Doses of 2.0 m<sub>g</sub> produced some nausea (but no vomiting), dizziness and sedation. The subjects were aware of gastrointestinal contraction and some inability to concentrate. Doses of 3.0 m<sub>g</sub> produced some nausea in practically all subjects, vomiting occurred in two different subjects on one occasion each and dizziness occurred in all subjects. Sedation, inability to concentrate and awareness of gastrointestinal symptoms were experienced by all subjects. In one subject vomiting occurred five to six hours after the injection. No euphoria was experienced by any of the subjects. In general 3.0 mg of Nu 2206 produced fewer and less severe symptoms than an equivalent analgesic dose of morphine. All subjects on 3.0 doses stated they either went to bed 11<sup>1</sup>/<sub>2</sub> hr after dinner (five to six hours after injection) or were too sedated to do any studying during the course of the evening. Respiration was not studied but by casual observation no significant respiratory changes were noticeable.

#### NU 2206 IN THE TREATMENT OF POSTOPERATIVE PAIN

Nu 2206 was used subcutaneously in a total of fifty-eight postoperative urological and general surgical patients. Thirty-six patients (twenty-nine urological and 7 general surgical) were given 1.5 milligrams. Twelve urological patients were given 4.5 milligrams. Six general surgical patients were given

TABLE I COMPARISON OF ANALGESIC POTENCIES BY SUBCUTANEOUS INJECTION

DRUG	DOSE (MG)	NUMBER OF DOSES	HIGHTEST % RISE THRESHOLD $M \pm \sigma$	TIME TO REACH PEAK $M \pm \sigma$ (MIN)	DURATION TO 10% OF PEAK $M \pm \sigma^*$
Morphine SO	10	(	$21.5 \pm 1.9$	$73.3 \pm 8$	$246 \pm 51$
Morphine SO	15	)	$21.2 \pm 2.3$	$84.0 \pm 7.7$	$280 \pm 74$
Nu 2206	1	11	$10.1 \pm 3.0$	$65.0 \pm 9.3$	$211 \pm 13.9$
Nu 2206	2	9	$18.2 \pm 2.1$	$82.0 \pm 5.9$	$267.0 \pm 21.4$
Nu 2206		9	$24.8 \pm 2.9$	$91.1 \pm 8.3$	$301 \pm 27.2$

$M \pm \sigma$  is the mean effect + its standard deviation

3.0 milligrams. Four general surgical patients were given 6 milligrams. The majority of the patients to whom 1.5 m<sub>g</sub> were given had transurethral resections. These patients usually have very definite discomfort and in some cases severe pain. Ordinarily these patients are given 10 m<sub>g</sub> of morphine sulfate immediately after completion of the procedure as the spinal anesthesia is wearing off and the same dosage is usually repeated in several hours. In these patients Nu 2206 in a dosage of 1.5 mg was uniformly ineffective. In the patients who had other miscellaneous urologic procedures—three nephrectomies, two suprapubic cystotomies and one orchidopexy—there was also failure to relieve pain. The one good result in urological patients was in a 9-year-old boy who had a nephrectomy. In the general surgical patients in this dosage range four obtained relief and three obtained no relief. These seven patients represented a variety of operations. It may be that these surgical procedures did not result

in as much postoperative pain as the average urologic procedure. It appeared that 15 mg of Nu-2206 was an unsatisfactory dose.

In six instances Nu-2206 was used in dosage of 30 mg for treatment of postoperative pain in general surgical patients. It afforded relief in three instances and gave insufficient relief in the remaining three. One of the latter patients subsequently obtained relief of pain with 6 milligrams.

Eleven urological patients who had had transurethral resection were given fifty one 45 mg doses. However, in this series, Nu-2206 was not given unless the patient had real pain and requested relief. In this dosage range, which was felt to be roughly equivalent to 15 mg of morphine, Nu-2206 was uniformly effective in relieving pain. Demonstrable effect was noted in most instances thirty minutes after administration of the drug. Analgesic effect was present longer than that observed with morphine and in most instances it was effective for six hours or more. There were no undesirable side effects.

Six milligram dosage was employed in four general surgical patients. In all of the patients to whom 60 mg were given, excellent relief was obtained. The following detailed case is presented as an example of this series.

Patient M W (48-9796), a 25-year-old man, was admitted on Aug 8, 1948, following multiple injuries received in an auto racing accident. Among his injuries were a perforating wound of the abdominal wall, peritonitis, traumatic rupture of the spleen, severe contusion of the colon, fractures of the transverse processes of the third and fourth lumbar vertebrae, and fracture of left zygoma. Surgical procedures included a splenectomy and colostomy.

TABLE II PATIENT M W

DATE	TIME	DRUG	REMARKS
8/31/48		100 mg Demerol 5 times per day	Relief

9/ 8/48	0345	3 mg Nu 2206	Asleep within 15 min

Control of pain was sought by 30 mg of morphine every four hours during the early stages of hospitalization. This dose was reduced as circumstances allowed, and on August 30, 100 mg Demerol were substituted for morphine. A tabulation of the drugs given this patient is presented in Table II.

## NU 2206 IN THE TREATMENT OF INTRACTABLE PAIN IN CANCER

Five patients with intractable pain due to cancer were observed for varying periods of time up to six months. The following case is presented in detail and is illustrative of some of the effects observed during a prolonged course of administration.

Patient G M, a 55 year old white woman was admitted to the University Hospitals on Oct 28 1947 with a diagnosis of carcinoma of the cecum. At operation a carcinoma of the ascending colon with regional lymph node metastasis was found and a right hemicolectomy was performed. She returned to the hospital on Jan 3 1949 with a large mass in the right upper quadrant of the abdomen which appeared to be liver involved by metastatic carcinoma. A posteroanterior radiogram of the chest revealed elevation and nodular outline of the diaphragm. The patient had been having very severe pain for two weeks and her physician had been unable to keep her free of pain by intermittent injections of morphine sulfate and Demerol. At the time of her admission she was emaciated and was apparently losing ground rather rapidly although she was still able to be out of bed for short periods of time. A right splanchnic block was done; this afforded temporary relief of the pain. This was repeated

once without satisfactory analgesia. Cordotomy and prefrontal lobotomy were considered but because of the patient's poor general condition and the short life expectancy, it was deemed advisable to try to obtain relief from pain by using analgesic agents rather than to subject the patient to a hazardous operative procedure. As may be seen from Table III, she received a total of twenty-three doses of 6 mg of Nu-2206 subcutaneously. This was given from January 8 to January 31 when she expired. The degree of relief accomplished by this means was considerable, and particularly gratifying was the long period of analgesia afforded. It was usually possible for her to sleep throughout the night without awakening with pain. This was in marked contradistinction to what had been observed with 10 mg doses of morphine and 100 mg doses of Demerol. In two instances during the period the patient was in the hospital, 150 mg of Demerol were given and the result appeared to be less enduring than with Nu-2206 in a dose of 6 milligrams.

In one urological patient who had an inoperable retroperitoneal tumor with continuous severe pain, Nu-2206 in repeated doses of 4.5 mg twice daily for a total of 113.5 mg in twenty-three doses was given throughout his stay in the hospital. He required no other analgesic drug.

In another patient, a 75-year old white man (Patient E. T.) who had severe pelvic pain following recurrence and local metastasis of carcinoma of the rectum after abdominal perineal resection, Nu-2206 proved to be very effective in producing analgesia. A total of 111 doses, totaling 353 mg, was given over a period of sixteen weeks. Three milligrams proved sufficient when given at bedtime to produce comfort throughout the night so that the patient did not require other analgesic agents or barbiturates for rest. Occasionally during the daytime he took small doses of aspirin (0.6 Gm.) and in a few instances 60 mg doses of codeine sulfate. During the first five weeks on Nu-2206, he received only eight doses of codeine. After he had received the drug for seven and one-half weeks, complete withdrawal was done for five days. The patient had no symptoms attributable to withdrawal. Examination five days after withdrawal showed no signs indicating withdrawal effect. Due to severe pain the patient was again placed on the drug and the dose was increased to 5 mg shortly before death. After fourteen weeks he developed symptoms and then signs indicating subtentorial brain metastasis. Three weeks later he expired. No Nu-2206 was given during the last six days of life because of coma.

A summary of our experience with Nu-2206 in the treatment of pain in patients with cancer is presented in Table IV.

Naturally the question of habituation and withdrawal effects is also raised. In addition to the instance already cited (Patient E. T.) in which withdrawal of the Nu-2206 was done after many weeks, ten other patients were studied in this regard. These all received the drug for much shorter periods. None of them demonstrated withdrawal effects. This experience is summarized in Table

TABLE IV. NUMBER OF DAYS IN TREATMENT OF PAIN OF CANCER

PATIENT	SEX	AGE	INDIVIDUAL DOSE (mg)	NUMBER OF DAYS ADMINISTERED	TOTAL DOSE (mg)	EFFECTIONS	SIDE EFFECTS	DIAGNOSIS OF TUMOR
C.H.	M	41	10 mg	4	40 mg	Maximal	None	Carcinoma of lung (exploratory thoracotomy)

## SUMMARY

- 1 Nu 2206 has desirable analgesic properties when administered subcutaneously in doses of 30 to 60 milligrams
- 2 For most adults 15 mg Nu 2206 is an ineffective dose
- 3 The duration of analgesia is more prolonged than with 10 to 15 mg morphine sulfate
- 4 Untoward reactions to Nu 2206 are not severe or frequent
- 5 The prolonged effect of Nu 2206 is beneficial in those patients who require protracted relief and in whom frequent injections with shorter acting analgesics are undesirable
- 6 No withdrawal symptoms have been observed in this study

# THE EFFECT OF SPLEEN PROTECTION ON MORTALITY FOLLOWING X-IRRADIATION

L O JACOBSON, M D, E K MARKS, M J ROBSON, B S, E GASTON, AND  
R E ZIRKLL, PH D  
CHICAGO, ILL

LEAD protection of the surgically mobilized spleen of CF-1\* mice during the delivery of 600 r total body x-radiation obviates the development of anemia and significantly lessens the severity and duration of the leucopenia and thrombocytopenia that regularly follow total body exposure at this level<sup>1</sup>. On the basis of previous work,<sup>2</sup> a single total body exposure to 550 r x-radiation produces death of one half of the mice of this strain in twenty eight days (LD<sub>50</sub>/28 days) †. Survival data on groups of mice exposed to single dosages of total body radiation with or without lead protection of the surgically mobilized spleen are presented in this paper.

## MATERIAL AND METHODS

The mice used in this study were all females and were 10 to 12 weeks of age when the experiment was initiated. The mice were kept in the animal farm in a constant temperature room (74° F) for four to six weeks before use and were maintained on a diet consisting of Derwood<sup>‡</sup> and water ad libitum before and after the experimental procedures described below.

**Dosimetry**—The x-rays administered in these experiments were generated in a 250 kv machine operating at 15 milliamperes. A 0.25 mm copper filter was used. The half value

I	0	No operation	54	52	96

\*On Oct. 3, 1949, five or more months after these exposures all mice which had lead protection of the spleen during irradiation still survive and appear grossly normal.

layer in copper of the filtered beam using 240 kv was 1.0 millimeter. The exposures were measured with a Victoreen condenser meter equipped with a 250 r chamber. Measurements were made in air at the position occupied by the center of the animal's body. The dose rate averaged 58.9 r per minute at 55 centimeters.

Groups of mice were exposed to single doses of 600, 700, 900, 975, 1,050, and 1,200 r total body  $\gamma$  radiation with or without lead protection of the surgically mobilized spleens.

Fig. 2—A, Photograph of a mouse with mobilized spleen within lead box and B, with lead cover in place

## EXPERIMENTAL PROCEDURE

As is indicated in Table I four groups of mice were studied. Mice in Group I were untreated controls. The mice in Groups II, III, and IV were anesthetized with Nembutal (0.072 mg per gram mouse in a 1:10 dilution) given intraperitoneally; the abdomen was shaved, an incision was made in the left upper quadrant and the spleen was brought out through the incision. The main pedicle was left intact but to facilitate mobilization a small

Fig. 3—Photograph of mice showing surgically mobilized spleens within lead boxes. The mice were irradiated in this arrangement.

vessel at the distal end of the spleen was cut but not tied. Severing this vessel regularly produced an infarct in the tip of the spleen. The infarct varied in size involving up to one-fourth of the distal tip. No significant bleeding was encountered. During irradiation which required from nine to twenty-two minutes depending on the dose given the spleens of Group III mice were placed in paraffin boxes that offered no appreciable shielding (Fig. 1); the spleens of Group IV mice were placed in lead boxes with walls of one-fourth inch thickness (Fig. 2 A and B and Fig. 3) that afforded essentially complete shielding of the spleen from irradiation. The spleens of Group II were kept in lead or paraffin boxes during the irradiation.

tion of Groups III and IV. The spleens of all groups thus mobilized were kept moist with physiologic saline during the period in which they were outside the body cavity. After completion of these procedures, the spleens of all groups were returned to the abdominal cavity and the incision was sutured with silk. Complete recovery from the anesthetic required from two to three hours. The mice were returned to the animal farm, and deaths were recorded in twenty-four hour periods through twenty-eight days.

#### RESULTS

As indicated in Table I, the percentages of survival of animals in Groups I and II (untreated controls and operated controls) were 96 and 100 per cent respectively. With a dosage of 600 r, 40 per cent of the animals in Group III survived the twenty-eight day period. Accordingly, the  $LD_{50}$  for animals whose spleens were mobilized but not protected was somewhat less than 600 r and probably close to the  $LD_{50}$  of intact animals (550 r). On the other hand, in mice of Group IV which were provided with lead protection of the spleen during irradiation of the balance of the body, a dosage of 975 r was required to reduce survival to about 50 per cent. In other words, these data show that the  $LD_{50}$  for total body  $\alpha$ -irradiation exclusive of the lead-protected spleen is nearly twice as great as the  $LD_{50}$  for total body  $\alpha$ -irradiation inclusive of the spleen.

#### DISCUSSION

The precise mechanism whereby lead protection of the spleen so significantly increases survival following irradiation is yet to be determined. The capacity of the spleens of these mice to compensate so quickly for the destruction of hematopoietic tissue elsewhere in the body may be the significant factor, but other possible direct or indirect functions of the spleen may be involved. For example, data from a preliminary experiment<sup>3</sup> indicate that rabbits retain the capacity to produce antibodies to intravenously administered foreign red cells (1 cc of a 2 per cent suspension of sheep red cells) in a normal manner if either the spleen or appendix is lead protected during the delivery of 800 r  $\alpha$ -irradiation to the balance of the body, total body  $\alpha$ -irradiation with this dosage but without lead protection of the spleen or appendix more or less completely inhibits the development of demonstrable antibodies to this antigen. The antigen was given two days after irradiation and observations on the development of hemolysin titer followed at intervals of seven days through twenty-eight days.

#### SUMMARY

Female CF-1 mice of 10 to 12 weeks of age were divided into four groups. Group I mice were untreated controls. Mice in Groups II, III, and IV were anesthetized with Nembutal, an incision was made in the left upper quadrant of the abdomen, and the spleen was mobilized. Mice in subgroups of Groups III and IV were given various single dosages of  $\alpha$ -irradiation. During irradiation the mobilized spleens of Group IV mice were protected from radiation by lead shielding, whereas no shielding was provided for the spleens of mice in Group III. Group II mice served as "operated" controls. The dosages administered were 600, 700, 900, 975, 1,050, and 1,250 r. Irradiation time ranged between

nine and twenty two minutes. After irradiation the spleen was returned to the abdominal cavity and the incision was sutured. The survival of the mice in these various groups was observed over a twenty eight day period. Without lead protection of the spleen the  $LD_{50}$  for irradiated mice in the twenty eight day period of observation was less than 600 r, whereas the  $LD_{50}$  for mice with lead protection of the spleen approximated 975 r.

#### CONCLUSIONS

The  $LD_{50}$  for mice exposed to total body  $\gamma$  radiation exclusive of the surgically mobilized lead protected spleen is nearly twice as great as the  $LD_{50}$  for mice exposed to total body  $\gamma$  radiation inclusive of the spleen.

# OBSERVATIONS ON MECHANISMS OF EDEMA FORMATION IN THE LUNGS

ROBERT PAINE, M D,\* HARVEY R BUTCHER, M D, FRANK A HOWARD, A B, AND  
JOHN R SMITH, M D  
ST LOUIS, MO

## INTRODUCTION AND REVIEW OF LITERATURE

**K**NOWLEDGE of the pathologic physiology of pulmonary edema has been considered fundamental to the understanding and management of clinical heart failure, and the condition has received extensive study. From a great body of experimental and clinical observation, two theoretical conceptions of the genesis of pulmonary edema from heart failure have emerged.<sup>1, 2</sup> First, many observers have stated that pulmonary edema depends on failure of the left ventricle (the right remaining essentially competent), leading to congestion and edema of the lungs. The second concept has held that pulmonary edema occurs when the pulmonary vascular bed becomes widely dilated from noxious or aberrant reflexes permitting inundation of the lung tissue. This concept has further held that pulmonary edema is not caused primarily by failure of the left ventricle. The importance of the problem of pulmonary edema has seemed to warrant a re-exploration of the condition from the experimental standpoint.

In 1878 Welch<sup>3</sup> stated, in his now famous paper, that severe strain imposed upon the left ventricle by gradual occlusion of the aorta resulted in lung congestion and edema. His experiments indicated that ligation of the aorta distal to the large vessels arising from the arch did not restrict left ventricular output sufficiently to strain the chamber. However, if the vessels to the head and upper extremities were tied off one by one after occlusion of the aorta distal to these vessels, the vascular bed was finally reduced so as to overwhelm the left ventricle, marked pulmonary congestion and transudation followed. Subsequently, a number of German workers were able to offer general confirmation of Welch's observations. Sahli<sup>4</sup> found that obstruction of pulmonary venous drainage by constriction of the left auricle was attended by an outpouring of fluid into the lungs. Sahli was unable to reproduce Welch's results by ligation of the aorta, but it is not clear from his paper where aortic constriction was applied. Other observers<sup>5, 6, 7, 8, 9, 10, 11, 12, 13, 14</sup> were able to show that experimental maneuvers capable of overloading the pulmonary venous circuit could precipitate pulmonary edema. Modrakowski<sup>8</sup> demonstrated that isolated lungs could withstand high arterial perfusion pressures without apparent harm, as long as venous outflow was unimpaired. On the other hand, when the lobes were congested by the prevention of venous outflow, only a moderate elevation of perfusion pressure was necessary to provoke edema.

This work was done under a grant from the Life Insurance Medical Research Fund.

Received for publication Aug. 8, 1949.

\*Rockefeller Fellow in Cardiology, 1948-1949.

Similar experiments were carried out on denervated heart lung preparations<sup>9 10 11</sup>. The data from these experiments indicated that as left ventricular output was diminished (e.g., from cardiac damage by asphyxia "toxic frosts," or acute strain), venous engorgement of the lungs occurred, ultimately causing severe edema. The work of Barry<sup>1</sup> was of particular interest. He observed in heart lung preparations that if the viscosity of the blood was decreased by the addition of saline edema of the lungs could be induced. This effect was apparent when the specific gravity of the blood was reduced from 1.053 (normal) to 1.045 or 1.050. However Barry also observed in these preparations that excessive venous inflow, together with high peripheral arterial resistance overloaded the left ventricle so that congestion and alveolar edema ensued. Barry's observations were of significance in their demonstration that the Starling principles<sup>13</sup> of vascular pressures and tissue fluid balance may apply to the lung as well as to structures supplied by the peripheral vascular system.

On the basis of such experiments the concept of pulmonary engorgement and transudation from predominant left ventricular failure has been widely accepted, and much of the rationale of the management of clinical heart failure has rested upon this premise.

Many observers, however, have accepted the alternative concept that pulmonary edema may result from intense reflex vasodilatation of the vascular bed of the lungs or from increased capillary permeability. They have argued that failure of the heart may not be primarily concerned in initiating pulmonary edema. Lambert and Giemels<sup>15</sup> insisted that the formation of edema in heart lung preparations was accompanied by only a slight rise of pulmonary venous and arterial tensions. These pressures became significantly elevated after edema was established. They thought the capillary leakage was caused by the "toxicity" of the shed blood used in the preparations. A number of others<sup>11 16 17 18</sup> have shared the view that toxic factors occurring in the blood may injure the pulmonary capillaries and facilitate transudation.

Cataldi<sup>19</sup> used a technique similar to that of Coelho and Rocheta<sup>14</sup> and he noted the precipitation of pulmonary edema when portions of the right ventricle were destroyed by solutions of silver nitrate or absolute alcohol introduced into the ventricular wall. He contended that failure of the left ventricle was not a necessary prerequisite to the onset of pulmonary edema, for damage to the right ventricle might be equally deleterious to the lungs.

The contention that pulmonary vascular reflexes may lead to lung edema formation has rested largely on observations entailing marked disturbances of the sympathetic nervous system<sup>19 20</sup>. Lusada<sup>19</sup> produced paroxysms of edema in rabbits by the use of adrenaline. The paroxysms were often prevented by the use of sedatives (i.e. morphine or the barbiturates), or by transection of the spinal cord at the cervical level. He attributed these effects of adrenaline to stimulation of the central nervous system including centers controlling pulmonary vascular reflexes and capillary permeability. In contrast evidence has been evolved to show that adrenaline may seriously affect the heart<sup>9</sup> and provoke myocardial failure. Lusada and Sainoff<sup>22</sup> declared that experimental

procedures producing cerebral anemia may alter the distribution of blood within the lungs by vasomotor mechanisms, so that alveolar transudation occurs. A similar explanation was suggested by Janisch and co-workers<sup>23</sup> for the edema resulting from the intracisternal injection of veratrine in rabbits. Faiber<sup>24</sup> reported that edema of the lungs frequently occurred in guinea pigs following bilateral cervical vagotomy causing the loss of vasomotor control of the lungs. However, Sussman and co-workers<sup>25</sup> could find no such effect of vagotomy in guinea pigs when respiration was optimally maintained.

On the basis of clinical observation, a number of workers have suggested that pulmonary edema may be touched off by failure of autonomic control of the pulmonary vascular bed. Salmon<sup>26</sup> implicated stimulation of the carotid sinus as a means of inducing transudation. Intracranial hemorrhage<sup>31</sup> and injuries of the spinal cord<sup>32</sup> and of the medulla oblongata<sup>33</sup> have likewise been reported to cause intense pulmonary edema.

In most of the clinical and experimental observations of "neurogenic pulmonary edema, measurements of cardiac performance were not reported. If the function of the heart were seriously curtailed through aberrant autonomic stimulation from various causes, one might expect lung congestion and its consequences from a critical decrease of left ventricular output. In fact, Campbell, Haddy, and Visscher<sup>34</sup> have shown recently that elevation of intracranial tension may be accompanied by marked bradycardia, diminution of cardiac output, and elevation of pulmonary venous and arterial pressures, with the occurrence of pulmonary edema. These responses were modified by severance of the vagus nerves.

The conflicting views of the genesis of pulmonary edema, as indicated in this review, have not been reconciled. Luisada has stated that "the generally unsatisfactory basis for the backward failure theory of pulmonary edema strongly favors its abandonment."<sup>13</sup> On the other hand, there is a paucity of evidence to support the "neurogenic theory" as the sole cause of edema of the lungs. Furthermore, other evidence has indicated that the latter concept must be viewed with skepticism until reflex effects upon the heart and its function have been investigated more thoroughly.

It seems clear however that any attempt to reexplore the cause of pulmonary edema requires an understanding of the means by which abnormal fluid exchange may occur in the lungs. Although the concise precepts of fluid balance described by Starling<sup>13</sup> are widely accepted as applying to the lung as well as to other tissues, there has been little controlled observation of the Starling principles on the lungs. Experiments were therefore designed to test the effects of increased capillary hydrostatic pressure and of diminished osmotic tension (the Starling principles) on pulmonary circulatory function. Experiments dealing with this aspect of the problem will be reported in this paper.

#### METHOD

Experiments were performed on dogs under Nembutal anesthesia. The right thoracic duct was isolated, and the rate of lymph flow was measured by the method previously described by us.<sup>35</sup> Under positive pressure respiration, the thorax was opened and the

pericardium incised. The animal was then heparinized in the usual manner after careful hemostasis had been secured. Systemic and pulmonary arterial pressures were recorded from cannulae placed in the left abdominal artery and right upper pulmonary lobar artery, these were connected to simple mercury manometers. A water manometer was attached to a cannula tied into the left atrial appendage. Ordinary heart lung preparations were then set up.

In order to study the effects of decreased osmotic pressure the protein content of the blood was reduced by partial replacement of the plasma with Locke's solution (six experiments). Dilution was accomplished by centrifuging a quantity of blood approximately equal to that in the circuit; the plasma was removed to the level of the packed cells by suction, and the original plasma volume was then restored by the addition of warmed Locke's mixture. At any given time the normal blood in the venous reservoir could be drained away and replaced by the red cell suspension. The rates of lymph flow, the various pressures, and the appearance of the lungs were repeatedly observed. Sections of the lungs for histologic examination were taken during and at the termination of the experiments. Plasma protein levels were determined by the methods of Campbell and Hanna<sup>36</sup> and of Howe.<sup>36, 37</sup>

The effect of increased pressure in the pulmonary capillaries on edema formation was studied in six preparations. Pulmonary engorgement was produced by overloading the left ventricle. Elevation of venous inflow (and therefore cardiac output) or increase of the peripheral resistance singly or together produced left ventricular dilatation and left atrial engorgement. The effects of this treatment on pulmonary arterial and venous pressures and on blood volume were noted. Lymph flow was frequently determined and sections for microscopic study of the lungs were taken.

All specimens of lung tissue were fixed in formal saline solution (Trowell<sup>3</sup>) so as to facilitate preservation of edema fluid and were stored in 80 per cent alcohol.

## RESULTS

*Effects of Diminution of Plasma Proteins on the Formation of Pulmonary Edema*—During the control periods the heart lung preparations functioned under loads that appeared to place no strain upon the myocardium. Usually the peripheral resistance was adjusted to produce a mean aortic pressure of 90 to 110 mm Hg; the cardiac inflow was about 400 cc per minute. Under these conditions mean pulmonary arterial pressure varied from 10 to 20 mm Hg, and left intra atrial tension ranged from 3 to 6 cm of water. Thereafter the suspension of cells in Locke's fluid was placed in the venous reservoir after removal of as much of the normal blood from the circuit as possible without introduction of air into the venous tubing. Usually 200 to 300 cc of the cell suspension were used. In most experiments it was estimated that approximately one half of the circulating blood volume was replaced when these quantities of cell suspension were used.

The effects of the addition of diluted blood were first manifested in the flow of lymph from the lungs. The flow increased notably within one to ten minutes and thereafter was progressively accelerated. The level of blood in the venous reservoir decreased indicating a loss of circulating blood volume. However, the size of the heart was not increased and pressures in the pulmonary arteries and left atrium were not materially altered. In four experiments pulmonary arterial pressure was not affected at all; in one instance a decrease of 4 mm Hg tension was noted while in two examples there were transient elevations of the pulmonary blood pressure of 5 mm Hg. Pulmonary venous pressures were unaltered in two instances and rose from 2 to 6 cm of water in four

preparations. Therefore, the continued normal size of the heart and the general level of performance indicated that cardiac function was not impaired (Fig 1 and Table I)

After the cell-saline suspension was circulating in the preparations, and during the period of fluid loss into the lungs, there was a gradual return of plasma protein concentration to normal values. In some instances the plasma

Fig 1—The effect of hypoproteinemia upon fluid exchange in the lungs. At the time indicated low protein blood was placed in the heart lung system. Protein concentration of the blood is indicated by curve. Columns represent lymph flow. Abscissa is time in minutes. See Table I Experiment 48.

proteins continued to rise to concentrations greater than those in the normal, undiluted blood (See Table I). However, with the rise of plasma protein concentrations to control (or above control) values, a corresponding diminution of lymph flow and reduction of pulmonary edema was *not* observed. This phenomenon is well illustrated in Fig 1. Note that the curve indicating plasma protein concentration of the cell suspension showed a progressive increase, but that lymph flow also showed a continuous rise. The persistence of accelerated lymph flow after the return of plasma proteins to normal levels probably represented the drainage of the previously accumulated fluid from the lungs. However, the mechanism by which the plasma proteins subsequently rose to levels

above control values is not clear. Possibly the interstitial fluid produced by the initial hypoproteinemia obstructed aeration of the lung tissue causing anoxic damage to the pulmonary capillaries and abetting transudation of protein poor fluid. Another explanation may be that plasma protein lost into the extravascular space during initial transudation increased tissue fluid osmotic tension to such a degree that transudation went on despite the increase of blood protein level, producing greater hemoconcentration.

*Influence of Cardiac Insufficiency and Pulmonary Congestion on the Formation of Edema of the Lungs*—These observations were carried out on six heart lung preparations. For control purposes the venous inflow and peripheral resistance were adjusted so as to impose no undue strain upon the hearts as in the preceding experiments. In four experiments the cardiac load was augmented by increasing the aortic pressure from 90 to 110 mm Hg to 160 to 180 mm Hg. In two instances, overburdening of the heart was accomplished by sharp elevations of venous inflow to 600 to 700 cc per minute (control 200 to 300 cc per minute). With both means of taxation of the heart left ventricular dilatation became apparent. The pulmonary venous and arterial pressures then rose and congestion promptly ensued. Congestion of the lungs was manifested by turgescence, followed quickly by dusky of the tissue. Myriads of fine crepitant rales could be discerned by direct auscultation. The fluid volume in the venous reservoir diminished rapidly, and the passage of lymph from the right thoracic duct progressively increased beginning three to twelve minutes after the onset of congestion. As the process continued the pulmonary lymph became pinkish in hue and finally dark red. Microscopic examination of the red lymphatic fluid showed that it contained up to 600,000 red blood cells per cubic millimeter. Sections of the lung tissue taken at the time of accelerated lymph flow exhibited intense congestion and edema. In some instances pulmonary transudation was so mired that foam extended into the main bronchi and trachea. In all of these experiments pulmonary engorgement and edema was permitted to become extreme, no attempt was made to reverse the process by reducing cardiac load.

The difference in appearance between these lungs and those of the hypoproteinemic experiments was striking. When the hypoproteinemic lungs became edematous, they were pale and flaccid, the acceleration of lymph flow was not so rapid, and the general tempo of the reaction was rather gradual. In contrast, the congested lungs became red and turgid, the acceleration of lymph flow was rapid, and the lymph became hemorrhagic. Edema fluid was frequently profuse.

Fig 2—The effects of pulmonary congestion upon fluid exchange in the lungs. When the heart lung was established in this experiment, peripheral resistance was excessive and pulmonary congestion immediately appeared as indicated by venous and arterial pressure curves. Congestion was further increased at arrows. Columns represent lymph flow.

#### DISCUSSION

These experimental data suggest that the well-known Starling principles of vascular and tissue fluid balance are operative in the lung structures. The mechanism of pulmonary edema induced by low plasma protein—low blood osmotic tension—is clear and requires no particular comment. However, the production of pulmonary edema from congestion is more important from the standpoint of cardiac insufficiency.

The experiments show that in the heart-lung preparation, left ventricular load may be greatly augmented by elevation of aortic pressure or by increasing the stroke and minute output or by both. Thus the left ventricle can be overloaded so that venous inflow (and right ventricular output) may exceed the greatest possible left ventricular output. With failure of the left ventricle to accept all of the blood flowing to it through the lungs, pulmonary venous

outflow is impaired and blood is impounded in the lungs by the continuing competence of the right ventricle. Examination of Fig 2 and Table II shows that these events cause pulmonary venous and arterial pressures to rise to high levels. Since the normal pulmonary capillary pressure is estimated at mean values of 10 to 15 mm Hg in open chest preparations<sup>33</sup> and the normal blood osmotic pressure at 20 mm Hg (judged by normal plasma protein levels in these and other<sup>39</sup> experiments) it is apparent that capillary pressure may exceed that of the osmotic tension when the lungs are congested. Rapid filtration of fluid from the capillaries then occurs.

A contrasting explanation for experimental pulmonary edema was offered by Luisada and Sarnoff<sup>22</sup>. They reported experiments in which saline infusions, given in large quantity, produced pulmonary edema. They noted that when the solutions were injected cephalad into the carotid arteries under high pressure edema of the lungs frequently occurred. On the other hand when comparable amounts of fluid were injected into the systemic veins under lower pressure, edema was somewhat less frequent. They suggested that forcible irrigation of the cerebral circulation by salt solutions resulted in cerebral anemia and provoked pulmonary transudation by reflexogenic influences on the vascular bed of the lungs. Their results were compatible with sudden and serious cardiac overload. They paid scant attention to the possibility of altered circulatory dynamics, and the influence of massive saline infusions on the plasma proteins was not considered.

Other workers<sup>40-41</sup> have also reported that massive increases in the circulating fluid volume may introduce a load against which the heart cannot cope, with consequent pulmonary congestion and edema. This factor was particularly striking in the studies of Gibbon and Gibbon.<sup>7</sup> In cats they removed the right middle and both lower lung lobes so as to raise the pulmonary hydrostatic pressure by restriction of the circulatory capacity of the lungs. They found that intravenous saline infusions were especially likely to provoke pulmonary edema and rapid death in these preparations. Although these workers attributed the edema mainly to increased capillary permeability rather than to any dynamic effects, their results suggest that edema occurred from elevation of the pulmonary hydrostatic pressure and possibly from diminution of the plasma proteins.

The correlation of increased lymph flow and the onset and progression of pulmonary edema was strikingly evident in these experiments. We noted that in every instance where a significant elevation of lymph flow occurred, gross or microscopic pulmonary edema could be found.

#### SUMMARY

Experiments are presented which show that pulmonary edema may be induced in the heart-lung preparation by (1) the lowering of the plasma proteins from replacement of blood plasma with Locke's solution and (2) by elevation of pulmonary vascular (hydrostatic) pressures following imposition of left ventricular overload. It was demonstrated that abnormal fluid exchange in the lung tissue may result from disturbances of hydrostatic and osmotic pressure relationships as described by Starling.<sup>13</sup> Although the results of these experiments, involving the heart-lung preparation, do not necessarily explain the cause of acute pulmonary edema in intact subjects, they do demonstrate that Starling's principles apply to the pulmonary as well as to the systemic circulation. The Starling principles, therefore, must be considered in all future studies relating to the pathogenesis of pulmonary edema.

The onset and progression of pulmonary edema were always attended by an increase in the flow of lymph from the right thoracic duct. The measurement of an increased pulmonary lymph flow has been found to be a reliable indicator of the presence of pulmonary edema.

## LABORATORY METHODS

### POLYVINYL ALCOHOL-FIXATIVE AS A PRESERVATIVE AND ADHESIVE FOR PROTOZOA IN DYSENTERIC STOOLS AND OTHER LIQUID MATERIALS

M M BROOKE, D SC, AND MORRIS GOLDMAN, MS  
ATLANTA, GA

WITH THE TECHNICAL ASSISTANCE OF SADIE A JOHNSON, A B

TROPHOZOITES of intestinal amoebae deteriorate rapidly, and consequently it is frequently difficult for a physician to get laboratory confirmation of suspected cases of amoebic dysentery or amoebiasis. Submitting the stool to a distant laboratory for diagnosis has been unsatisfactory since the etiological agent, even if originally present, is usually unrecognizable by the time the specimen is examined. A negative report under these circumstances is, of course, meaningless.

In an attempt to solve this problem, Goldman<sup>1,2</sup> devised a technique for preserving fecal smears with a film of polyvinyl alcohol (PVA)-fixative. Smears so prepared could be shipped for long distances or stored in a dried condition for months without undergoing any deterioration. In the laboratory, the PVA films were removed and the smears were stained by standard hematoxylin procedures.

During 1948, this method was used by this laboratory in cooperation with local health officials and physicians in Georgia, Alabama, Mississippi, Kansas, North Dakota, Minnesota, and California. Out of thirty specimens submitted during several months, a diagnosis of *Endamoeba histolytica* was made in thirteen instances. The rest showed either no organisms or trophozoites and cysts of various other intestinal protozoa (*Endamoeba coli*, eleven, *Endolimax nana*, fifteen, *Dientamoeba fragilis*, one, and *Giardia lamblia*, one).

The purpose of the present paper is to report simplified and improved methods for preparing specimens and for handling them in the laboratory, and to point out possible applications of the technique to the study of organisms other than intestinal protozoa.

#### MATERIALS AND METHODS

*Polyvinyl Alcohol*—Polyvinyl alcohol is a synthetic water soluble polymer of vinyl alcohol that is available in the form of a white, odorless powder or granular material. Its aqueous solutions are stable over long periods of time. Viscosity of the solutions can be regulated

From the Laboratory Division, Communicable Disease Center, Public Health Service, Federal Security Agency.

Received for publication July 23, 1949

by concentration of PVA and by the degree of polymerization of the alcohol\*. Films formed by drying aqueous solutions are tough thin and transparent. They generally adhere firmly to clean glass surfaces and are resistant to alcohol, ether, acetone, xylol, oils, and even short exposures to water.

PVA has been used as an embedding medium for tissues<sup>3</sup> as a mounting medium for insects and fungi<sup>4</sup> and as a means of reducing motility of paramecia and other small organisms<sup>7</sup>.

**PVA Fixative**—The fixative was prepared as described by Goldman<sup>2</sup>. Five grams of powdered PVA were added to a mixture at room temperature containing 15 ml of glycerol, 5 ml of glacial acetic acid and 93.5 ml of Schaudinn's solution (2 parts of saturated aqueous mercuric chloride to 1 part of 90 per cent ethyl alcohol). Heating to approximately 75° C while stirring facilitated the preparation of a water clear nonlumpy solution. This was used as soon as it had cooled to about 20° C or less and it remained satisfactory for several months.

#### *Preservation of Specimens With PVA Fixative*—

**A On Microscope Slides** With the aid of an applicator stick, a drop of specimen was mixed on a microscope slide with 3 drops of fixative and smeared over approximately one third of the glass surface. To insure thorough drying smears were usually placed in an incubator at 37° C overnight.

**B In Vials** A quantity of specimen was thoroughly mixed in a vial containing three or more parts of fixative. Smears for staining were prepared immediately or months later by spreading a drop or two of the mixture on a microscope slide and allowing it to dry thoroughly. Care was taken not to have the smears too thick.

**Staining of Organisms in PVA Films**—In the original PVA fixative technique, fecal smears were covered but not mixed with fixative. In the laboratory the films were removed before staining the smears. The present methods of preservation were made practical by the observation that PVA films are permeable to all commonly employed staining reagents. This makes it possible to stain dried PVA smears in the same manner as smears fixed by conventional methods with Schaudinn's fixative.

Inasmuch as critically stained organisms were desired, the long Heidenhain iron hematoxylin procedure usually was employed. Diagnostically satisfactory preparations were obtained by more rapid staining procedures such as the ones proposed by Tompkins and Miller<sup>8</sup> and Goldman<sup>9</sup>. Delafield's hematoxylin was used in some instances as in staining *Paramecium*. In all of the staining procedures dried films were first placed in 70 per cent alcohol containing iodine for ten minutes or longer in order to remove mercuric chloride crystals.

Ordinarily if the PVA film on a slide is thoroughly dried before being stained it adheres perfectly. In rare instances, for reasons not entirely understood, films may wrinkle around the edge or in the middle and show a tendency to slip off the slide during prolonged exposure to aqueous solutions. This tendency may be minimized by preparing relatively thin, rectangular smears. To prevent the loss of a wrinkling film the slide may be placed in the incubator in a horizontal position and allowed to dry before continuation of the staining process.

In order to test the effect of drying organisms in PVA films, such films were thoroughly dried (over three hours at 37° C) after each of the different steps in the iron hematoxylin procedure. After each interruption the slides were placed in the next solution and the staining was completed in the usual manner. Only those slides were unsatisfactory which were dried after removal from the graded alcohols during dehydration. Therefore, contrary to the usual direction never to allow fecal smears to dry during the staining procedure, in the PVA fixative technique no particular harm is done at most of the steps.

Polyvinyl alcohol is marketed under the trade name of Elvanol in various grades representing degrees of polymerization and hydrolysis. The product used in this study was Elvanol 90-90 obtained from E. I. du Pont de Nemours and Co. Electrochemicals Department, Wilmington 98, Del. This does not represent an endorsement of the product by the Public Health Service.

## OBSERVATIONS AND DISCUSSION

No differences have been observed between organisms stained after preservation with PVA-fixative and those stained after usual methods of Schaudinn fixation. Nuclear details and cytoplasmic inclusions are clearly defined. Rapid and complete fixation apparently occurs, since many trophozoites exhibit protruding pseudopods.

One distinct advantage of PVA-fixative is that it makes possible successful staining of organisms in liquid specimens. Anyone who has ever attempted to prepare permanent stained mounts of protozoa in cultures, watery stools, or pond water has experienced the difficulty of retaining organisms on the slide during staining procedures. When PVA-fixative is used, it serves to adhere as well as to preserve the organisms and prevents their loss during staining. Stained slides containing many organisms have been made from the following liquid specimens: diarrhetic stools and liquid overlay of cultures containing trophozoites of *E. histolytica* (Figs 1 and 2), loose stools containing trophozoites of *E. coli* (Fig 3), *Iodamoeba buetschlii* (Fig 4), *E. nana* (Fig 5), *D. fragilis* (Fig 6), and *G. lamblia* (Fig 7), cultures and pond water containing *Paramecium* (Fig 8) and other protozoa, and tap water containing miracidia of *Schistosoma mansoni* (Fig 9). The only other way known to the authors to stain consistently large numbers of organisms in such specimens is the bulk centrifuge method employing test tubes. However, the PVA-fixative technique is considerably simpler, particularly when only a few slides are to be prepared.

The technique is also useful for preserving interesting specimens or teaching materials for subsequent staining. A variety of organisms have been preserved in liquid fixative and in dried films for about a year without showing any changes when stained. Of particular interest is a specimen of aspirated material from an amoebic lung abscess preserved in a vial with PVA fixative (Fig 10).

At present PVA-fixative cannot be recommended unreservedly for preserving specimens containing cysts. Larger cysts are frequently distorted, apparently during drying of the PVA film. However, in specimens containing many cysts, enough of them with distinct characteristics are usually present to insure correct identification. Occasionally, exceptionally good preparations are obtained even of *E. coli* (Fig 11) and *I. buetschlii* (Fig 12) cysts. Smaller cysts such as *G. lamblia* (Fig 13) and *E. nana* (Fig 14) are usually not adversely affected. As would be expected, staining PVA-fixative films is not an efficient technique for diagnosing helminth eggs.

In general, stool specimens containing cysts and eggs are best examined in wet mounts prepared either directly from the specimens or following a concentration procedure. In such mounts the refractive appearance of unstained cysts and eggs makes them relatively easy to detect with a low-power objective. Helminth eggs and some cysts usually can be diagnosed in temporary mounts of PVA-fixed specimens, but the fixative destroys the refractiveness of the organisms and renders them more difficult to find and identify.

Although the PVA fixative technique might be applied to the study of many different types of organisms, it has been developed primarily to assist the public health laboratory in securing diarrheic, dysenteric, purged, and protoscopic specimens in a satisfactory condition for diagnosis of amoebiasis. The methods described in this report can be adapted easily to this need. For submitting stool specimens small vials (15 ml capacity), two thirds full of PVA fixative, can be distributed to physicians in the same manner that vials containing other preservatives are supplied. Since the PVA fixative technique is not a good method for diagnosing cysts and eggs, the physician should also be supplied with a vial containing no preservative. He should be instructed to place approximately 4 ml portions of *fresh* liquid or formed stool in each vial and to mix the specimen thoroughly in the vial containing fixative.

With the two vial method of submitting specimens, a variety of parasitological techniques can be performed and demonstrations of protozoa and helminths can be made regardless of their stage of development. For example, the vial containing PVA fixative will furnish material for many smears which can be stained and examined for trophozoites and cysts of amoebae and other intestinal protozoa. The vial containing no preservative will furnish material for such gross examinations as consistency of stool, blood, mucus, portions of adult worms, etc. for microscopic examination of temporary mounts (saline and iodine) for protozoan cysts and helminth eggs and larvae and for concentration procedures for cysts and eggs.

The expense involved in preparing PVA fixative is nominal. One pound of PVA costs less than a dollar and is sufficient to make enough fixative to fill a thousand 15 ml vials approximately two thirds full. Other ingredients of the fixative—mercuric chloride, ethyl alcohol, acetic acid and glycerine—are standard laboratory reagents.

#### SUMMARY

1 Methods are described for the use of polyvinyl alcohol (PVA) fixative as a preservative for intestinal protozoa and other parasitic and free living organisms.

2 Organisms so preserved will remain suitable for staining for several months. Best results are obtained with amoebic trophozoites which are otherwise difficult to preserve.

3 In addition to its preservative action, PVA fixative acts as an adhesive to prevent loss of organisms from smears during staining procedures.

4 The technique has been developed primarily to aid in the diagnosis of amoebiasis and is readily adapted to this need. A two vial method for shipping stool specimens is suggested which would enable the laboratory to recover all diagnostic stages of the intestinal parasites.

## DESIGN OF A PUMP SUITABLE FOR BLOOD

ABRAHAM SALTZMAN M D AND STEPHAN S ROSENAK M D  
NEW YORK N Y

THERE has been a need in experimental medicine and therapeutics for a pump that could convey blood under sterile conditions without hemolysis, acceleration of the clotting process or introduction of pyrogens. Our special interest has been in a pump which will bring the blood of a human subject from a vein to a dialysis apparatus for the removal of products of uremia at variable and appropriate rates. Recently, a number of types of extracorporeal blood dialyzers have been made some of which utilize pumps of various designs. However, none of these completely satisfies all of the above mentioned requirements. The various dialyzing procedures for the treatment of uremia in relation to dietary and other measures have been the subject of a comprehensive review by Snapper<sup>1</sup>. De Leeuw and Blaustein<sup>2</sup> and Vanatta, Muirhead, and Grollman<sup>3</sup> have noted that the Beek pump which forms an integral part of the original Kolff 'artificial kidney' and serves to return blood from the dialyzer to the vein of the patient itself produces hemolysis of the blood circulating through it. Vanatta and co workers have eliminated, therefore, the use of the pump for this purpose and were able to substitute gravity for the return of the blood.

In the following report a simple pump will be described that meets our stringent requirements rather well. In this apparatus there are no valves, close fitting or metal parts in contact with the blood. Dead spaces where the current moves slowly are eliminated and air bubbles are not introduced. A self regulating pressure principle provides safety for the cellophane tubing in the dialysis apparatus proper and sterility is accomplished by autoclaving.

In principle the pump consists of a Tygon tube of suitable wall thickness and diameter which is compressed in a wave like motion by a series of twelve keys that push the column of fluid ahead. Behind the crest of the wave the plastic tubing expands by its own resiliency to fill up again. The baffle plate against which the tubing is compressed is adjusted so that the compression of the tubing is incomplete. Pumping will then cease at a predetermined pressure if increased resistance in the outer circuit causes that pressure to be attained. Furthermore the compression of the tubing is largely performed by one elevated edge of the key rather than by a flat surface, reducing thereby the area in which mechanical trauma may occur.

In the apparatus (Fig 1) a constant speed electric motor with a gear device drives a screw shaped series of twelve rings on an axle. The rings elevate a series of twelve keys to create pressure on the tubing. The rings are evenly spaced at intervals to form one complete sine wave. The amplitude of the wave can be limited by restricting the extent of motion of the keys. The

Received for publication July 20, 1949.

tubing lies between the keys and the adjustable plastic baffle. In usage, the tubing is autoclaved and placed on the keys and the baffle is fastened on top. The baffle can be set for complete compression of the tubing, with the attainment of pressures well over 300 mm Hg. By loosening the set screws, the baffle can be adjusted to allow leakage at any intermediate pressure.

Fig 1—Cross-section diagram of pump. Compression incomplete at height of wave.

Fig 2—Relationship between output and pressure within the system.

In Fig 2 the inverse relationship between output and pressure within the system is shown in an experiment in which the baffle was regulated to have pumping stop at about 200 mm Hg. The increase in pressure within the output or arterial side of the system is attained by increased peripheral resistance. Increased resistance on the suction or venous side of the pump would have the same effect of lowering the output of the pump. By limiting the maximal pressure, the cellophane tubing used in dialysis can be safely guarded against undue stress which can result in breakage.

Outputs of from 1 to 18 liters per hour were obtained by varying the stroke volume and the diameter of the tubing used in the model at hand. The output remained constant as long as the peripheral resistance was unchanged.

The pump in the Kolff "artificial kidney" has rollers that create shearing stresses in the tubing and provide a large area for mechanical trauma. In the apparatus described in this report no shearing motion is possible since the keys can move only in the vertical plane. The rate of hemolysis of the blood recirculated through a closed circle of tubing of 20 ml<sup>3</sup> volume at 37° C was determined with the pump herein described. Since hemolysis was not observed with normal blood, freshly drawn heparinized blood from a patient in uremia (urea N 148 mg per cent) was taken for testing. The rate of blood flow was 125 ml per minute and the maximum pressure attainable was set at 220 mm Hg. Absolutely no hemolysis was discernible after 12 minutes (72 circuits of the blood). In 18 minutes of recirculation of the blood (108 circuits) a very faint trace and in 24 minutes (144 circuits) a faint trace of hemolysis appeared. Since about 50 circuits of the blood volume through our pump and dialyzer is the maximum recirculation to be expected the mechanical trauma to the blood by the pump is negligible.

In summary, a pump is described that conveys blood under sterile precautions without hemolysis for 72 circuits of the blood volume. It is without valves, contains no dead space and provides safety when coupled to a cellophane tube dialyzer by ceasing to pump at predetermined pressures.

The cooperation of Mr G J Frank, Jr and Mr J C Marsh of the Marsh Laboratory, Pittsburgh, Pa., is gratefully acknowledged.

# AN ELECTROMETRIC METHOD FOR THE DETERMINATION OF RED BLOOD CELL AND PLASMA CHOLINESTERASE ACTIVITY

HARRY O MICHEL, PH D  
ARMY CHEMICAL CENTER, MD

THE method for the determination of cholinesterase activity described in this paper was developed to provide a more convenient procedure than those used previously, and one which would require only apparatus generally available in the average laboratory rather than the specialized apparatus heretofore necessary

The principle of the method is fundamentally the same as that used in all of the chemical methods that have been described and depends upon measurement of the acid produced by the action of cholinesterase on acetylcholine. The acid production is measured in terms of the change in pH produced by enzymatic activity in a standard buffer solution over a definite period of time. The pH is measured with the glass electrode.

The rate of pH change will be a satisfactory measure of enzyme activity if an approximately linear relationship between these two quantities can be established. It is well known that cholinesterase activity decreases markedly with decrease in pH over the range from pH 8 to pH 6, which is approximately the range covered in this method. A buffer has been chosen therefore whose decrease in buffer capacity over this range closely approximates the decrease in enzymatic activity. A further consideration is the possible effect of the added enzyme source (plasma or red cells) on the total buffer capacity of the system. This has been minimized by sufficient dilution of the plasma or red cells so that any buffering effect is low compared with the total buffer present.

The data on which the method is based have been obtained using human blood, but the method is applicable in principle to the blood of other species, and to other tissues, provided that proper allowance is made for the buffer capacity of the material being used.

## EXPERIMENTAL

### Reagents Required —

1 *Buffer I (for Red Cells)* 0.02M sodium barbital (4.1236 Gm.), 0.004M  $\text{KH}_2\text{PO}_4$  (0.5446 Gm.), 0.60M KCl (44.730 Gm.) For 1 liter of buffer the reagents are dissolved in 900 ml of distilled water, 28.0 ml of 0.1N HCl are added while shaking the solution, and the volume is then made to the mark. The pH of buffer I should be 8.10 at 25° C.

2 *Buffer II (for Plasma)* 0.006M sodium barbital (1.2371 Gm.), 0.001M  $\text{KH}_2\text{PO}_4$  (0.1361 Gm.), 0.30M NaCl (17.535 Gm.) For 1 liter of buffer dissolve the reagents in about 900 ml of distilled water and add 11.6 ml of 0.1N HCl before diluting to volume. The pH of buffer II should be 8.00 at 25° C.

3 *Acetylcholine Substrate for Red Cells* 0.11M acetylcholine chloride (2.000 Gm in 100 ml of distilled water)

From the Biochemistry Section, Medical Division, Army Chemical Center, MD.  
A preliminary report was given before the American Society of Biological Chemists at Detroit 1949 (Federation Proc. 8: 229, 1949).  
Received for publication July 30, 1949.

✓ 4 *Acetylcholine Substrate for Plasma* 0.165M acetylcholine chloride (3.000 Gm in 100 ml of distilled water)

A few drops of toluene are added to all the foregoing solutions as a preservative and the solutions are kept in a refrigerator when not in use

5 0.01 per cent saponin

6 0.90 per cent NaCl

These two solutions are made fresh as needed

*Method for Red Cells*—Approximately 5 ml of freshly drawn blood, containing sufficient heparin to prevent clotting are centrifuged at 2,000 r.p.m. for fifteen minutes in a graduated centrifuge tube and the plasma is separated. The cells are mixed with 2 to 3 vol of 0.9 per cent NaCl and again centrifuged at 2,000 r.p.m. for fifteen minutes. After discarding the supernatant fluid the operation is repeated, centrifuging this time for twenty minutes. The volume of the cells is noted and then the saline supernatant is removed to the point where the remaining volume of cells and saline is twice the volume of cells alone. The cells are then mixed thoroughly with the remaining saline. After mixing 0.4 ml of cell suspension is hemolyzed in 9.6 ml of 0.01 per cent saponin solution. One milliliter of hemolyzed red cell solution, representing 0.02 ml of cells is added to 1 ml of buffer solution I and placed in a water bath at 25° C. After allowing ten minutes for equilibration, the initial pH ( $pH_i$ ) is determined with a pH meter reading to the nearest 0.01 pH unit. Then 0.2 ml of 0.11M acetylcholine solution is added with rapid mixing and the time is recorded. The enzymatic reaction is allowed to proceed for one to one and one half hours and then the final pH of the solution ( $pH_f$ ) is determined. It is necessary to shake the beaker containing the reaction mixture a few seconds after the electrodes have been immersed to establish rapid equilibrium. The time at which the pH was measured is recorded, and the cholinesterase activity in units of  $\Delta pH/\text{hour}$  is calculated by use of the following formula

$$\Delta pH/\text{hour} = \left( \frac{pH_f - pH_i}{t_f - t_i} - b \right) f \quad (\text{Equation 1})$$

where  $pH_i$  = initial pH

$pH_f$  = final pH

$t_i$  = time of mixing with acetylcholine

$t_f$  = time of reading pH

$b$  = nonenzymatic hydrolysis correction corresponding to pH

$f$  = correction for variations in  $\Delta pH/\text{hour}$  with pH corresponding to pH

The  $b$  and  $f$  corrections are given in Table I

TABLE I CORRECTION FACTORS FOR USE IN EQUATION 1

pH	RED CELL CHOLINESTERASE CORRECTIONS		PLASMA CHOLINESTERASE CORRECTIONS	
	$b$	$f$	$b$	$f$
7.9	0.03	0.94	0.09	0.98
7.8	0.02	0.95	0.07	1.00
7.7	0.01	0.96	0.06	1.01
7.6	0.00	0.97	0.05	1.02
7.5	0.00	0.98	0.04	1.02
7.4	0.00	0.99	0.03	1.01
7.3	0.00	1.00	0.02	1.01
7.2	0.00	1.00	0.02	1.00
7.1	0.00	1.00	0.02	1.00
7.0	0.00	1.00	0.01	1.00
6.8	0.00	0.99	0.01	1.00
6.6	0.00	0.97	0.01	1.01
6.4	0.00	0.94	0.01	1.02
6.2	0.00	0.97	0.01	1.04
6.0	0.00	0.99	0.01	1.09

This volume is dependent in part upon the centrifugal force and the time during which it is applied. The average centrifugal force used in this work was approximately 800 times gravity.

To express results in terms of per cent activity relative to some normal value, multiply the  $\Delta$  pH/hour value found for the sample by 100 and divide by the  $\Delta$  pH/hour value considered to be (or found to be) normal. For example, the average  $\Delta$  pH/hour value for red cell cholinesterase activity in twelve normal human subjects has been found to be 0.753. If an unknown sample gave a value of say 0.550, then the per cent activity would be

$$\frac{0.550}{0.753} \times 100 = 73 \text{ per cent}$$

The red cell buffer (buffer I) is made to give a pH of 8.00 after mixing with diluted red cells. Sodium barbital has its maximum buffer capacity in the region of pH 8.0<sup>1</sup> and this is also the region of optimal cholinesterase activity.\* With the ratio of buffer to red cells used, the decrease in buffer capacity parallels the decrease in enzyme activity with decreasing pH to give an almost constant value for the enzyme activity in  $\Delta$  pH/hour. This is shown by the relatively small deviations from unity of the  $f$  factors given in Table I. Potassium dihydrogen phosphate is added to maintain the nearly constant relationship down to pH 6.00. The buffer capacity contributed by the added red cells averages 12 per cent of the total buffer capacity, determined by titration between pH 8.00 and pH 7.00.

The activating effect of potassium chloride on red cell cholinesterase has been described by Mendel and Rudney,<sup>3</sup> and Augustinsson.<sup>2</sup> This salt was used in preference to the magnesium or calcium salts customarily employed as activators to avoid precipitation of phosphate. The concentration employed was found to be in the optimum range for activation. Hemolysis by saponin prevents the precipitation of the red cell stroma by the potassium chloride in the buffer.

Although the substrate concentration is greater than the optimum reported for mammalian red cell cholinesterase by Augustinsson,<sup>2</sup> it was necessary to use a final concentration of 0.01M acetylcholine in order to maintain the nearly constant rate of pH change over the selected pH range.

✓*Method for Plasma*—The plasma is diluted with water so that each milliliter of solution contains 0.02 ml plasma. One milliliter of diluted plasma is mixed with 1 ml of buffer solution II. The solution is allowed to equilibrate in a water bath at 25° C for ten minutes, and then 0.2 ml of 0.165M acetylcholine is added with mixing. The subsequent determination is carried out, and the activity calculated, in the same manner as described for red cells, using the correction values for plasma given in Table I.

Human plasma contains less cholinesterase activity and has less buffer capacity than the equivalent volume of red cells. Therefore, a more dilute buffer is used. However, similar considerations apply to the decrease in enzyme activity with decreasing pH, as discussed in the preceding section. The buffer capacity of the plasma averages 7 per cent of the total. Salts have a relatively small effect on the activity of human plasma cholinesterase,<sup>4</sup> but the pH of the dilute buffer used can be affected by changes in salt concentration. Sodium chloride is added to the buffer to reduce possible variations in total salt concentration.

Both buffers I and II slowly decrease in pH and buffer capacity after several weeks and should be checked with a pH meter at the time they are used. If the pH<sub>i</sub> reading for a determination is more than 0.03 pH units below 8.00, a fresh buffer solution should be prepared.

Pure acetylcholine salts will produce a pH change of less than 0.01 pH unit when added to buffers I or II in the concentrations specified in the Methods sections.

*Comparison of the Electrometric Method With the Manometric Method*—Cholinesterase was determined on thirty-one independent samples of plasma and twenty-seven independent samples of red cells from twelve male human subjects, using both the electrometric method described here and a modified form of the manometric method of Annon.<sup>5</sup> In the manometric procedure the reaction mixture for plasma cholinesterase contained 0.05 ml of plasma and 3.0 ml of 0.025M sodium bicarbonate. For determination of red cell cholinesterase

\*See reference 2 for bibliography.

each Warburg manometric vessel contained 0.02 ml of cells and 3.0 ml of 0.025M sodium bicarbonate containing 0.0342M magnesium chloride. In each instance the substrate was recrystallized acetylcholine bromide in a final concentration of 0.015M. The enzyme was tipped from the side arm after ten minutes of equilibration with 5 per cent carbon dioxide in nitrogen. Manometric readings were taken over a forty minute period, the temperature being maintained at 38° C. The electrometric procedure was carried out as described here, the temperature of the reaction being 25° C.

The mean value of the cholinesterase activity by the electrometric method was 0.703  $\Delta$  pH per hour for plasma and 0.753  $\Delta$  pH per hour for red cells. The corresponding values by the manometric method were 226.0 microliters per hour for plasma and 253.0 microliters per hour for red cells. Relative activities were calculated for both methods by dividing individual activities by the appropriate mean values. The differences between the relative activities determined by the electrometric method and the corresponding relative activities by the manometric method were calculated. The standard deviation of the differences was 5.49 per cent for plasma cholinesterase and 5.50 per cent for red cell cholinesterase.

*Nonenzymatic Hydrolysis Correction*—The nonenzymatic hydrolysis correction,  $b$ , was determined by measuring the pII change with time in solutions containing buffer, acetylcholine, and inhibited cholinesterase. Diisopropyl fluorophosphate (DFP) (10  $\mu$ g per milliliter of diluted cells or plasma) was used to inhibit the cholinesterase. The pII was determined at intervals of several hours and  $b$  was then calculated by subtracting the observed pH from 8.00 and dividing by the time in hours.

A slow lowering of pII occurs in the solution of the buffer and enzyme in the absence of substrate and is included in the  $b$  correction.

*Correction Factor  $f$* —The values for the correction  $f$ , given in Table I, are based on samples taken from ten subjects. To determine the values, activity measurements were made as described in the Methods section, but pH readings were taken successively on each sample at approximately ten minute intervals over the pH range from 8.00 to 6.00. The value of  $f$  at pII 7.00 was arbitrarily set equal to 1.00. Using Equation 1, the values of  $f$  were calculated for the selected pH range.

#### DISCUSSION

The advantages of the electrometric pII method are simplicity, a requirement for a minimum of equipment, and the possibility of doing a large number of determinations in a relatively short time. The pII readings may be made easily in a time of one minute for each sample. It is therefore possible to do a large series of determinations in a few hours by adding the substrate to the samples at one minute intervals.

After this method had been developed, a similar procedure by Cioatto and associates<sup>7</sup> was found in which rate of pII change is used as a measure of serum cholinesterase activity, the pII being measured colorimetrically in a Pulfrich photometer. This method is applicable only to relatively uncolored solutions.

## SUMMARY

1 An electrometric method for plasma and red cell cholinesterase activity is presented in which the enzymatic release of acetic acid from acetylcholine is measured in units of pH change per hour, in a solution of standard buffer capacity

2 The method has been compared with the standard manometric procedure. The standard deviation of the differences between the methods was 5.49 per cent for plasma cholinesterase and 5.50 per cent for red blood cell cholinesterase.

The author wishes to thank Mr. P. Zvirblis and Mrs. P. D. McNamara for their assistance in this work.

# STERILIZATION OF DIFUNCTIONALIZED LOOPS OF COLON IN PREPARATION FOR ANASTOMOSIS WITH OTHER VISCERA

## A METHOD OF STUDY AND APPROPRIATE SELECTION OF ANTIBACTERIAL AGENTS

CHESTER W. HOWE, M.D.  
BOSTON, MASS.

IN ADMINISTERING intestinal antiseptics for surgery of the large bowel a reduction of the bacterial count of the feces timed to be at a maximum on the day of operation is desirable. Two patients were recently treated with a combination of antibiotic and chemotherapeutic agents to prepare the colon for anastomosis with other viscera. At operation full thickness segments of colon approximately 10 cm. square were excised from the operative site for aerobic and anaerobic bacteriologic cultures. In the first case the cultures revealed no growth. Forty-eight hour cultures from the second case were sterile, but at the end of seventy-two hours rare colonies of *Monilia albicans* and diphtheroid bacilli were recovered. All organisms in the pretreatment cultures of colonic contents which showed the usual profuse mixed intestinal flora were absent (Table I).

The first patient (R. I.) was a 61-year-old man with recurrent obstructing carcinoma of the esophagus following a previous transthoracic resection at which time an extremely short jejunal mesentery was noted. After preliminary gastrostomy for the obstruction, a rigid transverse colostomy was done to facilitate the preparation of his bowel. On April 13, 1949, Dr. R. H. Smithwick did a transthoracic resection of the recurrent carcinoma and because the short jejunal mesentery precluded an esophagojejunostomy the transverse colon was used for an esophagocolostomy. At a second stage the continuity of the gastrointestinal tract was re-established, leaving a transplanted segment of colon within the thoracic cavity.

The second patient (W. O.) was a 64-year-old man with carcinoma of the anterior wall of the rectum. During a preliminary cystoscopy the instrument was inadvertently passed through the posterior urethra into the rectum through the carcinomatous mass. Because of this a transverse colostomy was done the same day and it later proved useful in preparing the bowel for surgery. On May 26, 1949, a resection of the rectum, bladder, prostate, seminal vesicles, and posterior urethra with uretero-intestinal anastomosis was done.

Both of these cases will be reported fully at a later date but the unexpected bacteriologic findings have prompted this preliminary report on the method used for study and preparation of the bowel.

### PLAN OF STUDY AND ANTIBACTERIAL TREATMENT

Therapy was planned to secure reduction in the flora of the colon, timed to be maximal on the day of operation. The choice of antibiotic agents was guided by the sensitivity of the intestinal flora in each instance. Cultures taken just before operation were used to work out the sensitivities to various antibiotics of the organisms remaining in the colon as changed by the intes-

TABLE I PREOPERATIVE AND POSTOPERATIVE CULTURES, INTESTINAL FLORA, AND COLIFORM COUNTS

	ORGANISMS	INITIAL CULTURE					PREOPERATIVE CULTURE				FINAL CULTURE (EXCISED COLON TISSUE)		
Case 1 (Patient R I)	<i>Staphylococcus albus</i>	+					0				0		
	<i>Diphtheroid bacilli</i>	+					+				0		
	<i>Nonhemolytic streptococcus</i>	+					+				0		
	<i>Alpha hemolytic streptococcus</i>	+					+				0		
	<i>Bacillus mucosus capsulatus</i>	+					0				0		
	<i>Escherichia coli</i>	+					0				0		
	<i>Acrobacter aerogenes</i>	+					+				0		
	<i>Bacillus pyocyaneus</i>	+					+				0		
Preoperative day		10	9	8	7	6	5	4	3	2	1		
Coliform count/gram of feces		10,000					0				0	0	0
Case 2 (Patient W O)	<i>Staphylococcus albus</i>	+					+				0		
	<i>Alpha hemolytic streptococcus</i>	+					0				0		
	<i>Alpha hemolytic streptococcus (enterococcus type)</i>	+					+				0		
	<i>Bacillus pyocyaneus</i>	+					+				0		
	<i>Escherichia coli</i>	+					0				0		
	<i>Proteus vulgaris</i>	+					0				0		
	<i>Bacillus mucosus capsulatus</i>	+					0				0		
	<i>Monilia albicans</i>						0				+		
Preoperative day		13	12	10	9	8	7	6	3	2	0		
Coliform count/gram of feces		10,000	12,000						30,000	5,500	0		

tinal antiseptic therapy. Aimed with this information in advance, it should be possible to give systemic or topical treatment with greater speed and specificity for an infection which might develop from the colon after operation. Because of the rapid development of resistance of certain organisms to streptomycin, it was decided to refrain from using it as an intestinal antiseptic but to reserve it for later use in case infection developed.

Cultures of colon contents were obtained through the distal limb of the colostomy. A sterile rubber tube was inserted as far into the bowel as possible and a long slender pipette passed through this tube was used to aspirate colonic juice. All cultures were planted on blood agar plates and inoculated into 60 cc of beef heart infusion broth enriched with sheeps' blood and fortified with 50 mg per cent of para-aminobenzoic acid, each inoculation consisting of a 2 mm platinum wire loopful of the juice. Tubes of chopped meat media fortified with infusion broth and sealed with petroleum jelly and paraffin were used for anaerobic cultures. Coliform counts were done by a modification of the streak method described by Poth.<sup>1</sup>

Cultures of feces were taken on the day the colostomies were opened and are shown in Table I. Colostomy and rectal enemas and instillations of 25 per cent magnesium sulfate served to clean out the isolated loops of colon. Patients were given a low residue diet and vitamin K parenterally.

In order to get a rough idea of the sensitivity of the intestinal flora upon which to base antibiotic therapy, blood agar plates were inoculated with swab cultures of the feces and tested by a filter paper disk contact method for sensitivity to aureomycin and chloromycetin.\*

\*A discussion of this method will be the subject of a separate report.

Twenty four hour broth cultures diluted  $10^6$  were also tested by a serial dilution technique against these same two antibiotics with the idea of using the most appropriate one as indicated by these sensitivities. The chosen antibiotic was given together with Sulfathaladine as an intestinal antiseptic. It was hoped that this combination would be effective against both gram negative and gram positive organisms. The results of these and the subsequent sensitivity tests are indicated in Table II. In the presence of an enterostomy or diarrhea or when enemas or purgatives are to be used Sulfathaladine is preferable to Sulfasuxidine because of its greater bacteriostatic activity; and therefore it was chosen in these cases. For the first patient (R I) chloromycetin was selected rather than aureomycin because, although the flora was within range of sensitivity to both antibiotics aureomycin would have been more likely to cause nausea and the patient was in precarious fluid and electrolyte balance. Inasmuch as chloromycetin was also within the effective range of sensitivity it was selected to be given with the Sulfathaladine. In the second patient (W O) the flora was within the range of sensitivity to both antibiotics so aureomycin was selected because it was more readily available. Administration of the chosen agents was then started via all available routes. Large doses were given as colostomy and rectal irrigations and also because of the possibility of spill over contamination from the proximal colostomy loop these drugs were given through the gastrostomy and by mouth as well. Table III indicates the dosage and routes of administration of the various agents.

On the third day before operation cultures from the colonic juice were obtained to work out the sensitivities of each remaining organism as changed by a period of therapy in order to better cope with infection should it occur (Table II).

On the second or first preoperative day it was desired to administer prophylactic penicillin and since Poth and co-workers have shown a definite penicillin Sulfathaladine antagonism affecting certain gram negative organisms the Sulfathaladine was discontinued and Sulfasuxidine was substituted. This allowed the unimpeded action of penicillin for the last one or two days before operation after having taken advantage of the superior action of Sulfathaladine during the major part of the preparation. Intramuscular penicillin was then started, and to the first patient (R I) penicillin aerosol and lozenges also were given in an attempt to cut down the gram positive flora in the nasopharynx throat and esophagus.

The daily dose of Sulfathaladine and Sulfasuxidine was crushed and suspended in saline in which the antibiotic had been dissolved. This was then instilled into the colostomy, gastrostomy and rectum in equally divided doses at 6 and 10 A.M. and 2 P.M. and 10 P.M., the volume of each instillation being about 100 to 200 cubic centimeters. The last day a dose was dispensed in a very small volume (10 cc. for each instillation) so that the bowel would be dry at operation. Oral medications were given in equally divided doses on the same schedule.

The following is a summary of the plan of study and treatment in outline form.

- 1 Reserve streptomycin for later use if infection should develop.
- 2 After the colostomy is open culture the transverse colon. Test the mixed cultures for sensitivity against available antibiotics suitable for oral administration.
- 3 Give colostomy and rectal enemas and magnesium sulfate instillations until the bowel is clean then use appropriate antibiotic agent along with Sulfathaladine for instillations into the bowel.
- 4 Three days before operation culture the mid colon and work out sensitivities of the constituents of the flora as now altered by therapy to various antibiotics.
- 5 Two days before operation omit Sulfathaladine and substitute Sulfasuxidine. Start intramuscular penicillin, penicillin aerosol and penicillin lozenges.

TABLE III DAILY DOSE AND ROUTES OF ADMINISTRATION OF ANTIBIOTIC ALIQUOTS

FLOPERVIR DAY	D										DAY OF OPERATION	
	1	2	3	4	5	6	7	8	9	10	1	2
By mouth or gastrostomy	Sulfathiazole (Gm)	5										0
	Sulfasuxidine (R I) (Gm)									10	10	0
	Chloromycetin (Gm)	1								1	1	0
	Sulfathiazole (Gm)									5	5	0
	Sulfasuxidine (W O) (Gm)	8					8*					0
I encellin	Aureomycin (Gm)									2.5	2.5	0
	Cysticillin (units)											300,000
	Penicillin (units)											300,000
	Penicillin aerosol (units)									90,000	90,000	0
	I encellin troches (units)									1,500	1,500	0
Installed into colonostomy or rectum	Crystalillin (units)	600,000	600,000	600,000	600,000	600,000	600,000	600,000	600,000	300,000	300,000	300,000
	Penicillin (units)											600,000
	Sulfathiazole (Gm)	5										0
	Sulfasuxidine (R I) (Gm)									15	15	0
	Chloromycetin (Gm)		2		2	2	2	2	2	2	2	0
Case 2 (W O)	Sulfathiazole (Gm)						8	8	8	8	8	0
	Sulfasuxidine (Gm)	12	12	12	12	12	12	12	12	12	12	0
	Aureomycin (Gm)	3	3	3	3	3	3	3	3	3	3	0
	Sulfathiazole (Gm)											0
	Sulfasuxidine (W O) (Gm)											0

Case 1 (Patient W. O.) was being treated with aureomycin, Sulfasuxidine, and procaine penicillin (crystallin) for the urethral perforation before the sixth operative day when the regime for preparation of the bowel as outlined in the text was begun.

† Given by error.

‡ On day 11 omitted because of marked skin irritation around colostomy.

## A TECHNIQUE FOR THE COLLECTION OF LYMPH FROM THE RIGHT THORACIC DUCT IN DOGS

ROBERT PAINF, M D,<sup>\*</sup> HARVEY R BUTCHER, M D, FRANK A HOWARD, A B,  
AND JOHN R SMITH, M D  
ST LOUIS MO

**S**TUDIES of experimental pulmonary edema have been frequently handicapped by the lack of a method for the detection of edema in intact and functioning lungs, particularly when the transudation was occult or of low intensity. In their studies of pulmonary lymph, Drinker and associates<sup>1</sup> noted that the flow of lymph from the lungs was increased when congestion was induced. We have recently investigated the outflow of lymph from the lungs in relation to congestion and edema of the pulmonary tissue from experimental heart failure.<sup>3</sup> These observations have indicated that the production of lung lymph is always increased with pulmonary engorgement and edema, and that the quantity of flow is greater with more intense grades of transudation.

It has been shown<sup>1</sup> that the pulmonary and cardiac lymph passes through lymph nodes lying along the superior vena cava. The fluid then courses from these nodes to the right subclavian vein through one or more lymphatics comprising the *right thoracic duct*. In some animals, the pulmonary lymphatics pass to the left, anastomosing with the thoracic duct or entering directly into the left subclavian vein. Drinker and co workers<sup>1</sup> have collected the pulmonary lymph by cannulation of the right thoracic duct. However, the procedure was so difficult as to be "accomplished satisfactorily in about one out of five animals." In our experience, the cannulation technique has had serious drawbacks. In many animals, the lymphatics were found to be too small to cannulate. In others, cannulation was successful but the lymph failed to flow because of mechanical obstruction by the cannula.

We have employed a simple method for the collection and measurement of right thoracic duct lymph which avoids the pitfalls of minute lymphatics and possible artificial obstruction of the vessels by the manipulation.

### METHOD

The procedure is carried out on dogs under Nembutal anesthesia. To facilitate identification of the lymphatic, 10 cc of 1 per cent solution of Evans blue is instilled into the lower part of the trachea through a glass tube. This tube may be introduced through a tracheotomy or through the glottis. A period of ten minutes is allowed for the absorption of the dye into the pulmonary lymphatics. A longitudinal incision is made along

From the Cardiovascular Division, Department of Medicine, Washington University School of Medicine and the Oscar Johnson Institute.  
This work was done under a grant from the Life Insurance Medical Research Fund.

<sup>\*</sup>Rockefeller Fellow in Cardiology 1948-1949

the right external jugular vein extending to the pectoral muscles and the first rib. The lower end of the jugular vein is then dissected free and followed to its confluence with the axillary vein and the right subclavian veins (see Fig 1). The subclavian vein, in its mid portion is in close apposition to the subclavian artery which arches up from beneath. Although there is considerable variation in the right lymphatic vessels, one or more lymphatics have been found in this area constantly, lying either across the ventral surface of the subclavian vein or between the artery and vein arching upward from the deeper tissue. If dissection is first carried out in this field location of the lymphatics requires a very short time; a tedious dissection is usually not necessary.

Fig 1

Collection of the lung lymph is accomplished by incising the vessel with fine scissors permitting the fluid to issue freely. The field is carefully wiped dry and the lymph is then caught on small pledgets of absorbent cotton (10 to 20 mg in weight) placed over the incised vessel for a measured time. In the properly executed dissection, where all bleeding has been controlled the lymph is the only fluid absorbed by the cotton. Furthermore the identity of the lymph is assured by the bluish stain from the dye. We employ a Roller Smith precision balance to facilitate rapid and accurate weighing of the pledgets.

In normal anesthetized dogs our method shows that the quantity of lymph from a right thoracic lymphatic vessel varies from 4 to 50 mg a minute. Drinker and co workers,<sup>1, 2</sup> by cannulation of the lymphatic find the flow to range from 2.7 to 59.4 mg a minute. While cannulation is extremely difficult being unsuccessful in four out of five animals, the pledget technique in all but rare instances is easily accomplished.

## SUMMARY

Anatomic landmarks which facilitate the location of the right thoracic duct are described. By incision of the lymphatic vessel, the fluid is collected on weighed cotton pledgets for controlled periods. The method has proved to be accurate and simple to carry out.

# PROCEEDINGS OF THE CENTRAL SOCIETY FOR CLINICAL RESEARCH

Twenty Second Annual Meeting  
Chicago Ill Nov 4 and 5, 1949

## ABSTRACTS

### 1 THE DYNAMICS OF COAGULATION

J GARROTT ALLEN M D PETER V MOULDER M D (BY INVITATION)  
DANIEL M ENERSON, M D (BY INVITATION) AND  
DONALD GLOTZER B S (BY INVITATION)  
CHICAGO ILL

Spontaneous (?) bleeding in the presence of hemophilia prothrombin deficiency and over heparinization is not explained by current knowledge or theories of coagulation. Presumably blood could be extravasated under these conditions because (1) blood is less viscous and its surface tension altered or (2) the continuity of the walls of the small vessels depends upon some continuing contribution from blood which is destroyed when the clotting process is delayed or inhibited.

Measurements of surface tension and viscosity have shown no significant changes in hemophilia prothrombin deficiency or excessive heparinization. Transfusion of normal dogs until hematocrit readings of 65 to 70 per cent were obtained resulted in a considerable increase in viscosity and a decrease in surface tension but these animals bled just as readily from prothrombin deficiency or over heparinization as did untransfused controls. The irradiated dog (450 r) given sufficient blood daily to maintain a hematocrit reading of 70 per cent had similar changes in viscosity and surface tension and developed increased clotting time, thrombocytopenia and hemorrhage. Anemia and hypoproteinemia produced by the daily withdrawal of blood in normal dogs reduced viscosity and increased surface tension but did not cause these animals to bleed or make them unduly susceptible to hemorrhage from Dicumarol or heparin.

Data are presented which suggest that coagulation is a dynamic and protective process. The activity of prothrombin rapidly falls and may disappear entirely fourteen to twenty hours after hepatectomy. Fibrinogen concentrations decline in a similar manner though less rapidly. That the removal of the liver is not necessary for the rapid decline of prothrombin is indicated by the rapid disappearance of transfused prothrombin in whole blood or fresh plasma. Apparently the turnover of prothrombin is rapid and nearly complete in twenty-four hours and that of fibrinogen is only slightly longer (two to three days). The fate of these proteins is not known. It is possible that fibrin is constantly formed and is concerned with the maintenance of the integrity of the vascular wall and that its formation consumes prothrombin.

## 2 SIMULTANEOUS CESAREAN SECTION AND SPLENECTOMY IN IDIOPATHIC THROMBOCYTOPENIC PURPURA

W R ARROWSMITH, M D, CURTIS TYRONL, M D (BY INVITATION),  
AND CHAMP LYONS, M D (BY INVITATION)  
NEW ORLEANS, LA

Although splenectomy has been done many times on pregnant patients, we are unable to find any record of simultaneous splenectomy and cesarean section in the management of a complicated pregnancy.

The patient, a 27-year-old white woman, with two preceding spontaneous abortions, was first seen by us in the seventh month of pregnancy, because of purpura. She had a long past history of abnormal bleeding for which no cause had been found. Physical examination showed innumerable petechiae over the legs, scattered purpuric lesions of the rest of the body, and findings compatible with a seven-month pregnancy. Laboratory studies showed an infinitely prolonged bleeding time, platelet count of 2,000 per cubic millimeter, and increased megakaryocytes in the bone marrow. Roentgenogram showed a mild cephalopelvic disproportion.

Because of the significant fetal mortality reported following splenectomy in the third trimester, and because of the relatively minor bleeding, it was decided that the safest course in this patient would be to allow her to try to deliver spontaneously and then perform a splenectomy post partum, early if necessary or later if bleeding was not too excessive. After six hours in labor at term it became apparent that cesarean section would be necessary. A low-flap cesarean section was performed, followed immediately by splenectomy. When the patient entered the operating room the bleeding time was twenty-one minutes, while the abdomen was being closed it was two minutes and thirty seconds. The postoperative course was uneventful and the patient has had no abnormal bleeding for the ensuing thirteen months.

The baby's platelet count at delivery was about 100,000 per cubic millimeter with normal bleeding and clotting times. She is healthy at the age of 13 months, has a normal blood count, and has never had any hemorrhagic phenomena.

The management of this case is not presented as standard treatment for purpura during pregnancy. Rather, it is a hitherto unreported example of the effectiveness of splenectomy in preventing major hemorrhage in a patient with thrombocytopenic purpura in whom another major surgical procedure was necessary as an emergency.

## 3 THE DETECTION OF INTRACRANIAL TUMORS BY THE USE OF DI-iodo<sup>131</sup>-FLUORESCEN

MOSES ASHKENAZY, M D (BY INVITATION), GEORGE V LeROY, M D,  
THEODORE FIELDS, B S (BY INVITATION), AND LOYAL DAVIS, M D  
(BY INVITATION), CHICAGO, ILL

Neoplastic tissues have the ability to combine with fluorescein dye. This combination is temporary, lasting for a period of two to four hours after intravenous injection of the dye. When di-iodo<sup>131</sup>-fluorescein (radiofluorescein) in amounts of 0.7 to 1.0 mc is used, the greater radioactivity of the tumor tissue permits one to detect its location by the use of suitably arranged Geiger Muller counters. This technique has been applied to the diagnostic study of patients with space-filling intracranial lesions. When the lesion is a neoplasm, good

concentration of the radiofluorescein occurs, and the location of the tumor can be established. When the lesion is a nonneoplastic cyst, or hematoma, there is no significant local accumulation of the radioactive material. A description is given of the differential counter method and of the apparatus developed in the Radioisotope Unit, Hines Hospital. The results of the examination of sixty patients with this technique are discussed. In every instance but one, to date, the diagnosis based on the isotope studies has been verified at operation.

#### 4 THE INHIBITION BY NORMAL SYMPATHETIC VASOCONSTRICTOR TONE OF THE SPONTANEOUS DEVELOPMENT OF A COLLATERAL CIRCULATION IN CHRONIC OBLITERATING ARTERIAL DISEASE OF THE LEG

LAWRENCE N. ATLAS, M.D., CLEVELAND, OHIO

In 1937 observations were made which suggested that a collateral circulation would spontaneously develop as a normal physiologic response to chronic ischemia of the leg and foot were it not for the fact that the flow of sympathetic vasoconstrictor nervous impulses to the arteries of the leg and foot acted as an inhibiting influence. To test the validity of this premise a series of cases of chronic thromboangitis obliterans and arteriosclerosis obliterans of the lower extremities were subjected to lumbar sympathetic ganglionectomy. During the past eleven years a total of 128 operations has been performed on 112 individuals. On the basis of history, age and physical findings, 32 probably had thromboangitis obliterans and 80 arteriosclerosis obliterans. The latter group included 20 diabetic subjects.

The original thesis proved to be valid. A gradually progressive, measurable increase in the magnitude of arterial pulsation in the denervated leg has been a constant postoperative finding. The maximum postoperative increase in pulsation frequently was not attained until a year had elapsed and has been maintained in some instances, for as long as ten years.

This presentation includes a brief discussion of the physiology of collateral circulatory development in the presence of chronic ischemia, the clinical observations giving rise to the original premise, the clinical selection of cases, and the presentation and interpretation of recorded oscillometric evidence of the spontaneous development and prolonged maintenance of an effective collateral circulation in cases of chronic obliterating arterial disease of sympathectomized legs.

#### 5 OCCURRENCE OF ANTIHEMAGGLUTININS AGAINST NEWCASTLE VIRUS IN HUMAN RESPIRATORY INFECTIONS WITH A POSSIBLE INSTANCE OF VIRUS ISOLATION

MALCOLM B. BAWELL, M.D. (BY INVITATION), MARGARET LEGIER, M.S. (BY INVITATION), FRANCES MURREY, B.S. (BY INVITATION), WILLIAM SCHOFIELD, D.V.M. (BY INVITATION) AND G. O. BROWN, M.D., St. Louis, Mo.

Newcastle disease, a pneumoencephalitis of fowl causes human conjunctivitis, and serologic evidence suggests it may cause infections resembling poliomyelitis or influenza. The causative virus agglutinates chicken cells and anti-hemagglutinins occur in sera of inoculated or infected fowl.

Having isolated this virus from infected chickens we sought evidence of human infection by serologic studies of patients suffering from influenza or virus pneumonia. Sera of thirty-six such patients collected in the autumn

There were no marked changes in blood pressure response noted in any of the patients studied

This and other preliminary data indicate that a cold stimulus, particularly following a meal, materially increases the positive tests for so called "ischemia of heart muscle" This may be of clinical value in detecting coronary insufficiency

It would appear that the cold stimulation of the external skin of the face, especially about the nose, is one of the factors which may contribute toward initiating attacks of angina in patients walking against a cold wind

## 8 EVALUATION OF THE ZINC SULFATE TURBIDITY AND TOTAL LIPID DETERMINATIONS IN LIVER DISEASE

JEROME R. BERMAN, M.D. (BY INVITATION), AND LEON SCHIFF, M.D.,  
CINCINNATI, OHIO

(WITH THE TECHNICAL ASSISTANCE OF LILA DOHM, B.S., AND  
ELIZABETH ROBINSON, B.S.)

In order to assess the clinical value of the zinc sulfate turbidity and total lipid determinations as described by Kunkel, a series of 871 consecutive "liver profiles" were studied. These new turbidity tests were contrasted with the routine liver "function" tests simultaneously performed. The 871 determinations were made in approximately 400 patients, more than half of whom had clinical evidence suggestive of liver disease. Needle biopsy of the liver was performed in many instances.

The zinc sulfate turbidity test was contrasted with the thymol turbidity test. 120 units was chosen as the upper limit of normal for the zinc sulfate turbidity, and 50 units for the thymol turbidity. The cases were divided in to the following groups: cirrhosis (nutritional, postnecrotic, and portal), hepatitis (infectious and homologous serum), obstructive jaundice, carcinoma (primary and secondary), and miscellaneous. The miscellaneous group included patients with nonhepatic disease as well as a few with granuloma of the liver and fatty infiltration of the liver.

The zinc sulfate turbidity was elevated while the thymol turbidity was normal in 19.4 per cent of the determinations. The thymol turbidity was elevated and the zinc sulfate turbidity normal in 5.6 per cent of the determinations.

When the determinations were divided according to diagnosis, the following significant data appeared:

(a) In cirrhosis the zinc sulfate turbidity was elevated and the thymol turbidity was normal in 16.8 per cent of the tests, whereas the zinc sulfate turbidity was normal and the thymol turbidity elevated in 3.7 per cent. (b) In hepatitis the zinc sulfate was elevated and the thymol turbidity was normal in 8.5 per cent of the tests, whereas the zinc sulfate turbidity was normal and the thymol turbidity elevated in only 0.7 per cent. (c) In obstructive jaundice and carcinoma of the liver the zinc sulfate turbidity and thymol turbidity tests did not show the significant differences seen in cirrhosis and hepatitis.

It was felt that the zinc sulfate turbidity test was particularly useful in cases of cirrhosis of the liver.

The values obtained for total lipids using the method of Kunkel were contrasted with the values obtained for cholesterol using the method of Bloch. A total of 167 determinations were so compared. It was seen that the values of

the total lipid and cholesterol roughly paralleled one another. The ratio of total lipid to cholesterol was determined and it was found to be  $3.76 \pm 0.7$ . In 17.9 per cent of the determinations this ratio was exceeded. Most of these were instances of hepatitis and/or cirrhosis. The significance of these ratios is to be discussed.

It was felt that these new turbidity tests provide useful information and deserve inclusion in routine liver function studies.

## 9 AN ANTIDIURETIC SUBSTANCE IN THE URINE OF PATIENTS WITH CARDIAC FAILURE

BERNARD A. BERCU, M.D. (By Invitation), STANLEY N. ROKAW, M.D. (By Invitation), AND EDWARD MASSIE, M.D., St. Louis, Mo.

Recently, much doubt has been cast upon the conventional explanations of the mechanisms involved during cardiac decompensation. Because of the controversial state of this subject at present, it was felt that examination of other factors involved in water balance would be worth while. Therefore patients with congestive heart failure were studied for the presence of increased amounts of antidiuretic material excreted in the urine.

Patients with definite heart failure were selected for study. None with associated kidney disease or cirrhosis were used. Urines from normal subjects and patients with mental diseases were used as controls. Urines were acidified to a pH of 5.5 to 6.5 with 3 per cent acetic acid evaporated at room temperature beneath a fan, and then dialyzed in a cellophane sac for six to twenty-four hours. Urines were concentrated so that a fifteen minute output sample would equal 2 to 4 c.c. and this amount was used as the test dose. Assay was performed on trained normal female dogs in which water diuresis had been produced by giving 35 c.c. per kilogram body weight by stomach tube. Urine samples were collected through an indwelling catheter. A decrease in urine output following intravenous injection of the test material was used as a measure of antidiuretic activity and this was compared with the change in urine output following the injection of known amounts of Pitressin.

Ten patients were studied. Of these, three had hypertensive cardiovascular disease, three had arteriosclerotic heart disease, three had rheumatic heart disease, and two had cor pulmonale. Nine of these were found to have amounts of antidiuretic substance equivalent to 0.5 to 1.0 m $\mu$  of Pitressin in a fifteen minute urine sample. None of the controls showed any antidiuretic activity in their urine samples. Investigations now in progress indicate that this antidiuretic material is not the same as commercially prepared Pitressin.

## 10 VICARIOUS EXCRETION BY MEANS OF PERGASTRIC INTESTINAL PERFUSION

LIONEL BERNSTEIN, M.D. (By Invitation), PHILIP B. O'NEILL, M.D. (By Invitation), ARTHUR BERNSTEIN, M.D. (By Invitation), AND WILLIAM S. HOFFMAN, M.D., CHICAGO, ILL.

Pergastric intestinal perfusion was carried out in nine preterminal uremic patients as a means of vicarious excretion. The subjects were placed on a Bradford frame with head end elevated. The perfusing fluid was introduced into the stomach and collected from a rectal tube after transit through the entire intestine. To prevent overdistention of the stomach and vomiting suction was

applied at the cardia through a second lumen of the gastric tube. Such a scheme avoided many of the disadvantages of other artificial means of vicarious nitrogenous excretion. It required no elaborate equipment, no surgical procedure, no preparation of sterile solutions, and avoided the danger of thrombosis or peritonitis. It could be instituted with a minimum of delay.

A significant fall in the serum nonprotein nitrogen concentration was recognizable after six to eight hours of perfusion. The nonprotein nitrogen level of the intestinal perfusate was directly proportional to the serum nonprotein nitrogen level and inversely to the rate of flow. The mean intestinal nitrogenous excretion was equivalent to a urea clearance of 136 cc per minute (range, 69 to 210 cc). At the optimal rate of flow of 2 liters per hour, the clearance was of the order of 210 cc per minute. In contrast, gastric perfusion alone was only about one sixth as effective.

Blood levels of creatinine, phosphate, and phenols were not appreciably lowered. Alteration of serum sodium, chloride, and bicarbonate levels generally was toward normal.

Serum potassium levels dropped considerably in all instances, though less so when the potassium concentration of the perfusate was made 40 mg per 100 cubic centimeters. In prolonged perfusions, the serum potassium might fall to the dangerously low level of 12 mg per 100 cubic centimeters. The high concentration of potassium in the intestinal perfusate implied the nonosmotic secretion of potassium in the intestinal juice. The total negative balance of potassium was as much as five times as great as the total extracellular content of potassium. The lost potassium was therefore largely intracellular. This made the extent of the fall in serum potassium concentration unpredictable. In perfusions of more than six to eight hours, the potassium loss might be dangerous. This is the limiting factor in the use of this method, which otherwise appeared to be of distinct potential value in prolonging life.

## 11 EXPERIENCE WITH HEPARIN-PROTAMINE TITRATION

WILLIAM R. BRIST, M.D. (BY INVITATION), AND LOUIS R. LIMARZI, M.D.,  
CHICAGO, ILL.

Allen and co-workers first noted that in certain hemorrhagic states a heparinemia-like condition exists which will respond to the parenteral administration of protamine or toluidine blue. They devised a heparin-protamine titration technique to detect this state. Using a simplification of this titration, suitable for clinical laboratory analysis, ninety-one tests were performed using forty-eight patients with various hematologic diseases and twenty-three normal subjects. One cubic centimeter lots of blood rendered incoagulable with 90 gamma of heparin are titrated against selected 0.02 cc increments of a standard protamine solution until an end point of coagulation at room temperature in one hour is achieved. Normal end points range from 0.12 to 0.18 cc of solution, depending on potency of successive batches. Tests were read as -, 0, +, ++, or +++ according to the relationship in 0.02 cc increments of the patient to the control value. Of twenty-three tests run on normal subjects, three were -, eleven were 0, and nine were  $\pm$ . Thus a  $\pm$  value is of no significance. Six patients with thrombocytopenic purpura, four with acute leucemia, seven with chronic leucemia, two with aplastic anemia, nine with pernicious anemia, four with polycythemia, three with miscellaneous anemias, five with prolonged roentgen therapy, six with obscure bleeding problems, and one each with multiple myeloma, Hodgkin's disease, and myeloid metaplasia of the spleen were tested. Of these, only three of the four acute leucemias and two of the seven

chronic leucemias showed a significant increase. Interestingly, three of the six obscure bleeding problems showed a - reaction possibly indicating a compensatory increased tolerance for heparin.

## 12 DISTRIBUTION OF BLOOD TYPES IN THE LEUCEMIAS

WILLIAM R. BEST, M.D. (BY INVITATION) LOUIS R. LIMAURI, M.D.,  
AND HENRY G. PONCHER, M.D. CHICAGO, ILL.

Of five hundred thirty-two patients with leucemia studied, most of whom have been observed over the past twelve years, Landsteiner blood groups were recorded in one hundred thirty-seven and Rh types in thirty. Four of those with known Landsteiner types were Negro; all the others were white. Of those typed, 42 per cent suffered from acute leucemia, 45 per cent from chronic, 5 per cent from monocytic, and 7 per cent from other types of leucemia. The larger group studied consisted of 31 per cent acute, 52 per cent chronic, 6 per cent monocytic, and 11 per cent miscellaneous varieties. Thus blood groups were recorded in a significantly greater percentage of acute conditions than chronic. The distribution of blood types among the one hundred thirty-seven patients was: O 39 per cent, A 41 per cent, B 13 per cent, and AB 7 per cent. The distribution of blood types as recorded in over four thousand five hundred recent routine blood bank tests is: O 44.1 per cent, A 38.6 per cent, B 13.2 per cent, and AB 4.2 per cent. If the figures from the cases of leucemia are compared by chi-square with those of the larger hospital group, the probability of differences being due solely to random selection is 0.55. Thus there is no significant difference of distribution between the two groups. Similarly there is no significant variability of blood type distribution in the smaller groups of chronic myelogenous leucemia, chronic lymphatic leucemia, and the pooled cases of acute leucemia.

Of the thirty patients Rh typed, 77 per cent were positive, 23 per cent negative. Comparison by chi-square with the published figures of 85 per cent positive and 15 per cent negative gives a probability of 0.20, revealing no significant difference between the leucemic and the general groups.

## 13 OCCURRENCE OF HEMOPHILIA IN FEMALES

KENNETH M. BRINKHOUS, M.D. AND JOHN B. GRAHAM, M.D. (BY INVITATION),  
CHAPEL HILL, N. C.

Hemophilia is considered ordinarily as a disease of the male sex only, inherited as a sex-linked recessive characteristic through the X-chromosome. Of the possible types of crosses in human hemophilia, only two, conductor female  $\times$  normal male ( $Hh \times HY$ ) and normal female  $\times$  hemophilic male ( $HH \times hY$ ), are well established. Rare instances are reported of matings between conductor females and hemophilic males. In this cross  $Hh \times hY$ , half of the female offspring should be of the genotype  $hh$  and would be expected to be bleeders. However, authentic cases of female hemophilia have not been described. As a result, it has been postulated that the gene combination  $hh$  is lethal, or that the bleeding tendency does not become manifest in females.

Recently a strain of dogs with an inherited bleeding disease was discovered. On the basis of the  $Hh \times HY$  cross, a sex-linked type of inheritance was demonstrated. The clotting defect appears to be identical to that in human hemophilia. As a result of a breeding program carried on in our laboratory, bleeder males have been reared to maturity. This report deals

with the mating of bleeder males with conductor females. Six litters from such matings have been studied. Nearly half of the males were hemophiliac, while the remainder were normal. Approximately half of the females were hemophiliac, while the rest showed no evidence of the disease. The distribution into bleeders and nonbleeders in these litters was close to the expected ratio of 1:1 for the cross,  $Hh \times hY$ .

The clotting defect in the affected animals was the same, regardless of sex. All showed consistently prolonged clotting times, normal bleeding times, normal prothrombin values, and a slow disappearance of prothrombin from clotting blood in spite of normal platelet values. The clotting defect was corrected in vitro by normal plasma or small amounts of thromboplastin. Further studies indicated that the bleeder females, just like the bleeder males, lack a plasma factor required for platelet utilization.

No sex difference in the bleeding tendency was observed. Hemarthroses and subcutaneous hematomas have occurred frequently. Some animals have had evidence of internal bleeding. Hemorrhagic episodes have been controlled by plasma transfusions.

The occurrence of hemophilia in female dogs suggests that the genetic combination  $hh$  in human beings is not lethal. Absence of human cases may be due to lack of opportunity for their occurrence, or to inadequate investigation of possible cases.

#### 14 OBSERVATIONS ON THE EPIDEMIOLOGY OF INFECTIOUS HEPATITIS

JOHN W. BROWN, M.D., AND EDNA M. CREE, M.P.H. (BY INVITATION),  
MADISON, WIS.

The occurrence of infectious hepatitis was studied in two widely separated areas in Wisconsin. One region, in the north-central section, consists of a city of 10,000 inhabitants and surrounding rural communities. The other, 250 miles away in the southwestern section, is a prosperous farming region. The geology of the areas is different. The chief method of study consisted of interviews with each individual who had had the disease and with his suspicious contacts. Most of the cases were discovered in this way. An attempt was made to ascertain pertinent facts concerning the development of each case and to document the individual and environmental factors. Similar interviews were obtained with 60 families in which hepatitis had not occurred. Sanitary surveys were made by the State Board of Health, and other data were obtained relative to terrain, climatic variations, and disease rates. For the purpose of this study, jaundice was made a mandatory criterion for diagnosis.

In the northern area, 168 cases of infectious hepatitis occurred, beginning in January, 1947. In the south, 31 cases had appeared, the first in December, 1945. The disease appeared in all months of the year, with a significantly greater number in winter. The greatest number of cases occurred in patients between the ages of 10 and 30, the disease rarely appearing in preschool children or persons over 50. There was a clear tendency to distribution by families. In the 115 families concerned, there were 199 cases (17 persons per family). Of the 579 persons in these families, 34 per cent developed the recognizable syndrome. Members of other families in the vicinity were not involved, even though all activities were shared, so far as could be determined. The occurrence of the disease seemed to present a pattern by groups. In the southern region it was confined to an area of approximately four square miles.

Various environmental factors were studied. The drinking water from wells was found to be contaminated in 30 per cent of homes where cases occurred and in only 5 per cent of homes which had been free of the disease. Other considerations tend to minimize the importance of this as the source for transmission. The occurrence of the disease in localized areas by groups seemed to be the most important aspect of these observations.

## 15 RATES OF TURNOVER AND BIOLOGIC DECAY OF CHLORIDE AND CHLORIDE SPACE IN DOGS DETERMINED WITH THE LONG LIFE ISOTOPE $\text{Cl}^{36}$

G. E. BURCH, M.D., S. A. THREEFOOT, M.D. (BY INVITATION), AND  
C. THORPE, R.V.M.D. (BY INVITATION), NEW ORLEANS, LA.

The long life radiochloride  $\text{Cl}^{36}$  ( $T_{1/2} \approx 2 \times 10^6$  years) made possible the study of the early concentration time course in the blood serum, biologic decay rates and rates of turnover of chloride in six normal dogs observed continuously for eighteen to thirty one days under controlled metabolic conditions. These experiments yielded the following information:

(1) The mean concentration time course of  $\text{Cl}^{36}$  in the serum for the first sixty minutes after intravenous administration can be expressed by the multiple exponential equation

$$\text{CN}_t = 1250e^{-2.079t} + 680e^{-0.308t} + 144e^{-0.0377t} + 674e^{-0.0001t}$$

where

$\text{CN}_t$  = concentration in the serum at any time  $t$   
 $e$  = natural log

(2) All the serial chloride leaves the serum each minute and about one third of the nonserial chloride returns to the serum each minute. Thus in a dog weighing 4.54 kilograms (10 pounds) with a chloride mass of 5.5 Gm. about 2.75 Gm. of chloride pass into and out of the serum each minute.

(3) The mean  $\text{C}_{1/2}$  value for the serum was 2.51 days (range 2.16 to 3.00), the mean  $\text{U}_{1/2}$  3.50 days (range 2.75 to 4.00) and the mean  $\text{E}_{1/2}$  3.40 days (range 2.75 to 3.80).

(4) The mean recovery was 91 per cent of that injected (range 83 to 97)—88 per cent (range, 81 to 90) in the urine and 2.6 per cent (range 0.6 to 5.9) in the feces.

(5) The mean chloride space in "serum equivalents" was 35 per cent of body weight (range 32 to 38) and the mean total body chloride 6.84 Gm. for a dog weighing 4.54 kilograms.

(6) These and other data to be presented indicate that (a) The chloride space is larger than previously reported. (b) Chloride cannot be employed as a measure of extracellular fluid space. (c) Chloride is present in considerable quantities outside the extracellular fluids. (d) Man would require a daily intake of 43 Gm. NaCl or 15 to 22 lb. of food to have a diet comparable to that of a dog weighing 4.54 kilograms. (e) A diet of 200 mg. sodium for a man weighing 70 kilograms is equivalent to a diet of 13 mg. for a dog weighing 4.54 kilograms. Thus the usual studies of low sodium metabolism in small animals with "hypertension" must be evaluated cautiously.

The importance of these studies in planning tracer experiments with chloride and bromide and in understanding the metabolism and excretion of chloride and bromide in edematous states, intoxication due to radiochloride and radiobromide in atomic warfare and other physiologic processes is evident from the data.

16 ORAL ADMINISTRATION OF VITAMIN B<sub>12</sub> IN PERNICIOUS ANEMIA

## II STUDIES ON THE NATURE AND SOURCE OF INTRINSIC FACTOR

DONALD C CAMPBELL, M D (BY INVITATION), BYRON E HALL, M D, AND  
EDWARD H MORGAN, M D (BY INVITATION), ROCHESTER, MINN

Vitamin B<sub>12</sub>, when administered parenterally to patients having pernicious anemia in relapse, behaves in the same manner as does the active principle in liver. However, when vitamin B<sub>12</sub> is administered orally it acts as does extrinsic factor, as Berk and co-workers, Hall and associates, and others have shown. Since patients with pernicious anemia lack intrinsic factor, orally administered vitamin B<sub>12</sub> is not utilized, in most cases at least, unless the intrinsic factor is given also, either simultaneously or within a period of six hours (Castle and associates). If the quantity of vitamin B<sub>12</sub> is kept constant, various unknowns can be tested for the presence or absence of intrinsic factor. We have utilized this procedure with seventeen patients having pernicious anemia in severe relapse. The following data have been gathered from these studies:

(1) Intrinsic factor is present in fresh, Berkefeld-filtered, pooled human gastric juice. (2) It is also present in extracts of hog stomach and duodenum. (3) It is destroyed by heating to a temperature of 63° C for thirty minutes. (4) It is not destroyed in human gastric juice when the latter is stored at a pH of 1.7 at a temperature of 5° C for three months. (5) Trichloroacetic acid and cold alcohol (95 per cent) precipitates from human gastric juice (prepared for us by Dr. J. L. Bollman) did not contain the intrinsic factor. (6) In vitro mixtures of pooled human gastric juice and vitamin B<sub>12</sub>, after standing at room temperatures for twenty-four hours, were heated to 70° C for sixty minutes. When these were administered orally to a patient with pernicious anemia in relapse, no hematopoietic response was elicited. (7) The minimal amount of human gastric juice required to produce optimal hematopoietic responses when administered daily by mouth with 5 or 10 µg of vitamin B<sub>12</sub> has not been accurately determined, but in our experience the daily administration of 75 cc, plus vitamin B<sub>12</sub>, has given optimal results. (8) Variation in the response to large quantities of vitamin B<sub>12</sub> administered alone by mouth has been noted. One patient failed to show a hematopoietic response to a single oral dose of 1,000 µg of vitamin B<sub>12</sub> concentrate. A second patient exhibited a suboptimal response to a single dose of 75 µg of crystalline material. From this, and similar observations by others, it is possible to theorize that lack of intrinsic factor in patients with pernicious anemia is not absolute.

17 CONGESTIVE HEART FAILURE AND HYPONATREMIA UNTO  
WARD EFFECTS OF MERCURIAL DIURESIS

DAVID CITRON, M D (BY INVITATION), BERNARD BERCU, M D (BY INVITATION),  
RICHARD LEVNER, M D (BY INVITATION), AND EDWARD MASSIE, M D,  
ST LOUIS, MO

Recent literature concerning the treatment of congestive heart failure has emphasized the value of dietary salt restriction and the frequent use of mercurial diuretics. One of the complications incident to the rapid diuresis produced by this type of therapy is the profound change in the electrolyte balance.

Such an instance was encountered in the case of a 50-year old man who became critically ill and comatose as the result of treatment of his severe congestive failure with low salt diet and mercurial diuretics. It was not until three

days subsequent to the appearance of coma, when the plasma chloride concentration was found to be low that the true pathogenesis of his condition was suspected and treatment with sodium chloride solution seemed justified. The patient improved clinically and this improvement paralleled the restoration of electrolyte balance. Since this initial experience eleven other patients presenting a similar therapeutic problem have been treated.

In patients with well established congestive failure with edema the extracellular fluid compartment is expanded. The removal of the excess fluid in the extracellular space may be accomplished by a combination of low salt intake and mercurial diuretics. During the excretion of this fluid however sodium and chloride are removed at a relatively faster rate than water. Consequently the sodium chloride values fall and the fluid becomes hypotonic. In the presence of subnormal plasma sodium and chloride concentration the diuretic response to organic materials is inhibited. Clinically the situation which at this point presents itself is one of a patient with chronic cardiac failure who in spite of vigorous treatment is getting worse rather than better and does not respond to mercurial diuretics. Dizziness, drowsiness, muscular pains and apathy appear and if correction with adequate amounts of sodium chloride is not made in time confusion, convulsions and death may result.

#### 18 METABOLIC CHANGES INDUCED BY SUBTOTAL ADRENALECTOMY RESULTING IN CURE OF CUSHING'S SYNDROME EFFECTS OF LATER ADMINISTRATION OF ACTH

J. W. CONN, M.D., L. H. LOUIS, S.C.D. (BY INVITATION), S. FAJANS, M.D. (BY INVITATION) AND BETTY J. JOHNSON, B.S. (BY INVITATION)  
ANN ARBOR, MICH.

A metabolic study was carried out upon a 22 year old woman with typical Cushing's syndrome proved to be due to bilateral adrenocortical hyperplasia. It affords comparative data in the same person under three separate conditions: (1) before subtotal adrenalectomy, (2) after metabolic and physical normalcy had been established by removal of more than 90 per cent of adrenal tissue and (3) during stimulation of the adrenocortical remnant with large amounts of ACTH (100 mg per day Armour Standard). The data include observations upon the metabolism of nitrogen, carbohydrate, uric acid, glutathione, cholesterol and electrolytes as well as daily excretions of 17 ketosteroids and of 11 oxysteroids.

To be emphasized are the following results and conclusions:

(1) Before operation fasting blood glutathione averaged 26 mg per cent (highest value 28 mg per cent) and carbohydrate tolerance was greatly impaired. Intravenous reduced glutathione (GSH) abruptly converted the diabetic tolerance to normal but it quickly reverted to the diabetic type. Four months after operation fasting blood glutathione averaged 43 mg per cent (lowest value 39 mg per cent). Carbohydrate tolerance was then normal and has remained so.

These observations are in accord with our previous reports upon the role of GSH in ACTH induced diabetes in normal human beings. A deficiency of free sulfhydryl (-SH) groups appears to be importantly involved in the pathogenesis of the diabetes observed in Cushing's syndrome.

(2) Excretion of 17 KS and of 11 OS (both elevated threefold preoperatively) became persistently normal after adrenalectomy. ACTH acting upon the adrenal remnant returned these values to their preoperative levels. They became normal again upon cessation of ACTH.

Upon sufficient stimulation and for, at least, a short period of time, a small remnant of adrenal cortex can give rise to the same quantity of steroidal end products as had been produced by two hyperplastic glands during the active stage of Cushing's syndrome. Conversely, the hyperplastic adrenals of active Cushing's syndrome are not receiving maximal functional stimulation from endogenous ACTH.

(3) Despite an ACTH-induced return of excretory corticosteroids to preoperative levels, some of the preoperative metabolic aberrations failed to reappear. This was true also of the preoperative vascular hypertension.

It is likely that some of the clinical and metabolic manifestations of increased cortical activity are a function of time as well as of intensity, that mildly increased cortical activity of sufficient duration eventually will manifest itself. This may be important with respect to therapeutic uses of ACTH.

## 19 A CLINICAL-PATHOLOGICAL SURVEY OF 108 TUBERCULOUS PATIENTS

THOMAS H. DAVIDSON, M.D. (BY INVITATION), JOSEPH M. LUBITZ, M.D. (BY INVITATION), AND MAURICE HARDGROVE, M.D.,  
MILWAUKEE, WIS.

Autopsies were performed on 108 patients who had active tuberculosis. The diagnosis of tuberculosis was established by clinical means in 95 (Group A), but the disease was not recognized before death in the other 13 patients (Group B).

*Group A*—Tuberculosis was the primary cause of death in 73 of the cases in which it was diagnosed before death, but in 18 patients other diseases than tuberculosis were the cause of death. In 13 of these 18 the nontuberculous disease causing death was recognized clinically, in the other 5 it was not suspected. There were four other patients in this group in whom it appeared that the tuberculous process and another disease were of equal importance in the patient's demise. Adequate attempts were made in the treatment of recognized nontuberculous diseases in this group, but in those five patients who had clinically uncovered diseases early treatment might have helped. There were the following conditions unrecognized before death in the five patients in whom the clinical diagnosis of active tuberculosis was made: carcinoma of the pancreas, heart failure due to arteriosclerotic heart disease, pulmonary infarction, and two cases of pulmonary atelectasis.

*Group B*—Analysis of the 13 patients who had active tuberculosis discovered only at the time of the postmortem showed that two died primarily of the tuberculous process, one from acutely disseminated miliary tuberculosis and one from tuberculous peritonitis. The other eleven patients had clinically recognizable nontuberculous diseases and were properly though unsuccessfully treated. The clinically unrecognized tuberculosis involved the lungs and respiratory passages in all but one patient in whom primary tuberculosis of the kidney was found at autopsy. The other diseases which caused death in this group were generally so acute, severe, or advanced that treatment of the tuberculous lesion would have been of little avail.

Accuracy of clinical diagnosis involving both the tuberculosis and other associated diseases in the group of 108 patients was 121 (86 per cent) in 141 instances. Active tuberculosis was missed clinically in 13 (12 per cent) of the total group studied. Nontuberculous diseases went undiagnosed pre mortem in 65 per cent (7).

Tuberculosis services need to seek consultation from other branches of medicine and surgery as much as do medical and surgical services need the help of pulmonary disease students. This need should encourage hospitals to provide frequent cross consultations. Close proximity of tuberculous hospital and sanatorium units to other medical and surgical units will aid in this endeavor. Therapeutic advances not only in tuberculosis but in other diseases as well will then be readily available to the patients.

## 20 POLYCYTHEMIA VERA WITH HEPATIC VEIN THROMBOSIS CASE REPORT WITH SERIAL LIVER BIOPSIES AND APPARENT RECOVERY

W D DAVIS, JR, M D, WILLIAM R. ARROWSMITH, M D, AND  
A A CLURE III, M D (BY INVITATION) NEW ORLEANS, LA

A case is presented of a patient who apparently recovered from spontaneous thrombosis of the hepatic vein (Chaili's syndrome). It is believed to be the first case to be reported in which the patient recovered.

*Case Report*—A 39 year old shipyard machinist came to the Ochsner Clinic on Aug 30, 1948 because of weakness, failure to gain weight, and a feeling of fullness in the abdomen of ten months' duration. Three weeks before admission edema of the legs and ankles and slowly progressive enlargement of the abdomen were noted.

Physical examination and laboratory studies revealed the combined features of polycythemia vera and severe hepatic disease. The patient had a florid complexion with dilatation of superficial vessels and engorgement of the retinal veins. Spider angiomas were noted over the shoulders and chest. The abdomen was filled with fluid. The edge of the liver could be felt about 10 cm below the right costal margin and there was considerable enlargement of the left lobe. The spleen was ballotable 6 cm below the left costal margin. Pitting edema was apparent in both ankles and pretibial areas.

There was pronounced elevation of the red blood cell count, hemoglobin, hematocrit, white blood cell count and platelets. The serum bilirubin value was elevated to a total of 3 mg per cent. Bromsulfalein test showed 46 per cent retention in forty five minutes. Urine urobilinogen excretion was increased and prothrombin time was 27.8 per cent of normal.

The patient was hospitalized on September 6 for paracentesis and repeat phlebotomies, and 7 mc of radioactive phosphorus were given intravenously. Initial liver biopsy revealed considerable engorgement of the sinusoids in the central area of the liver with pressure atrophy and beginning fibrous replacement. A small branch of the hepatic vein was seen in one section with a recanalizing thrombus occupying the greater part of its lumen. Despite repeated low prothrombin times Dicumarol therapy was instituted. Because of recurrent ascites and hemorrhage with paracentesis a peritoneal button was inserted on October 23. With institution of a low sodium diet and repeated administration of mercurial diuretics the patient improved steadily. The liver and spleen showed progressive decrease in size and on discharge, Dec 2, 1948, the patient was free of edema and bromsulfalein retention was reduced to 13 per cent in forty five minutes and total serum bilirubin to 1.16 mg per cent.

During the next few months the patient required hospitalization once for slight bleeding due to Dicumarol poisoning and once for an intercurrent acute infection. Since that time he has continued to improve, has gained weight,

and is now working full time without difficulty. Two subsequent liver biopsies have shown progressive improvement. P<sup>32</sup> has been given once since discharge.

The only usual sign of hepatic vein thrombosis which this patient did not exhibit was the presence of pain in the right upper abdominal quadrant. His recovery is believed to be related to the establishment of unequivocal diagnosis by means of liver biopsy and prompt institution of therapy for the polycythemia, with additional control of the ascites and clotting tendencies of the blood during the period of readjustment.

## 21 RENIN SENSITIVITY AND HYPERTENSINOGEN LEVELS IN ADRENALECTOMIZED DOGS

W D DAVIS, JR, M D, A SEGALOFF, M D, WILLIAM JACOBS, M D  
(BY INVITATION), AND J B CALLAHAN, M D (BY INVITATION)  
NEW ORLEANS, LA

Studies undertaken in an attempt to clarify the relationship of the adrenal gland to renin sensitivity and hypertensinogen levels revealed a definite vascular responsiveness to renin and the presence of hypertensinogen in adrenalectomized dogs in both the immediate postoperative period and after frank adrenal insufficiency had developed.

In four animals, after determination of blood pressure responses to 1 unit of angiotonin and 1 mg of renin, bilateral adrenalectomy was done in two stages. Four days following the second stage, when definite hypotension and pronounced increase in the blood urea nitrogen indicated frank adrenal insufficiency, the renin and angiotonin responses were determined again in the anesthetized animals. Hypertensinogen assays were made on control and experimental animals in these instances. In three of the dogs the intravenous injection of 1 mg produced essentially the same rise after as before adrenalectomy, whereas in one dog the response was somewhat less but was proportionately as great when calculated as a percentage of the basal blood pressure. In the hypertensinogen assays the amount of this substance was normal in two and questionably reduced in a third.

In four other dogs anesthetized with pentobarbital sodium four days following the second stage of adrenalectomy, when advanced adrenal insufficiency had developed, injection of 1 mg of renin produced a rise in blood pressure in three instances equal to that produced by 1 to 2 units of angiotonin and in the fourth a smaller rise. In one of these animals 50 mg of desoxy corticosterone glucoside did not increase the vascular response to injected renin. In two dogs in which the second stage adrenalectomy was done immediately prior to assay there was no essential change in the renin response before or after second stage adrenalectomy. In these dogs tachyphylaxis to renin was as difficult to produce after adrenalectomy as it was before.

In one dog studied immediately after bilateral adrenalectomy, the blood pressure subsequently dropped to 10 mm of mercury and little renin response could be elicited whereas the angiotonin response was somewhat higher though still considerably reduced. In one normal dog, rendered unresponsive to renin by repeated injections, 50 mg of desoxycorticosterone glucoside did not materially hasten recovery.

## 22 FURTHER STUDIES ON EFFECT OF DESOXYCORTICOSTERONE ACETATE IN EXPERIMENTAL HYPERTENSION

W D DAVIS, JR, M D ALBERT SEGALOFF M D WILLIAM JACOBS M D  
(By INVITATION) AND J B CALLAHAN M D (By INVITATION)  
NEW ORLEANS LA

Studies of the blood pressure response in hypertensive and normal dogs revealed (1) a usual but not invariable transient pressor effect from intravenous injection of 2 cc of propylene glycol (2) no further effect from the addition of 5 mg of desoxycorticosterone to this material, (3) abolition of this response by a local or general anesthetic and (4) from continuous subcutaneous administration of desoxycorticosterone acetate in sesame oil, a sustained and equal pressor effect which could be abolished by elimination of sodium from the diet and quickly precipitated by addition of large amounts of sodium during administration

In all instances direct blood pressures were taken by femoral arterial puncture and the use of a mercury manometer. Hypertension was induced in the dogs either by use of perineal silk wrapping or by application of Goldblatt clamps. Several months were allowed to elapse for standardization of pre experimental pressures

In thirty eight determinations on five hypertensive and thirteen normal unanesthetized dogs, no difference in response to the injection of 2 cc of propylene glycol alone and 2 cc of propylene glycol with 5 mg of desoxycorticosterone acetate was noted. In most instances a transient 30 mm rise in pressure was produced by the injection of both desoxycorticosterone and propylene glycol and propylene glycol alone. This was believed to be the result of phlebalgia since it was abolished by anesthesia in the dogs

In experiments conducted over a long period four hypertensive and two control dogs were given daily injections of desoxycorticosterone acetate in sesame oil in doses of 0.15 to 1.28 mg per kilogram of body weight. In nine of ten experimental periods of six weeks each sustained blood pressure rises of 25 to 50 mm of mercury were noted. These were sustained at first but gradually tended to return toward normal and in repeated periods in the same dog tended to be of shorter duration and less magnitude. In such instances however, increasing the dose of desoxycorticosterone could again augment blood pressure response. These responses which were of similar magnitude in hypertensive and control animals, were preventable by the use of low sodium intake and precipitable by the addition of sodium chloride to the diet in both hypertensive and control animals. In one of four trial periods in hypertensive animals forced feedings of sodium chloride alone produced a similar rise in arterial pressure

## 23 AN EFFECTIVE METHOD FOR THE PREVENTION OF RHEUMATIC FEVER AFTER THE DEVELOPMENT OF A STREPTOCOCCAL INFECTION

CAPTAIN FLOYD W DENNY (BY INVITATION), CAPTAIN LEWIS W WANNAMAKER (BY INVITATION), AND CAPTAIN WILLIAM R BRINK (BY INVITATION), MEDICAL CORPS, ARMY OF THE UNITED STATES, FORT FRANCIS E WARREN, WYO, AND CHARLES H RAMMELKAMP, M D, AND EDWARD A CUSTER, M D (BY INVITATION), CLEVELAND, OHIO

From January through June, 1949, at Fort Francis E Warren, over 1,650 consecutive cases of exudative pharyngitis and tonsillitis were observed. These cases were divided into control and treated groups of approximately the same size according to An Force serial number. Treatment consisted of the parenteral administration of crystalline procaine penicillin G (suspended in peanut oil containing 2 per cent aluminum monostearate) in doses of 300,000 units on admission and again in seventy-two hours. Later in the study the dosage schedule was changed to 300,000 units on admission, 300,000 units at forty-eight hours, and 600,000 units at ninety-six hours. Studies for the detection of rheumatic fever were performed between the third and fourth week following the initial infection. Throat cultures and blood specimens were obtained from all patients on admission and at the time of re-examination.

That these infections were almost exclusively streptococcal in origin was established by the presence of group A streptococci in approximately 80 per cent of all the original throat cultures and a diagnostic increase of the anti streptolysin "O" titer in the convalescent blood of about 80 per cent of the control group.

In the entire group, twenty-seven patients developed symptoms suggestive of acute rheumatic fever during a period of from ten to thirty-five days following the initial streptococcal infection. Of these, a definite diagnosis of acute rheumatic fever was made in nineteen patients, seventeen of whom were in the control group and two in the treated group. A diagnosis of possible acute rheumatic fever was made in eight patients, six of whom were in the control group and two in the treated group.

It is concluded that the adequate early treatment with penicillin of streptococcal infections will prevent rheumatic fever in the majority of cases.

## 24 A COMPARISON OF TUBERCULIN AND ARTHUS TYPES OF HYPERSENSITIVITY, IN VIVO OBSERVATION IN THE RABBIT EAR CHAMBER

ROBERT H EBERT, M D, W R BARCLAY, M D, AND J J AHERN, M D,  
CHICAGO, ILL

(INTRODUCED BY ROBERT G BLOCH, M D)

Using the rabbit ear chamber technique it has been possible to compare *in vivo* the difference between tuberculin and Arthus types of hypersensitivity. The rabbit ear chamber provides a thin layer of living vascularized tissue 40 to 50  $\mu$  thick which can be inoculated directly. Microscopic observations can be made at frequent intervals under the highest magnification, and the dynamics of tissue change can be watched and recorded with Kodachrome motion pictures.

The tuberculin reaction was studied in five chambers inoculated directly with old tuberculin. One animal was sensitized with bovine tubercle bacilli, strain Ravenel RV, and the others with BCG. Dilatation of blood vessels occurred during the first thirty minutes after inoculation and persisted for at least seventy two hours. Generalized sticking of leucocytes to vascular endothelium developed during the first thirty minutes, persisted for forty eight to seventy two hours, but decreased in extent after thirty six hours. Diapedesis of white blood cells resulted in the accumulation of considerable generalized exudate within two to five hours after inoculation. The exudate increased in density during the first thirty six hours. In three experiments localized hemoconcentration due to seepage of plasma through damaged endothelium was followed by stasis and complete thrombosis of small venules. This occurred in the regions of densest exudate twenty two to thirty six hours after inoculation.

The Arthus reaction was studied in six chambers using both bovine albumin fraction V and horse serum as antigens. Immediately following direct inoculation of antigen into the chamber in the sensitized animal platelet thrombi formed in venules and washed away in the general circulation. Within fifteen to thirty minutes there was considerable admixture of white blood cells with platelets in the thrombi which continued to form. Twenty to sixty minutes after inoculation sticking of large clumps of white blood cells and platelets to vascular endothelium was observed in many vessels. Simultaneously other vessels thrombosed completely and plugs of platelets and white blood cells could be seen separating areas of densely packed red blood cells. Dense exudate developed in the regions where sticking was marked, but little or no exudate accumulated around vessels which thrombosed early. The peak of the reaction occurred after eight to ten hours although sticking of white blood cells, vascular dilatation and infrequent formation of new platelet thrombi could be observed after twenty four hours.

Endothelial damage characterized both types of hypersensitivity. In the tuberculin type damage was either primary or initiated by local tissue damage. In the Arthus type it seemed to be initiated by an intravascular reaction.

## 25 ELECTROCARDIOGRAPHIC PATTERNS IN PERSONS OVER 80

E FELDMAN, M.D. (BY INVITATION), E. J. CHESROW, M.D. (BY INVITATION),  
AND P. H. WOSIKA, M.D., CHICAGO, ILL.

Unipolar multiple chest and limb lead electrocardiograms, in addition to the standard leads, were obtained upon one hundred patients over 80 years of age at the Oak Forest Infirmary and the Illinois Masonic Hospital. The abnormalities are tabulated, the largest groups being: first degree heart block, twenty nine cases; left ventricular hypertrophy, twenty nine cases; bundle branch block, thirteen cases; myocardial infarction, eleven cases. The establishment of the cardiac position using the unipolar leads explained the axis deviation found in the standard leads. In fifty three cases of left axis deviation the heart was in the horizontal or semihorizontal position.

Twenty one electrocardiograms were considered normal using the criteria established by Myers and associates. Of these only fifteen were normal to careful physical examination. Of forty five patients considered normal to physical examination, thirty cases showed abnormal electrocardiograms. Arteriosclerosis and varying degrees of heart failure accounted in the majority for the physical abnormalities encountered.

Our patients being older than the patients of most other published series, together with the use of multiple chest leads ( $V_4R$ ,  $V_3R$ ,  $V_{1-3}$ ), as well as the unipolar limb leads, makes comparison with earlier series difficult. The advantages of the additional leads to electrocardiographic interpretation again become apparent.

## 26 CARDIODYNAMIC AND RENAL STUDIES IN CHRONIC PERICARDITIS WITH EFFUSION, WITH PARTICULAR REFERENCE TO THE MECHANISMS OF FLUID ACCUMULATION

A. P. FISHMAN, M.D. (BY INVITATION), J. STAMLER, M.D. (BY INVITATION), L. N. KATZ, M.D., L. RUBENSTEIN, M.D. (BY INVITATION), A. J. MILLER, M.D. (BY INVITATION), AND E. N. SILBER, M.D. (BY INVITATION), CHICAGO, ILL.

The cardiodynamic and renal changes in chronic pericarditis with effusion were investigated in the dog with particular reference to mechanisms of fluid retention in relation to congestive heart failure.

Pericarditis was induced with irritative cellophane. Post-mortem morphologic studies revealed chronic nonbacterial pericarditis with effusion, passive hyperemia of the liver, kidneys, and lungs, and anasarca.

The following determinations were done serially on unanesthetized dogs: (1) cardiac output (C.O.), (2) renal plasma flow (R.P.F.), (3) glomerular filtration rate (G.F.R.), (4) Na clearance, (5) plasma volume, (6) thiocyanate space, (7) hematocrit, (8) plasma proteins, (9) central and peripheral venous pressure (V.P.), (10) arterial blood pressure, (11) heart rate, (12) intrapericardial pressure, (13) weight.

As pericardial effusion developed, peripheral and central venous pressure rose. This was the initial change recorded. No dog had an increased plasma volume at this time. In some animals thiocyanate space was normal, in others it was moderately increased. Resting C.O., R.P.F., and G.F.R. were all normal at this time. Na clearances suggested slightly decreased Na excretory rate.

With progression of tamponade, V.P. rose further. Plasma volume was increased in some animals, at control level in others. Thiocyanate space was elevated. In this late phase, resting C.O., G.F.R., and R.P.F. were at control levels. Arteriovenous  $O_2$  difference was increased. Ability to increase C.O. in response to excitement and exertion was severely limited. Blood pressure and pulse pressure were moderately depressed.

Prior to exitus circulatory collapse occurred, with hypotension, markedly elevated V.P. and intrapericardial pressure, decreased right atrial effective filling pressure. Resting C.O., R.P.F., and G.F.R. were depressed. Na clearance was severely impaired, with prolonged retention of infused saline.

It is concluded from this study that in pericarditis with tamponade (1) Venous pressure rises as increased intrapericardial pressure jeopardizes right atrial effective filling pressure. Increased venomotor tone appears to be a key factor in the V.P. rise.

(2) Elevated hydrostatic pressure leads to edema formation. This occurs despite normal resting C.O., G.F.R., R.P.F., and plasma volume.

(3) It is suggested that with elevated renal venous pressure, increased tubular Na reabsorption brings about Na and  $H_2O$  retention. Plasma volume is thereby maintained despite increased hydrostatic pressure, edema develops without hemoconcentration. Inadequate C.O. during activity may also contribute to Na retention due to an inordinate fall in R.P.F. and G.F.R.

(4) Preterminally, a critical level of intrapericardial pressure is reached (10 to 15 cm of H<sub>2</sub>O) beyond which V P cannot rise to maintain right atrial effective filling pressure and C O Circulatory collapse ensues All mechanisms for Na and H<sub>2</sub>O retention are aggravated Exitus soon supervenes

## 27 CLINICAL AND EPIDEMIOLOGIC STUDIES OF MUMPS EMPLOYING THE COMPLEMENT FIXATION TEST

A E FELLER M D GEORGE F BADGER, M D (BY INVITATION),  
JOHN H DINGLE M D RICHARD G HODGES, M D (BY INVITATION),  
WILLIAM S JORDAN JR M D (BY INVITATION), AND  
CHARLES H RANVIELKAMP JR M D CLEVELAND OHIO

The complement fixation test has been employed for a clinical and epidemiologic study of mumps Data have been obtained concerning the persistence of antibodies following infection the occurrence of unrecognized infections, the diagnosis of suspected cases of mumps and of "aseptic meningitis" and a comparison of the "S" or soluble antigen and the "V" or virus antigen The results confirm and extend data presented previously from other laboratories

Tests on one hundred fifteen single sera employing infected allantoic fluid ("V" antigen) detected antibody in the sera of fifty of fifty one individuals who gave a definite past history of mumps This positive correlation is notable because the majority of these persons had had mumps ten to thirty years previously There were seventeen individuals whose sera contained no detectable antibody and it seems highly significant that fourteen of them had no history of mumps two had an equivocal history and only one had had mumps Sera from thirty two or 70 per cent of forty six individuals with a negative past history of mumps contained antibody, indicating that inapparent or mild infections are frequent

Diagnostic tests were made with acute phase and convalescent phase sera from thirty four patients with definitive results Twelve sets of sera showed large increases in titer eleven of these were from cases of mumps many with complications, and the twelfth was from a patient in whom mumps was strongly suspected Twenty two sets showed no significant change in titer, all were from patients in whom mumps was considered in the differential diagnosis and thirteen were from patients with "aseptic meningitis"

Tests employing "S" antigen indicated as Henle has reported, that antibody to this antigen usually does not persist as long as antibody to the "V" antigen "S" antigen afforded no decided advantage over "V" antigen for the detection of mumps with paired acute and convalescent phase sera

It is concluded that the complement fixation test is a valuable tool for clinical and epidemiologic studies of mumps In addition, the test has been of practical clinical importance in certain instances, such as in patients exposed during early pregnancy and in professional personnel

## 28 DETERMINATION OF TOTAL BODY SODIUM IN MAN WITH RADIOSODIUM<sup>24</sup>

GILBERT B FORBES, M D, AND ANNE M PERLEY, M A (BY INVITATION)  
ST LOUIS, MO

Previous methods for determining the sodium content of the human body have been based for the most part, on calculations from chemical analyses of various organs and an assumed ratio of these organs to the total mass of the

body Carcass analysis is obviously more accurate, yet reports of such analyses are available only for the fetus and newborn. Since knowledge of the sodium content of the body should be useful in estimating parenteral fluid requirements, an attempt was made to determine it by the isotope dilution principle.

Intravenously administered radiosodium quickly mixes with intravascular sodium and within two to three hours is in equilibrium (except for cerebrospinal fluid) with extravascular sodium. Equilibration with the sodium of brain and bone takes place more slowly but is believed to be complete in about eighteen hours. When equilibrium is complete, serum specific activity should equal total body specific activity, and from knowledge of the former, total body sodium can be calculated as follows:

$$\frac{\text{Na}^{24} \text{ injected} - \text{Na}^{24} \text{ excreted}}{\text{Serum Na}^{24} / \text{serum Na}^{23}} = \text{Total body Na}^{23}$$

Thirty determinations on twenty-seven healthy young men indicate that total body sodium has an average value of 41 meq per kilogram. In a series of seventeen children the average values are 43 meq per kilogram for the older children, 49 meq per kilogram for large infants, and 82 meq per kilogram for small infants. Comparison of these results with those of actual chemical analyses from the literature will be made.

## 29 COMPARISON OF THE ELECTROPHORETIC PATTERN OF SERUM AND PLASMA IN LIVER DISEASES WITH SPECIAL REFERENCE TO THE GAMMA GLOBULIN FRACTIONS

M. FRANKLIN, M.D. (BY INVITATION), H. POPPER, M.D., J. DE LA HUERGA, M.D. (BY INVITATION), W. B. BEAN, M.D., F. STEIGMANN, M.D., J. I. ROUTH, Ph.D. (BY INVITATION), AND J. BUDDE, M.S. (BY INVITATION), IOWA CITY, IOWA

Electrophoretic studies on patients with chronic liver disease revealed marked elevations of the fibrinogen peak and lower than expected levels of gamma globulin. To study this phenomenon, we made a comparative study of sixty-five pairs of plasma and serum from persons having various liver diseases, a miscellaneous disease group and a normal group. Electrophoretic studies were supplemented by chemical protein partition (Wolfson and Cohn), flocculation, and other hepatic tests in all except a few miscellaneous cases.

Chemical analysis did not agree with the marked electrophoretic elevations in fibrinogen, nor were fibrinogen peaks completely obliterated upon electrophoretic analysis of the serum. Total serum gamma globulin was higher than the apparent plasma electrophoretic gamma globulin. The serum gamma globulin appeared electrophoretically as two portions of different mobilities, one migrating in the fibrinogen range. This latter portion accounted for the difference between the serum and plasma gamma globulin and, having a similar mobility to fibrinogen, was buried in that peak in plasma determinations. This gamma<sub>1</sub> fraction added to the plasma gamma globulin gave values similar to those of serum and chemically determined gamma globulin. It also accounted for most of the abnormal electrophoretic fibrinogen elevation and when subtracted from the apparent fibrinogen, chemical fibrinogen values were approached. This gamma<sub>1</sub> fraction is apparently identical to the gamma fraction found by Deutch in normal individuals. In our normal group it formed

approximately 24 per cent of total serum protein and 16.1 per cent of total gamma globulin. In acute hepatitis it was somewhat higher than normal, averaging 39 per cent of total serum protein and 16.7 per cent of total gamma globulin. In obstructive jaundice it was 41 per cent and 24.0 per cent, respectively. In cirrhosis this gamma globulin fraction averaged 7.0 per cent of total serum protein and 22.7 per cent of total gamma globulin. Thus in chronic liver disease in addition to a total gamma globulin increase there is a disproportionate increase in the gamma<sub>1</sub> fraction. Fifteen cases of rheumatoid and one multiple myeloma showed expected total gamma globulin increases but little change in the gamma<sub>1</sub> fraction. The serum and plasma concentrations of albumin, alpha and beta globulins were essentially similar. Although plasma electrophoretic tracings appear to be more characteristic for chronic liver disease than do those of serum, their use in protein partition of liver disease is limited because their inability to separate components of the elevated fibrinogen peak gives false impressions of elevated fibrinogen values and lower than expected globulin values.

### 30 INTRA AORTIC BLOOD PRESSURE DURING SURGICAL RESECTION AND REPAIR OF COARCTATION OF THE AORTA

JOSIAH FULLER, M.D., BOWEN L. TAYLOR, M.D., O. THERON CLAGETT, M.D.,  
AND EARL H. WOOD, M.D. ROCHESTER, MINN.

(INTRODUCED BY HOWARD B. BURCHELL, M.D.)

A mobile oscillographic camera was used during nine operations for coarctation of the aorta to record continuously the electrocardiogram, heart rate, respiration, and direct blood pressure in the right radial artery. The pressure in the aorta above and below the stricture was recorded by direct puncture simultaneously with these other variables before and after repair of the coarctation.

Compression of the area of the stricture produced no significant change in the pressure in the radial artery or in the aorta, whereas compression of the left subclavian artery in four patients produced an average increase of 18 mm. Hg in the systolic and pulse pressures in the radial artery, and an increase of 17 mm. Hg systolic, and 15 mm. Hg in pulse pressure in the aorta above the stricture. In spite of an increased pressure above the stricture this maneuver in the three cases studied produced an average decrease in the pressure in the aorta below the stricture of 7 mm. Hg systolic and 5 mm. Hg, mean.

In eight patients the average time spent opening the anastomosis was 31 seconds, and during this time the mean pressure in the radial artery decreased an average of 11 mm. Hg.

Repair of the coarctation in six patients was associated with an increase of 34 mm. Hg, systolic, and 22 mm. Hg pulse pressure, in intra aortic pressure below the stricture.

In seven patients the onset of the pulse wave in the aorta distal to the stricture before repair was an average of 0.02 second later than in the right radial artery at the wrist, whereas after resection the onset of the pulse distal to the site of stricture preceded that of the wrist by an average of 0.05 second. This was not significantly different from the value obtained from the aorta above the site of stricture.

Correlation between (1) the pressures at operation and (2) preoperative and postoperative direct observations of radial and femoral arterial pressures was not sufficiently close to be evident in this study.

The dynamic responses of the strain gage manometer systems used were studied by measurement of their response to square wave and variable frequency sine wave pressure variations. The response to equal amplitude pressure variations was within  $\pm 8$  per cent of the true pressure change up to 30 cps. Higher frequencies were recorded with diminished sensitivity. The deflection time was 0.02 second and the damping coefficient was 0.62. These dynamic characteristics are superior to those of undamped manometers with resonant frequencies of 150 cps.

### 31 THE EFFECT OF CHOLESTEROL-FREE DIET ON SERUM CHOLESTEROL OF NORMAL AND THIOURACIL-TREATED DOGS

EDWARD D. FUTCH III, M.D. (BY INVITATION), SHIH YUAN TSAI, M.D. (BY INVITATION), AND RAYMOND GREGORY, M.D., GALVESTON, TEXAS

Experimental studies in dogs indicate that altered thyroid function is necessary for the production of atherosclerosis by cholesterol feeding. In order to elucidate the importance of dietary cholesterol, the following experiment was devised.

Weekly weight and serum cholesterol determinations were made on two groups of four dogs each. After a control period of ten weeks on a commercial dog food, both groups were placed on a diet composed entirely of vegetable products. After a second control period of eight weeks, blood samples were drawn from the hepatic vein and right auricle by means of the catheter technique. Animals in group 2 were then given 1.0 Gm. thiouracil daily. The dose was increased to 1.5 mg. at twenty-five weeks.

In two dogs of group 2, after serum cholesterol had increased to twice the highest control value, hepatic vein and right auricular blood was analyzed for cholesterol.

In group 1, average serum cholesterol was 210 mg. per cent for one dog and 130 mg. per cent for the remaining three animals. This fell to an average of 176 mg. per cent for Dog 1 and 100 mg. per cent for the others. The fall was steady and progressive, lowest levels occurring toward the end of the period.

Group 2 showed striking increase in serum cholesterol after being given thiouracil for ten days. The serum cholesterol reached an average level of 240 mg. per cent over a period of eleven weeks. This approximately doubled average control values.

Comparison of mixed venous blood from the right auricle and hepatic vein showed no significant difference in cholesterol content before and after thiouracil feeding.

It is concluded that (1) the dog can be maintained in good condition on a cholesterol-free diet, (2) all dogs maintained on such a diet show gradual diminution of serum cholesterol, (3) elevation of serum cholesterol produced by thiouracil is not dependent on exogenous cholesterol, (4) excessive production of cholesterol by the liver was not demonstrated in a limited number of animals, (5) the possibility that shift of cholesterol from various organs to the blood serum occurs is being further investigated.

### 32 THE RENAL CAPACITY OF NORMAL HYPERTENSIVE AND CARDIAC FAILURE PATIENTS TO EXCRETE SODIUM

RAYMOND GREGORY, M D HARRY LEVINE M D (BY INVITATION) DORIS DEPPENBROCK ADAMS M D (BY INVITATION) AND VERNIE STENBRIDGE M D (BY INVITATION) GALVESTON TEXAS

The capacity to excrete an intravenous dose of 20 Gm of sodium chloride per 70 kilograms of weight was studied in normal hypertensive, and cardiac failure patients. A salt free diet and distilled water were given one day before and for the two days of the experiment. The sodium content of two hour urine specimens was determined for the first twelve hours and for three additional twelve hour periods for a total of forty eight hours following the injection of sodium chloride. These studies were done on eight normal nine hypertensive and eight heart failure patients. The hypertensive patients were studied only if venous pressure kidney concentration tests PSP tests and blood non protein nitrogen showed no evidence of renal failure.

Marked impairment of the ability of the kidney of each patient with cardiac failure and slightly less impairment of the kidney of each patient with hypertension to excrete sodium was observed in every one of the periods studied.

### 33 PRELIMINARY REPORT OF EXPERIENCES WITH Rh HAPTEN

TIBOR J. GREENWALT M D MILWAUKEE WIS

(INTRODUCED BY MAURICE HARDGROVE M D)

Hapten is the term introduced by Landsteiner to designate that portion of the antigen complex which determines its specific reactivity. Separated from the protein portion of the antigenic substance the haptene fraction is incapable of calling forth an antibody response when injected into an animal but retains its ability to react with and bind its specific antibody *in vitro*. We have attempted to extract the haptene portion of the Rh agglutinin from Rh positive red blood cells with alcohol and ether using a modification of the procedures described by Carter and Price. This material was assayed *in vitro* by complement fixation, using the method described by Kolmer for the serodiagnosis of syphilis. The hapten material obtained was injected into patients with demonstrable anti Rh antibodies during pregnancy 100 to 200 mg of the crude material was injected intramuscularly at weekly intervals.

Sixteen of our patients have terminated their pregnancies. Five received eight or more injections and eleven less than eight injections. Of the five receiving "adequate" therapy two delivered Rh negative babies two had macerated stillborn fetuses at thirty two to thirty four weeks and one delivered an Rh positive infant with demonstrable antibodies coating its red cells but no clinical evidences of erythroblastosis fetalis. Eleven patients were seen too late and received only 2 to 6 injections of hapten. Two of these delivered macerated stillborn fetuses, one aborted at eleven weeks one infant was Rh negative, two survived after multiple transfusions, two survived after replacement transfusions and three showed no clinical or hematologic involvement although they were Rh positive and had positive Coomb's tests.

Definite conclusions cannot be drawn from this material. The anti Rh titers of our patients receiving hapten have tended to remain low. In spite of this, our results have been discouraging. For example, one patient delivered a macerated fetus during the thirty fourth week of pregnancy after receiving seventeen injections of hapten. Her titer had never risen above 8 in albumin.

and was only 2 three days before delivery. Another patient who had only four hapten injections delivered a normal Rh-positive infant even though anti bodies could be demonstrated coating its red cells. One must almost conclude that the hapten therapy was not the determining factor.

### 34 CARDIOVASCULAR LESIONS IN RATS SUBJECTED TO GROUP A BETA HEMOLYTIC STREPTOCOCCAL PULMONARY INFECTIONS

ROBERT J. GLASER, M.D. (BY INVITATION), GUSTAV J. DANMIN, M.D., AND  
W. BARRY WOOD, JR., M.D., ST. LOUIS, MO

The effect of repeated pulmonary streptococcal infections in the rat was investigated in an attempt to elucidate the nature of the relationship of group A beta hemolytic streptococcal infections to rheumatic fever.

Pneumonia was induced in albino rats by intrabronchial inoculation of group A beta hemolytic streptococci employing techniques previously described. Animals were subjected to from one to seven infections, two strains of streptococci were used alternately in the animals infected repeatedly. Beginning eighteen hours after inoculation, animals were treated with penicillin in amounts previously determined to be adequate for successful control of the infection.

Infections were produced usually at two-week intervals, animals were sacrificed at the end of given periods for study. The hearts were fixed in Zenker formalin, and microscopic sections were stained with hematoxylin-eosin.

Slight to moderate arteritis and periaarteritis of the coronary and/or myocardial arteries occurred in 30 per cent of the experimental animals, whereas 3 per cent of the normal controls exhibited this change. The lesions observed in the experimental group were more intense than those in the control group.

Myocardial lesions, consisting chiefly of pleomorphic cellular foci, were noted in 52 per cent of the animals repeatedly infected, 38 per cent of the controls had similar but less intense lesions.

The incidence of endocardial infiltration by mononuclear cells was slightly more frequent and more intense in the experimental animals than in the controls. Cellular infiltration within the valve substance itself, however, was noted with greater frequency in the control animals. The cardiac lesions observed did not resemble those of rheumatic fever and none of the animals developed arthritis.

Results of this study have demonstrated a significantly greater incidence of cardiac arterial lesions in rats subjected to repeated pulmonary infections with group A beta hemolytic streptococci than in normal control subjects. Single streptococcal infections were not identified with a higher incidence of cardiovascular changes than were found in normal subjects.

The failure of the rat to develop more striking morphologic manifestations of hypersensitivity is in keeping with previous observation. It is believed, however, that the experimental approach used in this investigation, applied to other animal species, may prove a valuable means of studying the problem of the relation of streptococcal infection to rheumatic fever.

### 35 OBSERVATIONS OF THE CHARACTER OF PLATELETS STUDIED WITH A NEW PHOTOGRAPHIC TECHNIQUE

F. R. HALL, M.D. (BY INVITATION), AND STUYVESANT BUTLER, M.D.,  
CHICAGO, ILL.

In previous reports of Butler, Thomas, and Sanford it was observed that in patients receiving intravenous histamine there was no decrease in the number of platelets, but there did occur a slight but definite decrease in the clotting time.

of platelet free plasma, the higher the histamine concentration the greater the decrease. It was also observed by Sanford Butler and Kennedy that the clotting time of children with hemophilia could be greatly reduced by intravenous histamine.

In order to correlate these observations with the disappearance of platelets and increased coagulation in shock we surmised that there must be a simultaneous increased production and destruction of platelets at these clinical levels. To study this theory we have given intravenous histamine to patients using techniques described for coagulation studies but for absolute accuracy, convenience, and a permanent indisputable record we have made serial photographs every three minutes of platelets in solution for many hours.

Platelets examined in this manner can be studied morphologically with great accuracy and appear to remain constant in number for a long time and after a period of settling are found to be of a uniform size and characteristic spindle shape.

*Conclusions*—(1) Platelets are a formed element of the blood. (2) Platelets in solution for many hours in contact with glass do not change their character. (3) A photographic technique for the accurate study of platelets is described.

### 36 THE DIFFERENTIAL DIAGNOSIS OF HYPERGLYCEMIC STATES BY LABORATORY METHODS

G HAMM, M.D. (BY INVITATION) AND E. VON HAMM, M.D. COLUMBUS, OHIO

The hyperglycemic state represents a symptom and not a disease and can be produced by various etiological factors. In twenty three patients in whom a disturbance of carbohydrate metabolism was suspected the glucose tolerance and the insulin glucose tolerance were studied in conjunction with other supplementary laboratory tests. The arterial venous difference in the glucose tolerance test was taken as evidence of peripheral glucose utilization. Since this utilization is influenced by insulin a normal arterial venous difference would imply normal insulin effect. Decreased insulin sensitivity was recognized in the insulin glucose tolerance test. It was taken as evidence of the presence of extrapancreatic factors influencing the carbohydrate metabolism. Using these criteria seven of the twenty three cases were recognized as having a normal carbohydrate metabolism. The sixteen patients suffering definitely from hyperglycemia could be divided into the following groups: 4 cases of true pancreatic deficiency hyperglycemia, 3 cases of hyperglycemia showing pancreatic deficiency and extrapancreatic factors, 4 cases of extrapancreatic hyperglycemia and 5 cases of hyperglycemia with insulin and insulin sensitivity. The latter group may include the nutritional hepatogenous and mild functional hyperglycemias.

The hypothesis is presented that patients suffering from carbohydrate metabolism disturbance may change from one type to another thereby either aggravating or improving the hyperglycemic state. Some confirmation of the foregoing classification was found in the supplementary laboratory evidence and the clinical data available. Patients in whom extrapancreatic influences were postulated as a factor in the hyperglycemia suffered either from obesity or from other demonstrable functional disorders. The possibility that nonglucose reducing substances may interfere with a correct interpretation of the arterial venous differences is discussed and illustrated with a pertinent case.

### 37 THE EFFECT OF 4-AMINO-PTEROYLGLUTAMIC ACID ON THE URINARY EXCRETION OF 17-KETOSTEROIDS AND CORTICOSTEROIDS IN ACUTE LEUCEMIA

DAVID G HANLON, M D (BY INVITATION), HAROLD L MASON, PH D, AND J M STICKNEY, M D (BY INVITATION), ROCHESTER, MINN

Dougherty and Higgins, working independently, observed atrophy of the thymus, spleen, and lymphoid tissues and hyperplasia of the adenal cortex after administration of toxic doses of 4-amino-pteroylglutamic acid (Aminopterin) to rats. Adenalectomy largely prevented the involution of lymphoid structures. These findings suggested that Aminopterin exerts its effect, in part at least, through the medium of the adenal cortex and led us to study adenal function by means of determinations of the urinary excretion of corticosteroids and 17-ketosteroids of patients with acute leucemia who were being treated with Aminopterin.

In a control series of eighteen patients who had untreated acute leucemia, the values for urinary excretion of corticosteroids were usually within normal limits for adults (0.3 to 1.0 mg in twenty-four hours), in one patient the value was less than normal and in three patients slightly more than normal. Low or low normal values (0.8 to 5.5 mg in twenty-four hours) were found for 17 ketosteroids.

Six patients having acute leucemia were treated with 0.5 to 1.0 mg of Aminopterin daily, there was no evidence of increased urinary excretion of corticosteroids or 17-ketosteroids. In four of the six patients the output of corticosteroids in urine was depressed significantly, and in two of these four it practically disappeared. In the remaining two of the six patients there was no appreciable change from the original values, despite the administration of a total of 23 and 9 mg, respectively, of Aminopterin.

Depression of the urinary excretion of corticosteroids after administration of Aminopterin may result from one or more of three possible causes: (1) cytotoxic effect of Aminopterin on the adenal cortex with reduced activity of this gland, (2) a toxic effect on the pituitary with failure of its adrenocorticotrophic function, and (3) altered metabolism of cortical hormones.

Administration of 25 mg of pituitary adrenocorticotrophic hormone to one patient who was excreting subnormal amounts of corticosteroids was followed by no change in the number of circulating eosinophils and only a 3 per cent increase in the ratio of uric acid to creatinine, which, according to the experience of Thorn, would indicate impaired adrenocortical function. Nevertheless, in response to the adrenocorticotrophic hormone there was a marked rise in the output of corticosteroids which showed that the adenal cortex was still capable of responding to pituitary adrenocorticotrophic hormone and suggests that Aminopterin may effect a depression of the adrenocorticotrophic function of the pituitary.

### 38 HEMORRHAGIC DIATHESIS ASSOCIATED WITH LOW THROMBOPLASTIC ACTIVITY AND A CIRCULATING ANTICOAGULANT

ROBERT W HEINLE, M D, AUSTIN S WEISBERGER, M D (BY INVITATION), PAUL J VIGNOS, M D (BY INVITATION), AND WILLIAM B HOLDEN, M D (BY INVITATION), CLEVELAND, OHIO

An acquired hemorrhagic disease occurring in a woman one year after a normal pregnancy and characterized by a prolonged coagulation time, the presence of a circulating anticoagulant, and an apparent deficiency of thromboplastin

has been studied over a period of six years. The hemogram, platelet count, bleeding time, clot retraction, tourniquet test, prothrombin level, plasma fibrinogen, serum calcium, plasma vitamin C and plasma proteins have all been within normal limits on repeated determinations. The administration of large amounts of both fresh whole blood and plasma has not had any effect on the prolonged coagulation time. Precipitins against plasma fractions I and III have not been demonstrable. There was no change in the clotting time of recalcified plasma following centrifugation at high and low speeds. Titration with protamine sulfate revealed no increase in heparin. The presence of a circulating anti-coagulant was demonstrated by the prolongation of the clotting time of normal bloods when serial amounts of the patient's blood were added. The anticoagulant effect was also demonstrable in the plasma. Heating at 60° C for ten minutes inactivated the anticoagulant effect of the plasma. Standing at room temperature or 4° C for forty-eight hours had little or no effect on the anticoagulant. Thromboplastin assay of the patient's plasma compared with normal plasma and a standard preparation of Maltine thromboplastin revealed low levels of available thromboplastin. Plasma staphylococcus coagulase activator was normal. On two occasions electrophoretic studies revealed the presence of an abnormal fast component of the albumin fraction of the serum. Administration of a course of nitrogen mustard to the patient did not alter the clinical or laboratory findings.

The defect in coagulation in this patient is the result of the presence of an abnormal circulating anticoagulant. The findings do not differentiate whether the mechanism involves (1) antagonism of thromboplastin, (2) antagonism of a precursor of thromboplastin, or (3) an antienzyme antagonistic to a platelet enzyme necessary for the conversion of thromboplastin precursor to thromboplastin. The end result, however, is a deficiency of thromboplastic activity in the blood which produces hemophilic type of bleeding in the patient.

### 39 CONTROL OF HEART RATE WITH AN INTRACARDIAC THERMODE

HERMAN K. HELLERSTEIN, M.D. AND IRVING M. LIFBOW, M.D. CLEVELAND, OHIO

(INTRODUCED BY HAROLD FEIL, M.D.)

Classical experiments of McWilliam, Flack and others have shown that the rhythmicity of the S-A node can be altered by thermal changes in excised and perfused hearts and in the exposed heart. We have devised a special thermode which can be placed in the region of the S-A node by venous (jugular, brachial) catheterization of the intact experimental animal.

The thermode consists essentially of a 4 x 30 mm copper U tube attached to the cardiac end of a double lumen catheter. The thermode temperature is regulated by perfusing water of various temperatures (4 to 60° C) through this closed system. In five Nembutalized intact dogs changes in heart rate and in the form of the electrocardiogram were determined by continuous tracings recorded before, during, and after thermal changes. In over 100 experiments it was possible to vary the rate in a manner similar to experiments on exposed hearts.

The most pronounced effects occurred when the thermode was located at the junction of the SVC and right atrium in the region of the S-A node. There was a latent period of two to twenty-five seconds. Changes in rate were considered to be due to alteration of the temperature of the region of the S-A node. Cold perfusion caused the sinus rate to decrease from the control level of 120 to 140 to 90 to 80 per minute. When the S-A node region was cooled excessively, the pacemaker shifted to the A-V node, with a rate varying from 57 to 86 per

minute Hot perfusion increased the sinus rate to a maximum of 200 to 232 per minute at 45 to 55° C The acceleration produced by heating was relatively greater and persisted longer than the slowing produced by cooling

Marked changes in rate occurred without T-wave alteration However, in some experiments, when perfusion was rapid there were T-wave changes which indicated that there had been sufficient temperature change of the blood passing the thermode to alter the rate of repolarization of the subendocardial lamina Thus, in accordance with our previous observations, cold perfusion produced large negative T waves in cavity leads and tall positive T waves in extra cavity leads, heating produced opposite changes

The intracardiac thermode may prove valuable experimentally and therapeutically

#### 40 THE EFFECT OF RUTIN ON THE HEMORRHAGIC PHENOMENA OF EXPERIMENTAL MALIGNANT HYPERTENSION IN THE DOG

H K HELLERSTEIN, M D (By Invitation), AND J L ORBISON, M D (By Invitation), CLEVELAND, OHIO, AND S ROBBARD, M D (By Invitation), M WILBURNE, M D (By Invitation), AND L N KATZ, M D, CHICAGO, ILL

A striking feature of the malignant phase of experimental Goldblatt hypertension is the occurrence of diffuse hemorrhages The cause of these hemorrhages is unknown, usually being attributed to degeneration and necrosis of arterioles and capillaries

In view of the contradictory reports concerning the effects of rutin in reducing capillary fragility and hemorrhage in the malignant phase of hypertension in man, the following study was undertaken Acute hypertension with uremia was produced by complete bilateral ligation of the renal arteries in sixteen dogs Rutin was administered subcutaneously, 200 mg per day, as indicated in Table I

TABLE I

NUMBER OF DOGS	RUTIN RECEIVED		HEMORRHAGIC LESIONS
	PREOPERATIVELY	POSTOPERATIVELY	
5	0	0	Severe
2	0	Daily	Severe
4	3 days	Daily	Severe
5	10 days	Daily	None

All the animals developed clinical uremia and hypertension, with death in three to six days The tissues were studied as unknowns

Severe hemorrhages in the gastrointestinal tract, heart, pancreas, urinary bladder, diaphragm, spleen, and adrenals, together with myocardial inflammation and necrosis, were seen in the first three groups By contrast, the animals pretreated with rutin for ten days showed complete absence of cardiomyopathy and of the hemorrhagic changes As a result of the complete obstruction of the main renal arteries, coagulation necrosis of the renal cortex and medulla, with an unexpected sparing of the corticomedullary junction, was noted

These experiments demonstrate that the hemorrhages usually seen in acute experimental malignant hypertension were prevented by pretreatment with rutin for ten days prior to operation This protective action may be due to a stabilizing effect of rutin on the ground substance of the arterioles and of the pericapillary sheath The fact that a shorter period of pretreatment did not provide protection suggests that all our animals were relatively rutin deficient

and that saturation required more than three days of pretreatment. The contradictory reports on the effect of rutin in malignant hypertension in man may also depend upon the relative rutin deficiencies in the patients studied. These experiments call attention to the possibility that the several dietary regimens now being used in the treatment of hypertension may be deficient in rutin and possibly other metabolites.

#### 41 A CLINICAL EVALUATION OF THE BLOOD "SLUDGL" PHENOMENON

JOHN S. HIRSCHBOECK, M.D. AND MISS WOOD, M.D. (BY INVITATION)  
MILWAUKEE, WIS.

The bulbar conjunctival capillaries of a variety of medical patients were observed with the capillary microscope. Erythrocyte sedimentation rates, erythrocyte counts, and serum protein determinations were made within a few days before or after the observation of the circulation in the capillaries. More than 1,200 observations were made.

In general, the degree of sludging was directly proportional to the sedimentation rate. Sludging was observed in a wide variety of pathologic conditions. Patients with hyperglobulinemia usually had an increased sedimentation rate and well developed "sludge". Anemia usually caused an increase in "sludging" and sedimentation, whereas erythrocytosis (polycythemia vera or congenital heart disease) always produced an opposite effect.

A discrepancy between the degree of "sludging" and the sedimentation rate occurred in 17.6 per cent of the 619 cases studied. In 5.5 per cent of the cases there was a minimal degree of "sludging" with a rapid sedimentation rate. Pneumonia was the most frequent diagnosis in this group. In 12.1 per cent of the cases well developed "sludging" with a slow sedimentation rate occurred. Heart failure and hepatic encephalosis were the most frequent diagnoses in this group. Well developed "sludging" in the absence of a rapid sedimentation rate is probably the result of stasis in the capillaries.

These observations indicate that blood sedimentation and blood "sludging" have a common cause which according to Fahreus and others is increased rouleaux aggregation.

#### 42 FURTHER EXPERIENCES IN THE MANAGEMENT OF LOWER NEPHRON NEPHROSIS

WILLIAM S. HOFFMAN, M.D., ARTHUR BERNSTEIN, M.D. (BY INVITATION),  
LIONEL BERNSTEIN, M.D. (BY INVITATION), AND PHILIP B. O'NEILL, M.D.  
(BY INVITATION) CHICAGO, ILL.

Lower nephron nephrosis was found to occur after a variety of shocklike episodes, only a few of which were associated with muscle injury or destruction of blood cells. It was seen in lobar pneumonia, acute pancreatitis, acute enteritis, and diabetic coma. The condition was at times difficult to distinguish from other diseases producing oliguria and hematuria, such as acute glomerulonephritis, and bilateral papillary necrosis. Factors producing rapid dehydration and sodium loss, which ordinarily lead to so-called extrarenal azotemia and which respond to fluid and salt administration, could in more fulminating episodes produce true lower nephron nephrosis. The ultimate clinical diagnosis in the patients who survived rested on the finding of severe oliguria from five to thirteen days unresponsive to management, with spontaneous and progressively

increasing diuresis, and with poor renal function even after subsidence of blood nitrogen levels, which function slowly but ultimately returned to normal.

The original illness which brought on the lower nephron nephrosis was important in the prognosis. If infection or trauma persisted throughout the period of oliguria, tissue breakdown was excessive and blood nitrogen levels rose precipitously. These patients died in uremia and heart failure under conditions in which previously well persons might easily survive. All five deaths in our series of eighteen patients occurred with such complications. All patients whose oliguria was associated with self-limiting or controllable conditions, like that of hemorrhage, transfusion reaction, or controllable infection, survived.

We continue to advocate only conservative management in these cases. In the first six cases, successful resistance to the ravages of uremia was achieved by slow induction of edema of nearly normal electrolyte composition. In the later cases, the same results were accomplished by raising sodium levels to normal by intravenous injections of small quantities of 3 per cent sodium chloride and by oral sodium bicarbonate. Thus edema was kept at a minimum. We continue to allow a soft diet ad libitum and believe the slight increase in blood nonprotein nitrogen concentration and edema thereby produced less harmful than the weakness, thirst, and anxiety produced by water and food deprivation advocated by others. Watchful symptomatic treatment of the emergencies of uremia still remains an important factor in successful management.

#### 43 TURBIDIMETRIC DETERMINATION OF SERUM GAMMA GLOBULINS AS CHECKED BY ELECTROPHORETIC ANALYSIS

J. DE LA HUERGA, M.D. (By Invitation), and HANS POPPER, M.D., CHICAGO, ILL.,  
AND MURRAY FRANKLIN, M.D. (By Invitation), IOWA CITY, IOWA

Recently a simple method for turbidimetric estimation of the gamma globulins was described by Huega and Popper. It follows closely the procedure of the thymol turbidity test and is based on recording of a precipitate which forms if serum is diluted with an ammonium sulfate-sodium chloride solution, simulating the chemical determination and partition of gamma globulins by Wolfson, Cohn, and others. The results of the turbidimetric method were found identical with this chemical method. The latter is supposed to give comparable results with electrophoretic partition. Nevertheless, the direct results of the turbidimetric readings for gamma globulins were compared with the results of electrophoretic partition in 163 blood specimens of 134 cases which included normal subjects, patients with various liver diseases, multiple myeloma, and miscellaneous disorders. In 58.1 per cent of the cases the difference between the results of the electrophoretic determination in plasma and the turbidimetric in serum was less than 15 per cent, in 71.5 per cent, less than 20 per cent. The results were not comparable at all in only 3.7 per cent of the cases, varying more than 50 per cent. The mean difference between the turbidimetric and electrophoretic method in per cent was  $17.0 \pm 15.3$ , the electrophoretic method giving slightly higher values on the average. In thirty-seven cases in which both determinations were performed in serum, the mean difference was  $13.5 \pm 8.4$  per cent. The differences were not more marked in pathologic conditions than under normal circumstances. This comparison indicates that the simple gamma globulin turbidity test may replace the electrophoretic determination of gamma globulins in clinical use. The results of the gamma globulin turbidity test are not identical with those of the zinc sulfate turbidity test of Kunkel, especially in hepatic disorders, since the latter may appear depressed in intra- and extrahepatic obstructive jaundice. This depression indicated by an abnormally low ratio between zinc sulfate and gamma globulin turbidity may therefore have diagnostic sig-

nificance. The normal gamma globulin turbidity values range between 0.60 and 1.25 Gm per 100 ml of serum. Any elevation above this level is significant. The gamma globulin turbidity values are markedly elevated in liver disorders especially in cirrhosis and viral hepatitis and also in rheumatic diseases, several forms of chronic tuberculosis, collagen diseases, chronic skin diseases and other chronic infections. Comprehension of the exact diagnostic value of elevation of the gamma globulin turbidity in the latter conditions requires additional investigation.

#### 44. AN UNUSUAL CLINICAL PICTURE RESEMBLING PROLONGED SERUM SICKNESS "THOUGHT TO BE CAUSED BY TRICHINOSIS"

JOHN S. HUNT, M.D., NEW ORLEANS, LA.

A young Negro laborer previously well except for nonseasonal attacks of asthma since childhood was hospitalized with an illness of one month's duration, characterized by an abrupt onset of fever, migratory arthritis, and severe pain and tenderness in the leg muscles. He had received no serum or drugs prior to this illness. When first seen the muscle pain had largely subsided, but he had persistent fever and arthritis and physical examination revealed, in addition, pronounced enlargement of subcutaneous lymph nodes. There was no rash or demonstrable edema. The clinical picture suggestive of serum sickness was supported by laboratory observations of marked leucocytosis, eosinophilia of 4 to 8 per cent, marked elevation of serum gamma globulin as evidenced by the zinc sulfate turbidity test, and the presence of serum heterophile agglutinins of the Forssman type in rising titer. Lymph node biopsy in the fifth week of illness showed marked hyperplasia and muscle biopsy in the sixth week revealed no trichinae or arteritis. There was a strongly positive immediate reaction to dilute trichina antigen injected intradermally. An electrocardiograph showed changes in T waves and QRS complexes suggestive of myocardial disease. Fever, leucocytosis, and joint pains slowly subsided over a six week period and there was a gradual decrease in the size of the lymph nodes. Pyribenzamine treatment during the stage of acute illness resulted in a slight decrease in fever and a definite improvement in the arthritis pain, and objective joint changes decreasing promptly and recurring explosively on two occasions after withdrawal of the drug.

On re-examination, eight months after the onset of the illness, he was asymptomatic and showed on examination nothing abnormal except for palpable lymph nodes of much smaller size. The leucocyte count was normal, but with 4 to 5 per cent eosinophiles. Heterophile agglutinins had disappeared from the serum. The electrocardiograph now showed a P-R interval of 0.22 second.

Trichinosis is suggested as the probable cause of this illness on the basis of the muscle pain and tenderness at its onset, the strongly positive intradermal test with trichina antigen, the persistent eosinophilia, and the electrocardiographic abnormalities. This suggests the possibility that on occasion the clinical picture of trichinosis may be chiefly one of hypersensitivity to the trichina antigen. In this connection the report of Reimann, Price and Herbut on the association of trichinosis with lesions of periaarteritis nodosa is of interest.

#### 45 FLUID AND ELECTROLYTE BALANCE IN THE MANAGEMENT OF ACUTE RENAL INSUFFICIENCY

LLOYD T ISERI, MD (BY INVITATION), ALBERT J BOYLE, PH D, MD (BY INVITATION), THOMAS M BATCHELOR, MD (BY INVITATION), SAMUEL D JACOBSON, MD, AND GORDON B MYERS, MD, DETROIT, MICH

Studies of Na, K, Cl, N, and water balance were carried out for periods of four to sixteen days in four patients with severe acute renal insufficiency due to lower nephron nephrosis, studies of sodium and water balance were continued for longer periods in these patients and in six additional ones. Calculations of extracellular-intracellular partition of water, sodium, and potassium were made in the four patients according to the method of Darrow.

Marked fall in plasma sodium was encountered during the oliguric phase as well as during the diuretic phase. The drop during the oliguric phase was due partly to dilution in extracellular fluid and partly to intracellular migration. The drop during the diuretic phase was traceable to the inability of the damaged kidney to retain sodium. Spontaneous resumption of capacity to conserve sodium tended to occur about five to seven days after the onset of diuresis. The importance of following plasma sodium levels and using these as a guide in the treatment will be stressed. Another cardinal feature in the treatment, namely, the daily calculation of fluid balance and utilization of this as an index to fluid intake, will also be brought out.

The plasma potassium did not rise to toxic levels in any of our cases. In one patient who went through ten days of extreme oliguria following circulatory collapse due to diabetic coma, the plasma potassium remained below toxic levels as a result of intracellular uptake of potassium which was released from endogenous protein catabolism. Impairment in capacity to conserve potassium was demonstrated during the diuretic phase and in some cases necessitated administration of supplementary potassium chloride to combat hypokalemia.

#### 46 THE EFFECT OF X-IRRADIATION ON ANTIBODY FORMATION

L O JACOBSON, MD, M E ROBSON, BS (BY INVITATION), E K MARKS (BY INVITATION), AND M C GOLDMAN, BS (BY INVITATION), CHICAGO, ILL

Hektoen, in 1915, first demonstrated that total body exposure of experimental animals to ionizing radiation suppressed the usual antibody response to antigens injected shortly before or shortly after irradiation. Hektoen's observations led him to ascribe this suppression to the destructive effect of radiation on the lymphatic tissue.

This communication relates an attempt to study the capacity of the rabbit to form antibodies during a period in which all lymphatic tissue of the body, with the exception of the spleen or appendix, is essentially destroyed.

Young adult rabbits were given 800 r total body x-irradiation (250 kv) twenty-four hours prior to intravenous immunization with sheep cells (1 cc of a 2 per cent suspension). Hemolysin titers were determined on serum obtained before immunization and at seven, fourteen, twenty-one and twenty-eight days afterward. Animals thus irradiated and immunized either developed no demonstrable hemolysin titer or developed titers of 1 to 80 or 1 to 40 which were demonstrated on the twenty-first day and the twenty-eighth day, respectively, after immunization. In the normal animal hemolysin titers of 1 to 5120 were produced by the fourteenth day after the intravenous administration of the antigen, diminishing to titers of circa 1 to 160 by the twenty-eighth day. Rabbits given 800 r total body x-irradiation exclusive of the surgically mobilized, lead pro-

ected spleen or appendix produce antibodies to this antigen in a manner comparable to normal nonirradiated control animals except that the maximum titer of 1 to 5120 is usually reached on the twenty first day rather than on the fourteenth. Surgical mobilization of the spleen or appendix was performed while the animals were under Nembutal anesthesia. In the experiments involving spleen protection, the spleen was drawn through a left upper quadrant incision and placed in a lead box one fourth inch thick with an opening for the pedicle only, during the period of irradiation. In the experiments involving appendix protection, the method was similar except that the appendix was drawn through a right lower quadrant incision and a cylindrical lead shield open at one end was used.

These experiments corroborate Hektoen's original classic findings that antibody formation is suppressed by total body irradiation. In addition it has been demonstrated that if the spleen or appendix of the rabbit is protected by lead shielding during irradiation of the balance of the body the capacity to produce antibodies to an injected particulate antigen in an essentially normal manner is retained, even though lymphatic tissue elsewhere in the body is largely destroyed.

#### 47 RENAL AND EXTRARENAL DISPOSAL OF CHORIONIC GONADOTROPIN IN THE IMMEDIATE POST PARTUM PERIOD

CARL E. JOHNSON, M.D. (BY INVITATION) & ALBERT PH.D. M.D. AND  
ROBERT B. WILSON, M.D. (BY INVITATION) ROCHESTER, MINN.

The fate of chorionic gonadotropin in the human being has not been well established. Not more than 20 per cent of chorionic gonadotropin administered parenterally to men appeared in the urine\*. Similar experiments in nonpregnant women indicated occasionally much larger urinary recoveries leading to the view that relatively little destruction or utilization of the hormone occurred in the body†. The foregoing results however are not necessarily applicable to the fate of the hormone during pregnancy.

We have studied the renal and extrarenal disposal of chorionic gonadotropin in fifteen pregnant women. Starting immediately on placental delivery samples of venous blood were taken at three hour intervals for two or more days. Urine was similarly collected by an indwelling catheter for three or more days. Bioassay of the serum and urine for chorionic gonadotropin was performed by Albert's method‡. The total circulating hormone was estimated at zero time (immediately after the delivery of the placenta) by multiplying the determined concentration of hormone per milliliter of serum by the estimated serum volume. The total amount of hormone appearing in the urine was obtained by addition of the determined values for all samples.

The mean total circulating hormone for the fifteen patients was 36,245 I.U. The mean urinary excretion was 2,105 I.U. Thus a mean of 5.8 per cent of the active circulating hormone was excreted in the urine. 94.2 per cent of it was disposed of extrarenally, presumably by endogenous inactivation or destruction.

This conclusion was further borne out by analysis of the blood and urine curves following placental delivery and by calculations involving the renal clearance of the hormone. In the immediate post partum period the renal clearance was 0.47 ml per minute. At this rate the serum would be entirely cleared

\*Friedman and Weinstein. *Endocrinology* 51: 489-193.

†Bradbury and Brown. *J. Clin. Endocrinol.* 5: 103, 1918. Lloyd and co workers. *J. Clin. Endocrinol.* 9: 68, 1949.

‡*J. Clin. Endocrinol.* 5: 619, 1948.

of hormone in 106 hours, or cleared to the extinction point of the bio assay in 89 hours. The blood disappearance curves have a mean half-life of 34 hours, or a time for extinction of 93 hours, which is grossly incompatible with the time (89 hours) that would be required for reaching the extinction point if the removal of the hormone from the blood depended entirely on renal excretion. Thus a major route of disposal of the hormone other than renal excretion of the active hormone is present.

## 48 THE MEASUREMENT OF THE PERIPHERAL CIRCULATION

### A QUANTITATIVE STUDY

CARL A. JOHNSON, M.D., CHICAGO, ILL.

To date, the clinical measurement of the peripheral circulation is made by indirect means only. The instrumental methods most commonly used are skin temperature studies, oscillometry, plethysmography, photometry, x-ray visualization of the blood vessels, and the use of isotopes.

It is not the purpose of the present paper to evaluate or discuss the relative merits of the various methods but to present a brief report on the results of the measurement of the peripheral circulation by a new method and to discuss the various components of the peripheral records such as amplitude, crest times, diastolic notch, and the central pulse as related to the peripheral pulse.

Slides will be shown illustrating the quantitative measurement of the pulsatile peripheral circulation in patients with such diseases as hypertensive heart disease, organic occlusive arterial disease, cardiac arrhythmias, and organic valvular disease. A few studies on the effects of smoking in sensitive subjects will be presented.

A special adaptor, for the lantern slide projector, has been made for demonstration purposes. By this means it is possible to project on the screen the circulatory changes from any location in the extremities. During the course of the discussion the circulatory changes from a normal subject will be shown, illustrating the speed and ease with which quantitatively calibrated records can be made.

## 49 COOMBS TITER VARIATIONS IN ACQUIRED HEMOLYTIC ANEMIA

WILLIAM S. JORDAN, JR., M.D. (BY INVITATION), AND  
JOHN H. DINGLE, M.D., CLEVELAND, OHIO

The erythrocytes from seven of ten patients with acquired hemolytic anemia have shown agglutinability with antihuman serum rabbit serum (direct Coombs test). Of the three instances of hemolytic anemia with negative Coombs tests, one was a severe but transient episode complicating pneumonia and empyema, one had persisted intermittently for six years in an individual with no family history of jaundice and a normal erythrocyte osmotic fragility, and one occurred as the terminal episode in a patient with Hodgkin's disease.

Two patients with Hodgkin's disease, one with carcinomatosis and one with pernicious anemia, experienced hemolytic episodes associated with a positive Coombs test. Agglutination of their erythrocytes occurred only in low dilutions of rabbit serum and decreased or disappeared with the termination of the episode. Because commercially available antiglobulin serum failed to give similar reactions the specificity of the local serum was checked against erythrocytes from sixty patients obtained as random samples from the blood bank. Only one

sample erythrocytes from a female patient hospitalized for transfusion for anemia gave a similar low titer reaction. Erythrocytes from fifteen anemic patients with carcinomatosis, Hodgkin's disease, multiple myeloma, leucemia, Gaucher's disease, hypersplenism and pernicious anemia all without evidence of hemolysis gave negative Coombs tests.

In contrast to the low titer agglutination observed in patients with symptomatic hemolytic anemia, erythrocytes from three patients with acute idiopathic hemolytic jaundice were agglutinated by high dilutions of antiglobulin serum. The direct Coombs titers persisted at high levels in two patients subjected to splenectomy. The patient without demonstrable serum antibody experienced partial remission; the patient with serum auto and isoagglutinins was not benefited. A third patient without splenomegaly received nitrogen mustard. This did not alter the Coombs titer or the degree of hemolysis and produced a fatal thrombocytopenia.

It is concluded that not all patients with acquired hemolytic anemia have positive Coombs tests and that potent antiglobulin serum is necessary to obtain positive tests in certain other cases. In those cases with low titer agglutination the finding of a positive Coombs test was correlated with the presence of a hemolytic episode. In two patients showing high titer agglutination splenectomy did not lower the agglutination titer of their erythrocytes in antiglobulin serum but did lead to a beneficial decrease in the rate of erythrocyte destruction in one case. Additional study is necessary to determine the effect of detectable serum agglutinins on the rate of hemolysis following splenectomy.

## 50 CLINICAL EXPERIENCE WITH A NEW ANALGESIC AGENT

CHARLES I. JUNKERMAN, MD, ROBERT C. HEEN, MD, AND  
HERBERT W. POHL, MD, MILWAUKEE, WIS.

(INTRODUCED BY I. W. MADISON, MD)

Clinical trial of a new analgesic, 3-hydroxy-N-methylmorphinan hydrobromide (NU 2206), has been carried out. Of thirty-five patients studied, eleven had advanced malignancy, nine were postoperative, and the remaining fifteen had pain from a variety of causes including renal colic, lupus erythematosus, peripheral vascular disease, rheumatoid arthritis, fracture, myocardial infarction, and congestive heart failure. Experience thus far indicates that the drug has approximately three times the analgesic potency of morphine. In seven patients relief of pain was inferior to that obtained when comparable dosage of other analgesics was used. Nausea and vertigo were encountered though less commonly than with morphine, Dilaudid, or Pantopon. When used over a long period of time, tolerance developed and the dosage had to be increased. Euphoria was noted in only four patients. One patient with advanced peripheral vascular disease received fourteen doses of 3 mg. and twenty-six doses of 5 mg. over a period of sixteen days. Following amputation on the sixteenth day, pain ceased and the drug was stopped without withdrawal symptoms. The most striking results were obtained in the group with advanced carcinoma where in many instances pain could be completely abolished without appreciable sedation or respiratory depression even when as large a dose as 20 mg. was given.

No major toxic effects have thus far been observed.

# 51 THE EFFECTS OF COLD ON MAN SPECULATIONS ON DISEASES OF COLD TEMPERATE CLIMATES, NUTRITION, AND THE PITUITARY-ADRENAL AXIS

ROBERT M. KARK, D C H., ROBERT E. JOHNSON, M D (BY INVITATION),  
CHAUNCEY G. BLY, M D (BY INVITATION), AND C. FRANK CONSOLAZIO  
(BY INVITATION), CHICAGO, ILL

Investigations on healthy young men exposed to the cold have uncovered adaptive changes which might provide clues for understanding the genesis of some diseases most prevalent in cold temperate climates. For example, it has been established for troops in the field that the voluntary caloric consumption is greater the colder the climate. Among men traveling in extreme cold there are, on occasion, alterations in water metabolism and electrolyte balance, creatinuria, retention of ascorbic acid, and other changes reminiscent of those observed in injury and other stress. Recently, metabolic changes were observed in thirty-two heat-acclimatized men abruptly exposed to a cold climate (mean temperature,  $-26^{\circ}$  F) for twelve days. The results were similar in many respects to those in man after injection of adrenocorticotrophic hormone and to the "general adaptation syndrome" of animals during stress. Statistically significant responses during the first day included hypothermia, diuresis, hemoconcentration, eosinophilopenia and lymphopenia, neutrophil leucocytosis with increase in the percentage of young cells, hyperuricemia, hyperphosphatemia, and hyperkalemia, hyponatremia and hypochloremia, transient retention of sodium and chloride, and diminution of ascorbic acid in the blood. Most of these changes reverted to normal after two days of exposure. However, in the last six days of exposure there were an increase in kidney and adrenocortical activity, a test dose of water being excreted rapidly at very low specific gravity, continued eosinophilopenia and lymphopenia, and continued hyperuricemia and hyperphosphatemia.

Mills and others have shown that diabetes, hyperthyroidism, pernicious anemia, Addison's disease, and leukemia are most prevalent in cold temperate climates, especially so in populations exposed to wide seasonal and diurnal variations in temperature. There are other chronic disorders such as multiple sclerosis, the rheumatic diseases, and certain cardiovascular diseases which have a geographic distribution similar to that of the five diseases just mentioned. In man, acute exposure to cold has been said to precipitate pneumonia, nephritis, and attacks of gout.

We accept the concept that climatic or environmental stresses are related to the genesis of certain disease processes in man. We would alter the hypothesis of Mills and others that the development of many diseases is directly related to the metabolic load imposed by stimulating climates to the hypothesis that exposure to cold stimulates the pituitary-adrenal axis. There may then occur pathologic changes, some of which have already been detected in studies of the "general adaptation syndrome."

## 52 PATHOLOGIC AND ELECTROCARDIOGRAPHIC STUDY OF THE AURICLES

JOSEPH KAUFMAN, M D (BY INVITATION) AND RALPH C SCOTT, M D  
(BY INVITATION), CINCINNATI, OHIO

(INTRODUCED BY JOHNSON MCGUIRE, M D )

By current standards, auricular disease is said to exist when the P wave in any of the standard leads exceeds 12 second in duration, or 3 mm in height. The validity of these criteria were studied as follows

1 Two hundred electrocardiograms on normal subjects ranging from birth to 20 years of age were examined. None of the 200 electrocardiograms exceeded the accepted criteria for auricular damage.

2 One hundred electrocardiograms in which the P wave measurements exceeded the limits mentioned were chosen by random selection. They were classified according to the clinical diagnoses. Abnormal P waves were found in 5 cases of myocardial infarction, 28 cases of hypertensive arteriosclerotic heart disease, 19 cases of rheumatic heart disease, 4 cases of congenital heart disease, 9 cases of cor pulmonale and in 35 cases comprising a miscellaneous group (beriberi heart disease, thyrotoxic heart disease, etc.). Broad P waves were recorded three times as frequently as tall P waves.

3 Necropsy findings in 122 unselected cases of heart disease were correlated with the P wave in the electrocardiogram. There were 42 cases of myocardial infarction, 28 cases of hypertensive arteriosclerotic heart disease, 25 cases of congenital heart disease, 15 cases of rheumatic heart disease, and 12 cases of cor pulmonale. Pathologic abnormalities of the auricles were found in 58 cases and consisted of dilatation, hypertrophy, intra auricular thromboses, endocardial thickening, or combinations thereof. P wave abnormalities were present in 28, or 49 per cent, of these cases. Where electrocardiographic and pathologic findings co existed there was no correlation between the type of P wave abnormality and the particular pathologic change recorded. Electrocardiographic evidence of auricular abnormalities was present in 42 cases of the entire autopsied series. In 14 instances of these 42 cases or 33 per cent, pathologic confirmation was absent. There were 50 cases in the series of 122 in which neither pathologic nor electrocardiographic evidence of auricular abnormalities was demonstrable.

It was concluded that (1) abnormal P wave changes may occur in the absence of gross pathologic changes in the auricles, (2) normal P waves may exist in the presence of gross pathologic changes in the auricles, (3) no correlation existed between the auricular chamber involved and the particular lead in which P wave abnormalities were found.

## 53 THE PRESENCE OF A PHOSPHATASE IN THE HUMAN AORTIC WALL

ESBEN KIRK, M D, AND E. PRAETORIUS, M D (BY INVITATION), ST LOUIS, MO

The failure to demonstrate a phosphatase in the human arterial wall has been a subject of significance in the discussion of the pathogenesis of arterial calcification. Since previous investigations appear to have been performed only at alkaline reactions, a study was undertaken covering a wider pH range.

After removal of the adventitia and the external part of the media from human aortas obtained at autopsy, the remaining part of the tissue was ground

finely with water in a Pyrex grinder and the samples were centrifuged. For study of the enzymatic activity portions of the supernatant solution were added to citric acid sodium hydroxide and Veronal sodium carbonate buffers, covering the pH range 3.1 to 10.1. Disodium phenyl phosphate was used as a substrate. Duplicate samples, controls, and blanks were run at each pH level examined. The reaction was stopped by the addition of trichloroacetic acid and the phenol content of the filtrates determined by Folin and Ciocalteu's method. The enzymatic activity was estimated by subtracting the color of the controls from that of the samples.

The studies showed a significant phosphatase activity with a maximum at pH 5.7 to 5.8. At this optimal pH level a fair proportionality was observed between the amount of supernatant fluid used and the phosphatase activity and between the reaction time and the enzyme activity.

#### 54 THE DIAGNOSTIC VALUE OF HIGH PRECORDIAL LEADS

HOWARD A. KLEIN, M.D. (BY INVITATION), AND GORDON B. MYERS, M.D.,  
DETROIT, MICH.

High precordial leads taken at the intersections of vertical lines through the  $V_3$ ,  $V_4$ ,  $V_5$ , and  $V_6$  positions with a horizontal line at the junction of the third interspace and sternum have been obtained on approximately 4,000 patients. The findings in these leads were correlated with those in the customary precordial and Goldberger limb leads and with the pathologic findings in 300 cases that came to autopsy.

Cardiac rotation appeared to have a greater influence on the QRS pattern in high precordial leads than in those taken in the usual positions. Clockwise rotation displaced the transitional zone farther to the left in high than in the customary precordial leads and often led to the registration of an RS pattern, typical of the potential variations of the epicardial surface of the right ventricle, in leads high in the axilla as well as in a  $V_L$ . Counterclockwise rotation tended to shift the transitional zone farther to the right in the high than in the routine precordial leads.

High precordial leads were of particular value in the detection of infarcts localized to the basal portion of the anterior or lateral walls of the left ventricle, as demonstrated by pathologically proved cases with diagnostic signs in high precordial but not in the routine precordial or limb leads.

High precordial leads were also of value in the estimation of the basal extent of anterior or lateral apical infarcts, as illustrated by cases of localized anterolateral apical infarction, showing diagnostic patterns in the customary but not in the high precordial leads and extensive anterolateral infarction with diagnostic patterns at both levels. The differentiation from high precordial lead patterns due to right and left ventricular hypertrophy and right and left bundle branch block is illustrated.

#### 55 STUDIES ON THE RENAL TUBULAR TRANSPORT MECHANISM FOR GLUCOSE

JULES H. LAST, M.D., PAUL JORDAN, M.D., ISADORE PITESKY, B.S.,  
GORDON JOHNSON, B.S., AND ELAINE GIANAS, R.Ph., CHICAGO, ILL.

(INTRODUCED BY ROBERT W. KEETON, M.D.)

Recent observations by Conn and co-workers indicate that the administration of adrenocorticotrophic hormone (ACTH) to normal human subjects results in a diabetic state. In addition to hyperglycemia, ACTH is be-

heved to decrease renal tubular resorption of glucose. Glutathione antagonizes this effect of ACTH presumably by reversing the inhibitory action of ACTH on tubular transport mechanisms.

Hyperglycemia has been reported to effect adrenal cortical discharge as reflected by a fall in the lymphocyte count in the rat and also in man. Thus hyperglycemia in itself can be considered as a stress phenomenon.

To obtain quantitative data on the effect of adrenal cortical discharge on the tubular mechanism for glucose it was planned to do  $Tm_g$  determinations in trained dogs before and after the administration of epinephrine. A preliminary experiment resulted in a 70 per cent drop in the  $Tm_g$  and a 77 per cent drop in the eosinophil count following the intravenous infusion of epinephrine (5 gamma per kilogram per minute for one hour). Eight periods fifteen to twenty minutes in duration were conducted in each experiment over a five hour period of glucose infusion. The  $Tm_g$  values for the last two to three periods were within normal limits as reported for the dog (200 to 300 mg per minute). In five of six dogs the initial two to three periods showed depressions of the  $Tm_g$  ranging from 33 to 59 per cent.  $Tm_g$  values as low as 92 mg per minute have been obtained under these conditions despite glucose loads of 15 to 20 times the animal's normal  $Tm_g$  level. In contrast to the gradual rise in  $Tm_g$  as a given experiment progressed the eosinophil count fell continuously to a low value at the completion of each run.

The marked depressions of tubular resorption of glucose seemed to coincide with high environmental temperatures. This is of interest since it is known that heat stress will fire the pituitary adrenal mechanism. It is postulated that environmental heat stress in combination with the stress of hyperglycemia may have been responsible for the anomalous  $Tm_g$  observations noted in this series of dogs.

## 56 AN INDIRECT QUANTITATIVE METHOD FOR THE ESTIMATION OF HEPARIN ACTIVITY IN VITRO. CLINICAL APPLICATION

GEORGE V. LEROX, M.D., BERNARD HALPERN, M.S. (BY INVITATION) AND  
RALPH E. DOLKART, M.D., CHICAGO, ILL.

Evidence has been presented which suggests that some hemorrhagic states are due to the presence of excessive amounts of heparin in the blood. In such conditions the antiheparin agents protamine sulfate and toluidine blue may be of great value clinically. A laboratory procedure which will permit the selection of patients for this type of therapy and which can be used to control such therapy is desirable. A method is described which utilizes a modified one stage prothrombin time type test. With this technique it is possible to detect the presence of heparin in amounts as small as 35  $\mu$ g per milliliter of plasma. Under the conditions of this test the ratio of the concentration of protamine sulfate required to neutralize heparin added in vitro or in vivo is 15:1. This ratio appears to be a constant. When the amount of protamine sulfate required to neutralize a certain amount of added heparin is greater than that predicted by this ratio it is concluded that the excess protamine neutralizes endogenous heparin. The utility of the test in the protamine sulfate therapy of certain hemorrhagic states is illustrated by case histories. In practice it has been possible to predict which patients will be benefited by the use of antiheparin agents. It has also been possible to determine the adequacy of the treatment even in the absence of frank bleeding.

## 57 THE EFFECT OF ATROPINE SULFATE AND DIBUTOLINE ON THE NOCTURNAL GASTRIC SECRETION IN MAN

ERWIN LEVIN, M D (BY INVITATION), JOSEPH B KIRSNER, M D, AND  
WALTER L PALMER, M D, CHICAGO, ILL

The effect of atropine and of atropine and adrenaline in oil on the fasting gastric secretion was studied in forty-five patients hospitalized for peptic ulcer. Atropine administered parenterally in dosages of 1.0 to 2.0 mg every 3 to 4 hours exerted a variable effect. A depression in acid secretion occurred in approximately 33 per cent of the studies, the effect was of short duration. Increases in gastric secretion were observed in approximately 26 per cent of the studies. Similar results were obtained with 2.0 mg doses. The action of atropine upon the parietal cell appeared to be related to the state of activity of the cells at the time of administration of the drug. Of the patients with duodenal ulcer in whom a reduction was obtained, the secretory rate in 66 per cent was less than the average hourly rate observed in such patients. However, a depression in gastric secretion was not obtained uniformly in all individuals with low rates of secretion. The reduction in output of acid in individuals with high secretory rates was associated with severe symptoms of atropine toxicity. Atropine also was administered in doses of 1.0 mg simultaneously with 2.0 mg of adrenaline in oil. No additive effect was noted insofar as the volume of gastric secretion was concerned. However, the concentration and output of acid were reduced more frequently by the combination of drugs than with atropine alone.

The effect of a pharmacologically related compound, Dibutoline (Dibutyl urethane of dimethyl-ethyl- $\beta$ -hydroxyethyl ammonium sulfate—Meick) on the nocturnal gastric secretion was studied in fifteen individuals. Dosages of 10 mg given intramuscularly every four hours during the night yielded results similar to those obtained with atropine. Although a decrease in the output of acid was observed more frequently with Dibutoline, the depressant effect, whenever it occurred, likewise was variable and of short duration.

## 58 STUDIES OF BLOOD COAGULABILITY AS INFLUENCED BY DIGITOXIN

WILLIAM C LEVIN, M D, AND ARTHUR RUSKIN, M D (BY INVITATION)  
GALVESTON, TEXAS

Digitoxin was administered to all subjects used in this study by either the oral or parenteral route. In all instances studies of the coagulation mechanism were performed both before and after digitalization with digitoxin. All subjects used presented no evidence of cardiac decompensation or of thromboembolic disease.

The bleeding time, prothrombin time, and coagulation time (Lee and White) were determined in five patients. Two of these patients received 0.6 mg digitoxin intravenously and three received 1.2 mg digitoxin intravenously. The aforementioned studies were then determined at intervals of five to ten minutes, one hour, four hours, seven hours, and twenty-four hours. In no instance was there any significant decrease in the bleeding time, coagulation time, or prothrombin time.

Eleven patients were then studied with heparin tolerance estimations before and after receiving a full digitalizing dose (1.6 mg) of digitoxin administered orally over a twenty-four hour period. No significant change in the

heparin tolerance curves was apparent after digitalization when the test was performed according to the method described by de Takats and associates. In order to make the method more sensitive it was modified by using the Lee and White coagulation time. With this modification six determinations on five patients revealed an increase in heparin tolerance and seven determinations on six patients revealed a decrease in heparin tolerance. It is suggested that the wide variations in these data are due to variations intrinsic in the method rather than to the effect of digitoxin.

The problem was then approached by studying the prothrombin times by a modified Quick one stage technique in twelve subjects. Following digitalization with digitoxin there were no significant alterations in the prothrombin times in any instance. After digitalization the subjects were Dicumarolized in the usual fashion. No inhibition of the effect of Dicumarol by digitoxin as measured by the effect on the prothrombin activity was evident.

Three patients were given Dicumarol so that prothrombin activity was reduced to a range of 10 to 30 per cent. After stabilization of prothrombin activity by the administration of maintenance doses of Dicumarol each of the three patients was digitalized with 16 mg of digitoxin given orally. In none of the three cases did the digitoxin appear to interfere with the effect of Dicumarol as reflected by the prothrombin activity.

Finally the problem was approached by the determination of the coagulation time both by the conventional Lee and White technique and in tubes treated with silicone for the purpose of simulating the endothelial lining of the vascular network. Ten patients were studied by this method for a three day control period. It was noted that there was considerable variation in the coagulation times in the same individual from day to day. This variation was noted in both techniques but was especially evident in the technique employing test tubes treated with silicone. These patients were then digitalized by the oral administration of 16 mg of digitoxin and they were placed on daily maintenance doses of this drug. The coagulation time was studied daily for three days according to the previously mentioned techniques. Again there were no consistent changes in the coagulation time as measured by either technique following the administration of digitoxin.

It is concluded therefore that the methods used in this study have demonstrated that digitoxin administered either orally or intravenously has no effect on the coagulation mechanism of the blood. Therefore if digitalization is indicated this study suggests that there should be no hesitation in carrying out this therapeutic procedure with a view that thromboembolism may result therefrom.

## 59 THE USE OF VIODENUM IN THE TREATMENT OF ULCERATIVE COLITIS

M C F LINDERT M D AND M F KOSZALKA M D MILWAUKEE WIS

(INTRODUCED BY ARMAND J QUICK M D)

A continuous search is being made to find an adequate means of combatting the etiological factors of chronic idiopathic ulcerative colitis. Among the more recent additions to our medical armamentarium is Viodenum. This substance is whole desiccated and defatted duodenum which is believed to contain certain antisecretory and antiproteolytic factors. Thirteen patients with chronic ulcerative colitis in acute exacerbation were treated with Viodenum in addition to the commonly used therapeutic measures. Tablets were administered

only after powder had been given in the initial phase of the treatment and until the acute flareup had subsided. The results are as follows: (1) one patient showed no improvement, (2) exacerbation of the disease was noted in three instances, in one of which the tablets passed through the bowel without disintegration, (3) two patients were forced to discontinue treatment because of intolerance as manifested by nausea, diarrhea, and cramps, (4) definite clinical improvement was observed in six patients, (5) no definite opinion could be reached in two.

## 60 THE EFFECT OF TETRAETHYLAMMONIUM BROMIDE ON THE CARDIAC OUTPUT OF NORMOTENSIVE AND HYPERTENSIVE PATIENTS

LAWRENCE G. MAY, M.D. (BY INVITATION), ALENE BENNETT, B.A. (BY INVITATION), RAYMOND GREGORY, M.D., SHIH YUAN TSAI, M.D. (BY INVITATION), AND MARY LYNN-SCHOOMER, B.A. (BY INVITATION), GALVESTON, TEXAS

In a previous study we have shown that the fall in arterial blood pressure of normal and hypertensive patients induced by spinal anesthesia is not associated usually with a significant fall in cardiac index. This evidence has been used to support our belief that the cause, or at least the sustaining cause, in essential hypertension is an increased vasomotor tone. In attempting further to elucidate the pathogenesis of essential hypertension, tetraethylammonium was used to lower the blood pressure in patients with essential hypertension, and cardiac output studies were made by the direct Fick method.

Sixty-one cardiac output measurements were made on nine normotensive and eleven hypertensive patients before, during, and after the intravenous injection of tetraethylammonium bromide. The twenty patients were divided into four groups: sedated and unsedated hypertensives, sedated and unsedated normotensives.

In both the sedated and unsedated normotensives tetraethylammonium produced a fall in blood pressure but no significant fall in cardiac index. After recovery from the tetraethylammonium, as shown by the disappearance of tachycardia and the return of the blood pressure to or toward control levels, the cardiac index remained lower than either the control level or the level obtained during the tetraethylammonium effect.

In the unsedated hypertensive group the control cardiac indexes were slightly lower than in the normotensive or sedated hypertensive groups. During the tetraethylammonium effect the cardiac index showed little change and in some cases rose to a level above that of the control value.

In the sedated hypertensive group there was little fall in the cardiac index during the tetraethylammonium period in spite of marked falls in the blood pressure. In no case in the whole series did the cardiac index fall below the normal limit during the tetraethylammonium effect.

In both normotensive and hypertensive patients a sympathicolytic agent such as tetraethylammonium may produce a fall in blood pressure without significant fall in cardiac index.

*(To be concluded in the December issue)*

# AMINO ACID EXCRETION IN DEGENERATIVE DISEASES OF THE NERVOUS SYSTEM

HUNTINGTON PORTER M D

BOSTON, MASS

THE recent investigations of Uzman and Denny Brown<sup>1</sup> and Cooper and co workers<sup>2</sup> have shown excessive urinary amino acid excretion to be a consistent feature of hepatolenticular degeneration even in early and mild states of the disease. Occurrence of this amino aciduria with only minimal evidence of general liver dysfunction suggests that it may represent the result of a specific metabolic defect and that such defect may have a direct relationship to cerebral degeneration. It therefore seemed of interest to study amino acid excretion in a group of patients with other syndromes characterized by chronic neuronal degeneration particularly those of familial type.

A second type of metabolic abnormality in Wilson's disease is indicated by the marked increase in copper content of both brain and liver noted by Haurowitz,<sup>3</sup> Glazebrook<sup>4</sup> and in the well controlled observations of Cumings.<sup>5</sup> Mandelbrote and associates<sup>6</sup> reported high urinary copper output in a single case of Wilson's disease and found that in this condition as in normal persons, the administration of BAL (2-3 dimercaptopropanol) greatly increased copper excretion. BAL might thus provide a tool for the demonstration of a possible relation between these two established biochemical abnormalities. The effect on the amino aciduria of a marked though transient disturbance of copper metabolism as produced by BAL was therefore investigated.

## MATERIAL AND METHODS

Amino acid excretion was studied in representative cases of Huntington's chorea, paralysis agitans, dystonia musculorum deformans, familial spastic paraplegia associated with mental defect and hepatolenticular degeneration. Urine samples were collected over a known time interval usually between two and three hours. In all female subjects and in male subjects uncooperative because of intellectual impairment collection was by indwelling catheter. The total fasting urinary amino acid nitrogen excretion in milligrams per hour was determined by the ninhydrin carbon dioxide method of Van Slyke, MacFadyen and Hamilton.<sup>7</sup> Analyses for tryptophane were carried out by the *p*-dimethylaminobenzaldehyde method of Bates<sup>8</sup> after mercuric sulfate precipitation as described by Fohn and Crocalteu.<sup>9</sup> Xanthurenic acid was tested for by the color reaction with ferric chloride reported by Lepkovsky and co workers.<sup>10</sup> Chromatographic analyses for the presence of unusually large amounts of individual amino acids were performed by the method of Dent<sup>11</sup> using the one dimensional technique with phenol as the solvent. In patients with hepatolenticular

degeneration, copper was estimated by the diethyldithiocarbamate method of Eden and Green<sup>12</sup>. Acid cleaned glass and water redistilled over glass were used throughout in the collections and analyses for copper. Blank determinations were performed to correct for minute amounts of copper in the reagents.

## RESULTS

With the exception of hepatolenticular degeneration, none of the conditions studied showed a significant elevation in urinary total  $\alpha$  amino acid nitrogen excretion per hour when compared with control values on eight individuals which averaged 4.7 mg per hour, range 3.5 to 6.8 mg per hour (Table I). Excretion of tryptophane and xanthuemic acid did not differ grossly from normal with the relatively crude methods employed. Chromatographic studies gave no indication of excessive excretion of any one amino acid. The usual finding by this method was two distinct spots with  $R_f$ \* values of about 0.34 and 0.51, identified by superposition with knowns as glycine and alanine. As in normal urine, a third faint spot with an  $R_f$  value of about 0.83 also was present occasionally.

TABLE I TOTAL URINARY  $\alpha$  AMINO NITROGEN IN DEGENERATIVE DISEASES OF THE CENTRAL NERVOUS SYSTEM

PATIENT	$\alpha$ N (MG PER HR)	PATIENT	$\alpha$ N (MG PER HR)
Huntington's chorea		Dystonia musculorum deformans	
M H	4.4	E S	3.2
	4.0		2.3
			7.9
R G	3.8	W McC	3.6
C W	5.2		
	4.4	Familial spastic paraplegia	
T B	3.5	W McD	3.3
	3.7		3.6
Paralysis agitans		J J	4.1
A H	4.9		4.0
	4.1	Hepatolenticular degeneration	
L F	3.0	A G	19.4
	3.6		16.5
		E R	11.0
		M R	12.0
			13.7

The average value of 14.5 mg  $\alpha$ -amino nitrogen per hour in the three cases of hepatolenticular degeneration confirms the marked increase in urinary total  $\alpha$ -amino nitrogen excretion previously observed in this disease by Uzman and Denny-Brown. The absence of such a finding in the other conditions studied suggests that  $\alpha$ -amino nitrogen determination may be of value in the differential diagnosis between Wilson's disease and other diseases which occasionally give similar clinical pictures.

The initial urinary copper values of 23.5 and 11.0  $\gamma$  per hour indicate a definitely increased copper excretion in hepatolenticular degeneration when

\* $R_f$  indicates the ratio of the distance along the filter paper moved by the amino acid to the total distance traveled by the solvent.

compared with control figures on four individuals averaging 5.3  $\gamma$  per hour, range 3.0 to 7.9  $\gamma$  per hour. These controls are in good agreement with the more extensive observations of Mandelbrote and co-workers<sup>6</sup> who reported a normal average of 4.85  $\gamma$  per hour, range 2.1 to 9.0  $\gamma$  per hour.

Administration of BAL sufficient to increase the copper excretion by more than seven times the pre-BAL figure did not reduce the amino aciduria of hepatolenticular degeneration to the control range (Table II). In the first patient injection of BAL was followed by a reaction characterized by profuse sweating, congestion of the sclera, puffiness of the face, nausea, vomiting of about 100 cc of bright red blood, and almost complete anuria which persisted for about one half hour. Intravenous saline infusion was started as soon as the severity of the reaction became evident. It is possible that the apparent drop in amino acid excretion in the first period immediately after BAL may be in part accounted for by this transient extreme oliguria. Subjective improvement, diminished tremor and increased activity about the ward were noted in this patient following BAL, but it is possible that these changes did not exceed the range of natural fluctuation in the disease. This improvement has persisted during the five months of observation since BAL administration. In the second patient the dose of BAL was smaller, reaction was minimal, and urine volume was maintained by constant intravenous saline infusion throughout the experiment. Amino acid output under these conditions showed no significant change. Subjectively and objectively the clinical status of this patient remained unaltered.

TABLE II THE EFFECT OF BAL ON AMINO ACIDURIA IN HEPATOLENTICULAR DEGENERATION

TIME OF COLLECTION PERIOD (MIN)	URINE VOLUME (ML PER HR)	$\alpha$ AMINO N (MG PER HR)	URINE COPPER ( $\gamma$ PER HR.)
Patient A G. Received BAL 7 mg per Kg intramuscularly			
90 min. before BAL	213	16.5	23
BAL administered			
0-125 min. after BAL	143	10.6	181
125-190	495	20.8	133
190-357	439	19.0	61
357-482	322	17.9	40
Patient E R. Received BAL 4 mg per Kg intramuscularly			
125 min. before BAL	85	11.0	11
BAL administered			
0-69 min. after BAL	76.5	11.7	101
69-131	136	14.5	87
131-256	190	12.3	26

It is necessary to emphasize that the small number of observations must limit conclusions from the data here reported. Further, chromatography and the methods used for estimating tryptophane and xanthurenic acid were employed only as screening procedures to detect changes of marked degree. However, they did serve to diminish the likelihood that alteration in excretion of individual amino acids was occurring without change in the total  $\alpha$  amino nitrogen. The method used for determination of total  $\alpha$  amino nitrogen, on the other hand, is one of great precision which appears to exclude increase in total amino acid excretion in Huntington's chorea, paralysis agitans, dystonia musculorum deformans and familial spastic paraplegia and to differentiate these

syndromes from Wilson's disease Increased copper excretion was observed in two cases of hepatolenticular degeneration, but no significant change in total amino acid excretion was found at the time of a marked rise in copper output

#### SUMMARY

1 No evidence of abnormal amino acid excretion was found in cases of Huntington's chorea, paralysis agitans, dystonia musculorum deformans, or familial spastic paraplegia These negative results are contrasted with the consistent amino-aciduria of hepatolenticular degeneration

2 Increased urinary copper excretion was observed in two cases of hepatolenticular degeneration

3 Administration of BAL sufficient to increase the copper output by sevenfold did not significantly reduce the amino-aciduria of hepatolenticular degeneration

## PARENTERAL NUTRITION

### X OBSERVATIONS ON THE USE OF A FAT EMULSION FOR INTRAVENOUS NUTRITION IN MAN

SHERWOOD W. GORENS, M.D., ROBERT P. GEYER, PH.D.,  
LEROY W. MATTHEWS, B.S. AND FREDRICK J. STARE, M.D.  
BOSTON, MASS.

**A**N EMULSION of fat consisting of 15 per cent coconut oil, 4.3 per cent dextrose, and a combination of 0.5 per cent soybean phosphatides and 1 per cent polyglycerol esters as stabilizers was reported by this laboratory to have been administered successfully to animals (rats, cats, rabbits, and dogs) and to man.<sup>1</sup> The size of the fat particles of this emulsion was below  $1\ \mu$  in diameter for the most part and none were larger than 3 microns. The preparation of this emulsion has been fully described in earlier papers.<sup>2-4</sup> While this emulsion (referred to as Emulsion 41 in the earlier report<sup>1</sup>) has repeatedly been used with success in man, it was pointed out<sup>1</sup> that it was not completely satisfactory from the clinical viewpoint because after a period of approximately one month it developed pyrogenic properties. The purpose of this paper is to present additional information on the use of Emulsion 41 in man, although neither the cause nor prevention of the slow development of pyrogenic activity is yet clearly understood. However, these studies were all carried out with batches of emulsion less than four weeks of age and hence, within the time period that it may be used clinically without pyrogenic reaction.

#### EXPERIMENTAL

The emulsion used in the present study was of the composition of Emulsion 41 and was prepared in this laboratory. Before clinical use, the sterility of each batch of emulsion was determined and the following routine tests were done: (a) rapid injection (15 ml per kilogram body weight) intravenously into three adult rats daily for seven days and subsequent post mortem examination, (b) rapid injection (15 to 20 ml per minute) intravenously into one adult dog for two successive days in an amount of 5 Gm. of fat per kilogram of body weight and (c) rapid injection (10 ml per kilogram body weight) intravenously into adult rabbits for pyrogenic assay. Every batch of emulsion had to pass satisfactorily all of these tests before it was used in the clinic. On the average, an emulsion had been prepared for approximately a week before it was used in man. Plastic disposable infusion sets were employed, and an infusion rate of 4 to 5 ml per minute was used in adults and 1 to 3 ml per minute in children, depending on the weight of the child. Viscosity of the emulsions was such that a No. 26 needle could be employed when necessary.

Received for publication Aug. 10, 1949.

terminated. The caloric intake of this patient for the immediate postoperative period is shown in Fig 2. It is seen that during the first three postoperative days, the fat emulsion contributed appreciably to the caloric intake, in fact, during the second and third postoperative days it furnished approximately 75 per cent of the total caloric intake. It was during this critical period that the favorable clinical response was especially noted. Because Emulsion 41 was not available, none was given on the fourth and fifth days. The data in Fig 2 also emphasize quite strikingly the importance of ordinary food as a source of calories.

Fig 2

*Patient 9*—This patient was a mentally defective child, 4 years of age, weighing 11 kilograms. Fat emulsion was given on six successive days in amounts varying from 100 to 300 ml, which furnished 30 to 60 per cent of the total caloric requirements. It was observed consistently that infusions of more than 250 ml (3.5 Gm fat per kilogram) at any one time produced an elevation of temperature of 1 to 2° which persisted for one to three hours following the fat infusion.

*Patient 10*—This patient was a 7 week old male infant, weighing 3 kilograms, with postoperative obstruction, who was on continuous gastric suction and complete parenteral feeding. The theoretical caloric requirement for this infant was approximately 300 calories and the usual parenteral fluids available could provide only approximately a third of this requirement. He was given fat emulsion by vein for eleven days, during which time he received on some occasions as much as 70 per cent of his basal caloric requirements from this source. Fig 3 illustrates the caloric intake of this infant during a twelve day period, the last nine days of which fat emulsion was given. Since the two preliminary small infusions of fat were well tolerated, the study presented in Fig 3 was begun. The fat infusions were increased gradually in amount until by the third day they contributed more than one half the total caloric intake (Fig 3). On the fourth day and for the next five days, the theoretical caloric requirement of the infant was more than met, and calories from the emulsified fat furnished approximately two thirds of the total caloric intake. Throughout this period the child was quite ill as a result of an extensive infection. Antibiotic therapy was ineffective and early in the morning of the thirteenth day of this study the child expired. Post mortem studies gave no evidence that the extensive fat infusions, daily for nine days and on two other days shortly before the period represented by Fig 3, had in any way contributed to the death.

*Patient 11*—This patient was a 6½ year old boy, weighing 15 kilograms, with a ruptured appendix, peritonitis, and multiple abscesses in whom complete parenteral nutrition was necessary. He received fat emulsion intravenously for twenty seven days in quantities providing him with 480 to 800 calories per day which provided 50 per cent or more of his

daily calorie requirement. It was observed regularly in this patient that if more than 100 ml of fat emulsion were given at any one time, there was a gradual rise of temperature of 1 to 2 during one to three hours following the infusion. This quantity of emulsion contained 60 Gm of fat which furnished this patient with 4 Gm of fat per kilogram. The infusions of fat in this child were clinically effective in that he presented a problem of complete parenteral feeding and further weight loss was prevented during the period fat infusions were given.

### TOTAL CALORIC INTAKE OF S.E.

Fig 3

In view of the fact that an increase in temperature of 1 to 2 was consistently obtained in Patient 11 when the amount of fat given exceeded 4 Gm per kilogram body weight it was thought desirable to attempt to determine which component of the emulsion was largely responsible for the temperature rise. The following three different preparations were studied in Patient 11: the usual 15 per cent fat emulsion (Emulsion 41), a 15 per cent emulsion identical to Emulsion 41 except that the costabilizer of polyglycerol esters was reduced from 1 per cent concentration to 0.4 per cent, a fat free emulsion which contained only the two stabilizers in the same concentration as in Emulsion 41 in 5 per cent dextrose. A different one of these three preparations was infused in Patient 11 in the same amount on each of three successive days. For the next three successive days these preparations were given in the same order, but the one without fat was given in twice the amount. The temperature rise occurred only when the amount of fat containing emulsion infused exceeded 4 Gm fat per kilogram of body weight.

That this temperature rise following infusion of a fat emulsion varies considerably among patients is suggested by the observations in Patient 9 in whom an amount exceeding 3.5 Gm fat per kilogram of body weight resulted in a rise in temperature and in Patients 2 and 10 in whom as much as 3 and 6 Gm fat per kilogram respectively did not give rise to an increase in temperature, yet it was the same batch of fat emulsion which was given to Patient 11. The data in Table I show that Patient 5, a 65 year old man, weighing 55 kilograms, with cerebral metastases from a hypernephroma, and in whom most of the left frontal lobe had been removed, developed a temperature rise if more than 300 ml of fat emulsion were given at any one time. This amounts to only 0.8 Gm of fat per kilogram of body weight.

Insufficient evidence is available to indicate whether this rise in temperature is due to the amount of fat per se or to pyrogens contained in the fat which, when they reach a certain concentration, give rise to the increase in temperature. At present the latter seems the more likely cause.

## DISCUSSION

The clinical observations presented in this paper indicate that fat emulsions as a source of calories in parenteral nutrition are useful in a wide variety of cases. Emulsion 41 furnished 1,600 calories per liter, and could be infused at the rates commonly employed for the intravenous administration of glucose or saline solutions.

Previous studies in the dog and rat have shown conclusively that such fat emulsions of fine particle size introduced directly into the systemic circulation are utilized for energy purposes as indicated indirectly by total carcass analysis for fat,<sup>4</sup> maintenance of normal weight,<sup>5</sup> conversion of negative to positive nitrogen balance on a low-protein low-calorie ration,<sup>5</sup> and growth of puppies,<sup>6</sup> and directly by radioisotope studies showing that  $C^{14}$  introduced as part of the fat molecule in a fat emulsion is rapidly eliminated in the expired  $CO_2$ .<sup>7</sup> In previous studies with experimental animals and man, it has been shown that fat emulsions such as have been employed in the studies can be given safely and without producing pathologic conditions.<sup>1, 3</sup>

The studies reported in this paper extend many of these observations in man. The observations on Patient 1 confirm the favorable effect of fat emulsions administered intravenously on nitrogen balance. The similar observations on potassium balance further emphasize the necessity of adequate calories for protein synthesis in the body. The very favorable clinical response observed in the patient severely ill with ulcerative colitis (Patient 2) is attributed in part to the calories supplied by the fat emulsion during the first three postoperative days. In Patients 10 and 11, fat emulsions were given for rather long periods, eleven and twenty-seven days respectively, and in generous daily amounts, approximating 6 and 4 Gm fat per kilogram of body weight. Patient 10, who was severely ill from a generalized infection, expired after nine successive days of fat infusion given in such an amount that calories from fat furnished two thirds of the total calorie intake for a period of seven days. However, at autopsy, there was no abnormal accumulation of fat in any of the organs and no evidence that the fat infusions in any way had contributed to the death. During this severe illness, when all nourishment had to be given by vein, weight loss was prevented.

An increase in temperature in Patients 5, 9, and 11 was regularly observed following a single administration of a certain amount of fat. However, the amount of fat necessary to cause this temperature rise varied widely among these three patients—from 0.8 to 4 Gm fat per kilogram of body weight. Patient 2, who received 3 Gm fat per kilogram of body weight, and Patient 10, who received 6 Gm fat per kilogram of body weight, showed no increase in temperature. It is thought that these temperature rises were due to pyrogenic materials in the fat and not to the fat per se.

Of the patients listed in Table I, three died by the time of the preparation of this paper—Patients 5, 8, and 10. Post-mortem examinations were obtained on the latter two and in neither was there any gross or microscopic pathologic condition attributable to the fat emulsions. Patient 5 expired approximately

one month following the last fat infusion Patient 8 three months following the last infusion and Patient 10 eighteen hours following the last infusion of fat

It should be pointed out that the reason more fat emulsion was not given to many of these patients and for longer periods of time was that not enough was available because of limited production and control facilities and the needs of various experimental studies with animals As stated in a previous paper<sup>1</sup> on this subject Emulsion 41 is still not considered completely suitable for clinical use because of the development of pyrogenicity after it is approximately four weeks old

#### SUMMARY

Observations are reported on the intravenous administration of a 15 per cent fat emulsion to eleven patients representing a variety of common illnesses Of these patients eight were adults two were children and one was a 7 week old infant The emulsion furnished 1 600 calories per liter and was given at rates ordinarily used for administering glucose or saline solutions Daily amounts up to 3 Gm fat per kilogram of body weight were given to adults and 6 Gm fat per kilogram of body weight in a 7 week old infant Infusion periods ranged from three to twenty seven consecutive days The emulsion was effective as indicated by favorable clinical response the prevention of weight loss and the maintenance of positive nitrogen and potassium balance Subsequent post mortem examination of three of these patients revealed that the fat emulsions had produced no pathologic changes either gross or microscopic

The authors wish to express appreciation to the Medical and Surgical Services of the Peter Bent Brigham Hospital and the Children's Hospital of Boston for their genuine cooperation in these studies and to The Upjohn Company Kalamazoo Mich which has supplied us generously with various materials used in this research

# THE ABSORPTION AND DISPOSITION OF ORALLY ADMINISTERED $I^{131}$ -LABELED NEUTRAL FAT IN MAN

MALCOLM M STANLEY, M D, AND SIEGFRIED J THANNHAUSER, M D, PH D  
BOSTON, MASS

NONE of the available methods for measuring the absorption and utilization of fat in man is greatly informative and, at the same time, accurate and simple to carry out. The direct chemical determinations of serum fat in serial fashion are tedious and time consuming, in the hands of all save the most expert they are subject to considerable inaccuracies. Relatively large samples are required. No information as to the disposition of the fat is available from this method, i.e., what proportions of the lipid which has disappeared from the blood stream are accounted for by degradation and by storage respectively. The vitamin A tolerance test obviates the first two of these objections, but not the third. Nephelometric techniques for fat analyses are now generally conceded to be unreliable.

The problem had been quite satisfactorily solved for animal work by Geyer and co-workers,<sup>1</sup> and Lerner and co-workers,<sup>2</sup> by the use of neutral fat containing radioactive  $C^{14}$ -substituted fatty acids. However, the extremely long half-life of this isotope precludes its use in man. In addition, other isotopes which emit radiation of greater penetrating power are more simple to measure.

Certain of the shortcomings mentioned may be overcome by the use of neutral fat which has been labeled with radioiodine  $I^{131}$  in the unsaturated fatty acids. It is the purpose of this communication to report tracer studies with such radioactive fat on eighteen patients, including ten normal subjects.

## METHODS

Commercial olive oil was iodinated with  $I^{131}$  \*. The following steps were employed. To the carrier free  $I^{131}$  solution (usually 10 mc), 10 mg of sodium iodide were added as carrier. The solution was then placed in a separatory funnel and acidified with 1 ml of 250 per cent concentrated nitric and sulfuric acid mixture. The liberated iodine was extracted with chloroform. Into the chloroform solution a stream of chlorine was then passed until the purple color of iodine just disappeared. The iodine chloride obtained was added to a chloroform solution of 20 Gm of olive oil. This mixture was allowed to stand for twenty-four hours. The chloroform solution then was shaken repeatedly with a solution of sodium carbonate in order to remove any free iodine. The chloroform solution was dried over anhydrous sodium sulfate and the chloroform evaporated off by means of an infrared lamp. The odor, taste, color, and consistency of the oil were unchanged following iodination.

One half to 5 ml of the oil, containing 100 microcuries of  $I^{131}$ , were soaked into bread and eaten, either during or immediately following a normal breakfast. In a few instances the patients were without breakfast all ate a normal mixed diet during the balance of the test period.

The radioactivity in the thyroid gland was estimated by serial counting at a distance of 35 cm from the neck with a sensitive directionally shielded gamma tube (Sylvania). The background (from extrathyroidal tissues plus cosmic and other extraneous radiation) was calculated by counting over the lower thigh this was subtracted from the thyroid count. The resulting net count was compared with that obtained under similar geometric conditions from a suitable aliquot of the original solution.

One milliliter portions of urine in uniform glass vials were counted with the gamma tube through an orifice in the shield and compared with equal volumes of suitable dilutions of the original solution. Since the bottoms of the vials were in contact with the metal tube surface, excellent reproducibility and sensitivity (272 net counts per second per microcurie) were obtained.

Two tenth milliliter aliquots of serum were pipetted onto flamed, 1 inch copper planchets, each of which was partially covered with a smaller disk of thin absorbent paper. Since the planchets were grease free and were coated with cupric oxide, the liquid was absorbed uniformly into the paper. After slow drying with an infrared lamp, the serum formed an evenly adherent film, the area of which was limited to that of the paper circle. The preparations were permanently mounted by covering with Scotch tape. Standards were prepared by evaporating suitable aliquots of petroleum ether solutions of the original material in the same manner, self absorption was equalized by adding identical amounts of serum. The samples were counted with a thin window Geiger Muller tube.

Two milliliters of serum were diluted, precipitated with zinc sulfate and the excess zinc precipitated with alkali by the method of Somogyi. Five milliliter portions of the supernatant (equivalent to 0.5 ml serum) were evaporated onto disks and the radioactivity was compared with similarly prepared standards as described. Since the lipids were precipitated with the proteins, the radioactivity in the watery fraction of the serum represented inorganic iodine which had been removed from the fat. By subtraction of this 'water soluble' portion from the total, a fraction designated as the 'lipid  $I^{131}$ ' was obtained.

In seven patients the sera were separated by means of Bloor's solution and the radioactivity was determined in the lipid and water soluble fractions of this extract. There was in general agreement between the results obtained by this procedure and the former one. However there was usually slightly more radioactivity in the portion resulting from petroleum ether extraction of the dried Bloor's extract than when this lipid fraction was calculated by subtraction. Because of the greater simplicity of the zinc precipitation method it was used exclusively later.

## RESULTS

In ten normal subjects the pattern of absorption and disposition was constant. The concentrations of total  $I^{131}$  in the serum were greatest at three to six hours following the meal and slowly decreased after this time. The peaks in both the 'total  $I^{131}$ ' and 'lipid  $I^{131}$ ' curves occurred simultaneously (Fig 1). These levels of total radioactivity ranged from 0.4 per cent to 0.6 per cent per 100 ml of serum, whereas the highest concentrations of the 'lipid' fractions varied from 0.20 per cent to 0.47 per cent per 100 ml of serum.

The accumulation of radioactivity by the thyroid gland varied from 10 to 25 per cent in twenty four hours (Fig 1). Although appreciable, this was somewhat less than the average collection of a dose of inorganic  $I^{131}$  administered for the purpose of ascertaining thyroid function.<sup>3</sup> Likewise, the excretion in the urine of 15 to 48 per cent of the ingested radioiodine by the normal controls in twenty four hours was distinctly less than if the material administered had been inorganic iodine.

Fig 1—Curves showing the fate in a normal subject of radioiodine introduced into the body as labeled fat. The time in hours following the ingestion of the iodinated fat is plotted on the abscissa. Along the left ordinate are plotted the concentrations of radioactivity attained on the serum; variations in these values are indicated by the solid lines. The broken lines show the percentage of administered radioactivity which was excreted in the urine and collected by the thyroid (right vertical scale).

Fig 2—The variation with time of the fraction of radioactivity in the water-soluble portion of the serum. The sera were fractionated as described in the text. The water-soluble  $I^{131}$  is plotted as per cent of the total radioactivity. The solid lines and circles show the values in four normal subjects while the broken lines and open circles denote a patient with idiopathic hyperlipemia (2) and the nephrotic syndrome (1). In the normal subjects this cent of the radioactivity was in the water-soluble fraction. In the iodinated olive oil sharply decreased during the next one to two hours as absorption of the iodinated olive oil reached a maximum and returned slowly to the high values during the next four to seven hours. In the hyperlipemic patients the percentage of radioactivity in the water-soluble portion of the serum remained low throughout the rest of the test after the first two hours.

Fig 3—The absorption and disposition of labeled fat in a patient with the nephrotic syndrome. The data are indicated as in Fig 1. It will be seen that the concentrations of radioactivity in the serum principally in the lipid fraction are much greater than normal, the decrease in these high levels is abnormally slow. The excretion of  $I^{131}$  in the urine and its accumulation in the thyroid especially during the early hours of the test are also somewhat slower than normal.

The changes in the ratio of serum inorganic to 'lipid' iodine also were uniform (Fig 2). During the first one to two hours from 60 to 90 per cent of the  $I^{131}$  was in the water soluble portion. Later as absorption of the iodinated olive oil progressed the size of the inorganic fraction decreased sharply then gradually returned to the high values during the ensuing eighteen hours.

In three patients with high serum neutral fat levels (two subjects with 'idiopathic' hyperlipemia and one individual with the nephrotic syndrome) the peak 'lipid  $I^{131}$ ' values were two to five times normal. There was an abnormally slow decrease in the radioactivity during the twenty four hours following these high values. A larger than normal portion of the radioiodine remained in the lipid fraction (Fig 2) and the accumulation of radioactivity in the thyroid and the excretion of the radioiodine in the urine were abnormally slow also (Fig 3). In one patient with hypercholesterolemic xanthomatosis the test was normal. In one case of sprue the highest serum concentrations of total  $I^{131}$  were about one half normal. The urinary excretion and thyroid collection were correspondingly low, but there was a normal relationship between the inorganic and 'lipid' fractions in the serum at all times.

#### DISCUSSION

It should be emphasized that the procedure under discussion was not a "tolerance test" in the usual meaning of the term. The amount of oil administered was never more than 5 Gm, this served to label the fat being absorbed from the meal eaten with the tracer as well as that already in the blood stream.

Olive oil contains about 80 per cent glycerol trioleate and about 7 per cent trilinoleate. The former of these 18 carbon fatty acids possesses one double bond between the 9th and 10th carbon atoms, while the latter has two such

bonds The saturated compounds tristearate and tripalmitate comprise the bulk of the remainder of the lipids of the oil

As a result of iodination the radioiodine was firmly attached at the double bonds in the unsaturated fatty acid chains, the process used was similar to the familiar method for determination of the "iodine number" of fats In order to be certain that this iodine was organically bound, petroleum ether solutions of the oil in each lot were repeatedly extracted with water, no radioactivity was detectable in the aqueous phase

It may be accepted as proved that the iodine collected by the thyroid gland is in the form of the iodide ion<sup>o</sup> The identity of the iodine excreted in the urine by the subjects in this study has not been determined, although it is entirely likely that it is in the same form The radioactivity in the water soluble portion of the serum and that collected by the thyroid and excreted in the urine represent iodine which has been removed from the fatty acid skeleton during the process of metabolism, these fractions provide an index of the rate of utilization of the iodinated fat

In this study, from 50 to 73 per cent of the administered radioactivity was collected in the thyroid gland and excreted in the urine of normal subjects during the twenty-four hours from the beginning of the test, with approximately one-half these amounts accounted for during the first six hours These figures indicate the extent of degradation of the fatty acid skeleton of ingested neutral fat which normally occurs in men, either as a preliminary to storage in the fat depots or, much more likely, for production of energy The characteristic appearance of an appreciable portion of radioactivity in the water soluble fraction of the serum during the early hours of the test suggests that a small amount of breakdown may have occurred during the process of absorption from the gastrointestinal tract

That a similarly rapid metabolism of intravenously administered neutral fat takes place in the rat has been recently demonstrated by Geyer and co-workers<sup>1</sup> and by Lerner and associates<sup>2</sup> The latter group used a 16 carbon fatty acid (as tripalmitin) with the 6th carbon atom labeled with C<sup>14</sup>, as much as 59 per cent of the injected C<sup>14</sup> was found in the expired air in twenty-four hours The type of fat administered and the position of the labeled atom were not identical in the experiment of Lerner and co-workers and in the present study However, the curves representing the sum of urinary excretion plus thyroid accumulation of I<sup>131</sup> in the normal subjects in this study closely resemble those depicting the cumulative excretion of C<sup>14</sup>O<sub>2</sub> by the rats in the experiment of Lerner, Chaikoff, Entenman, and Dauben

#### SUMMARY

Characteristic curves of absorption and utilization of physiologic amounts of lipid taken by mouth by subjects on a mixed diet were demonstrated by the use of unsaturated fats iodinated with I<sup>131</sup> The proportion of the administered radioactive iodine which was collected by the thyroid and excreted in the urine, as well as the magnitude of the water-soluble portion in the serum, indicated

the extent of break down of the labeled fat. Under these circumstances in normal subjects degradation of from 50 to 73 per cent of the orally administered iodinated fat took place within twenty four hours. Subjects with "idiopathic" hyperlipemia and the nephrotic syndrome utilized the labeled lipid much more slowly.

## INTRODUCTION

**R**ADIOSTRONTIUM ( $\text{Sr}^{90}$ ), a  $\beta$ -ray emitter with a fifty-five day half life, which is physiologically interchangeable with calcium, localizes largely in bone soon after enteral or parenteral administration.<sup>1,6</sup> The minimum intra peritoneally administered dose required to produce a significant leucopenia in CF-1 female mice<sup>7</sup> was found by Simmons and Jacobson<sup>7</sup> to be about 0.068 microcuries per gram of body weight. However, this leucopenia was relatively transient. Blues and co-workers<sup>8</sup> have reported that bone sarcomas are readily produced in this strain with this dose. Although a severe and persistent leucopenia developed after an intraperitoneal dose of 2.0 microcuries per gram of body weight, no significant anemia occurred.<sup>7</sup> In a preliminary experiment<sup>9</sup> histopathologic examination of mice sacrificed at intervals after injection revealed much depleted or aplastic bone marrow, whereas the spleens contained a remarkable increase in erythrocytopoiesis. The fact that anemia failed to develop under these circumstances was considered to be directly related to the rapid development of an intense ectopic erythrocytopoiesis in the spleens of the radiostrontium-treated animals. Accordingly, an experiment of greater scope, as described in this communication, was undertaken to determine the validity of this concept.

## MATERIALS AND METHODS

Young CF-1 female mice were divided into three groups of fifty or more animals each as shown in Table I. The mice in Group I were splenectomized, those in Group II received a single intraperitoneal injection of 2.0 microcuries of  $\text{Sr}^{90}$  per gram of body weight, and the mice in Group III were splenectomized and later injected with a dose of 2.0 microcuries per gram of body weight. A fourth group of animals not included in Table I, which was neither splenectomized nor given  $\text{Sr}^{90}$ , was used for base line hematologic controls and from this group animals were sacrificed at intervals to serve as normal reference for the histologic studies. Splenectomies were performed in Groups I and III while the animals were under ether anesthesia. Twenty-four days after splenectomy,  $\text{Sr}^{90}$  was administered intraperitoneally to the animals in Group III. The average weight of the mice at the time of injection was 20 grams. A second injection of 2.0 microcuries per gram was given to a representative number of animals in Groups II and III, 119 days after the original injection. Although a leucopenia of moderate degree persisted at this time in both groups (II and III), the animals in Group II which had been subjected to splenectomy and received  $\text{Sr}^{90}$  also had

TABLE I GENERAL SCHEMATA OF EXPERIMENT

GROUP	NUMBER OF ANIMALS	TREATMENT	PERIOD OF OBSERVATION AFTER ORIGINAL $\text{Sr}^{90}$ INJECTION
I	51	Splenectomy only	282 days
II	63	Injected intraperitoneally with $\text{Sr}^{90}$ in a dose of 20 microcuries per gram body weight	282 days
III	70	Splenectomy plus $\text{Sr}^{90}$ (20 microcuries per gram body weight)	282 days

Selected animals in Groups II and III were reinjected with a dose of 0 microcuries per gram body weight 119 days after original injection

recovered from the anemia. The purpose of the second injection of  $\text{Sr}^{90}$  was largely to determine whether or not compensatory ectopic erythropoiesis was sufficient in the splenectomized mice to prevent or minimize recurrence of anemia.

*Preparation of Radiostrontium ( $\text{Sr}^{90}$ ) Distribution and Excretion Studies*—As has been described elsewhere, the solution of radiostrontium was composed of  $\text{Sr}^{90}$  and  $\text{Sr}^{90}$ .  $\text{Sr}^{90}$  has a fifty five day half life and a maximum energy of 1.7 mev.  $\text{Sr}^{90}$  which represented 3 to 5 per cent of the initial stock solution on arrival from Oak Ridge has a half life of circa thirty years and a maximum energy of 0.63 mev. The final preparation for administration was strontium chloride in isotonic solution. The greatest part of the radiostrontium excretion occurred during the first three days and after ten to fifteen days virtually no more of the retained  $\text{Sr}^{90}$  was excreted. The average total excretion values were 34 per cent of the injected dose. Average total retention values were 45 per cent of the injected dose. By the third day after injection almost all of the retained  $\text{Sr}^{90}$  was deposited in the skeleton. Retention of  $\text{Sr}^{90}$  in the spleen was as follows:

First 24 hour	0.00 per cent/gram
24 to 72 hours	0.04 per cent/gram
3 days to 3 months	0.02 per cent/gram

In other soft tissues of the body the amount of radiostrontium per gram remaining after three days was well under 0.1 per cent of the injected dose.

*Hematologic Studies*—Studies of the peripheral blood were made on all four groups. These studies included determinations of the hemoglobin in grams per 100 ml (photoelectric), erythrocytes and leucocytes per cubic millimeter, leucocyte differentials (Wright's stain), and reticulocytes per cubic millimeter and in per cent (brilliant cresyl blue). Blood for study was drawn from the tail vein.

Control hematologic determinations were made on all animals after which splenectomy was performed on animals in Group I and III. Twenty four days after splenectomy  $\text{Sr}^{90}$  was injected intraperitoneally into the animals in Groups II and III. Repeat hematologic determinations were made on all animals seven days after the original  $\text{Sr}^{90}$  injection and thereafter at twenty one day intervals. After the second injection of  $\text{Sr}^{90}$  in selected animals, hematologic studies were made at less frequent intervals.

*Histologic Studies*—Animals prepared as described were sacrificed at intervals through 280 days after  $\text{Sr}^{90}$  injection for histopathologic study. In addition, random animals in all groups on which hematologic studies were being conducted were sacrificed at various intervals. This latter procedure was followed in an attempt to correlate more closely the peripheral blood studies with the actual histopathologic state of the blood forming tissue.

Tissues taken for study included skin, lung, small intestine (with Peyer's patch), adrenal, kidney, liver, spleen, thymus, lymph node and bone marrow (femur and vertebrae). The tissues were fixed in Zenker formal, embedded in 10 per cent nitrocellulose sectioned at 8  $\mu$ , and stained with hematoxylin-eosin-azure II.

## RESULTS

*Hematologic Studies on the Peripheral Blood —*

(a) *Effect of Splenectomy Alone* The mean leucocyte value in the peripheral blood of splenectomized mice rose after splenectomy to stabilize between 14,000 and 22,000 per cubic millimeter during the period of observation (Fig 3). Splenectomy alone reduced the hemoglobin and erythrocyte values slightly during the first three weeks after splenectomy, but thereafter, as is shown in Figs 1 and 2, no appreciable fluctuation occurred.

Fig 1—The effect of a single injection of 20 microcuries of radiostrontium per gram body weight on hemoglobin values of normal mice and mice splenectomized twenty four days prior to Sr<sup>89</sup>. One hundred nineteen days after the original Sr<sup>89</sup> injection a second injection of 2 microcuries per gram body weight was given to selected animals from the two groups which originally were injected with this isotope.

(b) *Effect of Sr<sup>89</sup> Injection on Leucocytes of Peripheral Blood* The intraperitoneal injection of 20 microcuries of Sr<sup>89</sup> per gram produced a comparable degree of leucopenia in animals with an intact spleen and in animals that previously had a splenectomy (Fig 5). As is shown in Figs 4 and 5, the initial injection of Sr<sup>89</sup> reduced heterophils and lymphocyte values by 52 and 36 per cent, respectively, in twenty-eight days. The mean heterophil value of Sr<sup>89</sup>-injected animals which had intact spleens returned to the preinjection level in about forty-nine days and thereafter was actually higher than the

control value. The mean heterophil value of animals which had been splenectomized and were given  $\text{Sr}^{89}$  returned to the normal control or preinjection level in seventy days. The lymphocyte reduction after  $\text{Sr}^{89}$  injection was sustained in the animals with intact spleens and in splenectomized animals. In animals to which a second injection of  $\text{Sr}^{89}$  was given 119 days after the first injection, the reduction in heterophil and lymphocyte values was greater and more persistent in the splenectomized mice than in the intact mice (Figs 4 and 5).

Fig. 7.—The effect of a single injection of 0 microcuries of radiostrontium per gram body weight on erythrocyte values of normal mice and mice splenectomized twenty four prior to  $\text{Sr}^{89}$ . One hundred nineteen days after the original  $\text{Sr}^{89}$  injection a second injection of 0 microcuries per gram body weight was given to selected animals from the two groups which originally were injected with this isotope.

(c) *Effect of  $\text{Sr}^{89}$  Injection on the Hemoglobin and Erythrocyte Values of the Peripheral Blood* No anemia of significance was produced in mice with intact spleens to which  $\text{Sr}^{89}$  was given by intraperitoneal injection. On the other hand, splenectomized mice injected with 20 microcuries per gram developed a significant anemia in twenty eight days which persisted through seventy days, but with recovery in 119 days (Figs 1 and 2). Selected animals with an intact spleen and animals which had been splenectomized were given a second injection of  $\text{Sr}^{89}$  (20 microcuries per gram) 119 days after the

original injection As after the initial  $\text{Sr}^{89}$  injection, the mice with intact spleens developed no anemia, whereas the splenectomized group developed a precipitous reduction in both hemoglobin and erythrocyte values Although recovery from the anemia proceeded in the splenectomized group, the anemia recurred between the fifty-sixth and seventy-seventh day after the second injection at which time all the remaining animals died or were sacrificed for study (Figs 1 and 2)

Fig 3—The effect of a single injection of 2.0 microcuries of radiostrontium per gram body weight on leucocyte values of normal mice and mice splenectomized twenty-four days prior to  $\text{Sr}^{89}$ . One hundred nineteen days after the original  $\text{Sr}^{89}$  injection a second injection of 2 microcuries per gram body weight was given to selected animals from the two groups which originally were injected with this isotope

(d) *Effect of  $\text{Sr}^{89}$  on Reticulocyte Values of the Peripheral Blood* Except for control studies no reticulocyte determinations were made until seven days after  $\text{Sr}^{89}$  injection, but at this point the reticulocyte values of animals which were splenectomized only and those which were given  $\text{Sr}^{89}$  only had actually risen, whereas the reticulocyte value of the group which was both splenectomized and strontium-treated had fallen significantly. Re-injection of  $\text{Sr}^{89}$  at 119 days produced no reduction in the reticulocyte value of mice with intact spleens. A reduction comparable with that seen after the original injection occurred, however, this was limited to splenectomized mice. As will be evident in the section on histology which follows, more frequent determinations

of the reticulocyte values of all the groups would have been of importance from the point of view of correlation

### Histopathologic Studies —

(a) *Observations on Lymphatic Tissue After Single Injection of  $\text{Sr}^{89}$*  No consistent difference in size of the spleens existed between  $\text{Sr}^{89}$  injected and control mice which were sacrificed during the 280 day period. However, an effect was observed in both the white and red pulp of the spleen in animals sacrificed three days after  $\text{Sr}^{89}$  treatment. This early effect consisted of a decreased cellularity of the white pulp and a marked hyperplasia of ectopic

Fig 4—The effect of a single injection of 2.0 microcuries of radiostrontium per gram body weight on heterophil values of normal mice and mice splenectomized twenty four days prior to  $\text{Sr}^{89}$ . One hundred nineteen days after the original  $\text{Sr}^{89}$  injection a second injection of 2 microcuries per gram body weight was given to selected animals from the two groups which originally were injected with this isotope.

erythrocytopenia and megakaryocytopoiesis in the red pulp. Ectopic granulocytopoiesis was practically absent at this stage. Only a few scattered mature granulocytes could be found. There was little evidence of destructive effects, however, for there was no observable increase in pigment or debris-filled macrophages or pyknotic nuclei at this stage as compared with the spleens of control mice. The spleens of control mice usually contained small foci of ectopic erythrocytopenia, granulocytopoiesis, and megakaryocytopoiesis scattered about in the red pulp. The erythrocytopenia in the spleens of the  $\text{Sr}^{89}$  injected animals, however, was diffuse and intense at three days and consisted of predominantly large hemocytoblasts, basophilic erythroblasts, and a lesser number of more mature forms.

The number of young megakaryocytes in the spleens of  $\text{Sr}^{89}$ -injected mice three days after injection was greatly above that of the controls. This intense erythrocytopoiesis and megakaryocytopoiesis persisted in the  $\text{Sr}^{89}$ -injected animals at all the periods of examination through 280 days. Photomicrographs of the spleens of  $\text{Sr}^{89}$ -injected and control mice at intervals of three, twenty-nine, forty-five, and ninety-two days (Fig. 6) illustrate especially the

FIG. 5.—The effect of a single injection of 2.0 microcuries of radiostontium per gram body weight on lymphocyte values of normal mice and mice splenectomized twenty-four days prior to  $\text{Sr}^{89}$ . One hundred nineteen days after the original  $\text{Sr}^{89}$  injection a second injection of 2 microcuries per gram body weight was given to selected animals from the two groups which originally were injected with this isotope.

degree of erythrocytopoiesis at these stages. Fig. 7 illustrates the closely packed erythroblasts in the red pulp at some of these stages at a slightly greater magnification.

No increase in ectopic granulocytopoiesis was observed in spleens of mice sacrificed at intervals of three and eight days after injection. Increased granulocytopoiesis became apparent in twelve days and increased to a maximum between forty-five and ninety-two days. In fact, in several of the mice examined during the forty-fifth and ninety-second days, granulocytopoiesis was qualitatively as intense as erythrocytopoiesis.

Changes in the white pulp in the spleens of  $\text{Sr}^{89}$ -treated mice were more or less universal at all stages studied from 3 to 280 days after injection. In normal mice the white pulp occupies circa 50 per cent of the spleen and, except for the distinct lymphatic nodules, blends gradually into the red pulp.

The splenic white pulp of the  $\text{Sr}^{90}$  injected mice almost without exception occupied less space than the red pulp and was distinctly separated from the intense erythrocytopoietic and granulocytopoietic red pulp by a zone of relative acellularity consisting largely of reticular cells (Figs 6 and 7). The decrease in cellularity of the white pulp was observed especially in the early

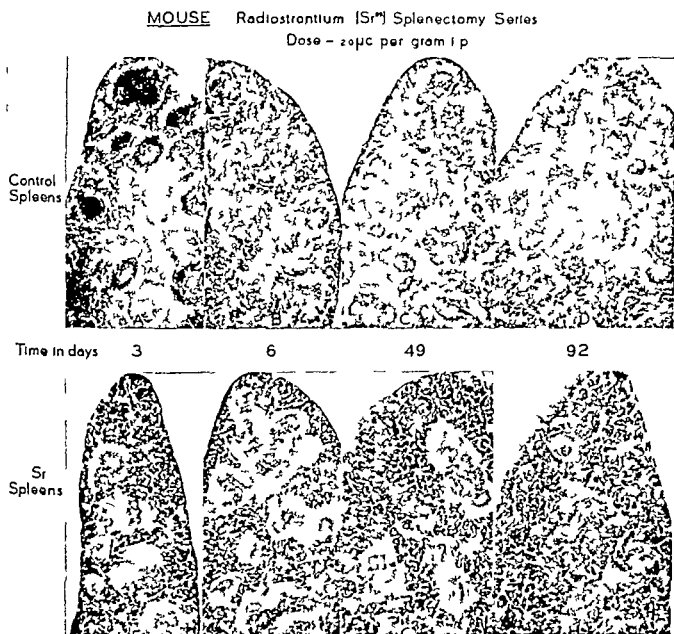

Fig 6—Photomicrographs of sections of the spleens of mice at intervals after  $\text{Sr}^{90}$  injection. The normal spleens show small areas of ectopic hematopoiesis in the red pulp and the normal variation in the white pulp, whereas the spleens of  $\text{Sr}^{90}$  injected animals show an intense ectopic hematopoiesis in the red pulp and a depletion of the cellularity of the white pulp (Hematoxylin-eosin azure II  $\times 15$ ).

stages after injection (i.e. three, six, twelve, fifteen, twenty one and twenty nine days), but the atrophy which persisted, is illustrated in the photomicrograph of the ninety second day specimen (Fig 7).

(b) *Lymph Nodes, Peyer's Patches of Intestine, and Thymus* Lymph nodes from the root of the mesentery and Peyer's patches from the small intestine from all animals sacrificed were studied in control and  $\text{Sr}^{90}$  injected groups. As opposed to the white pulp of the spleen of  $\text{Sr}^{90}$  injected animals in which atrophy, reduced cellularity and absence or diminution in the number of active lymphatic germinal centers were observed, the lymph nodes and

MOUSE Radiostrophium ( $Sr^{90}$ ) Splenectomy Series  
Dose -  $\mu\text{mc}$  per gram i.p.

Fig 7—Photomicrographs of normal spleens and the spleens of  $Sr^{90}$ -injected animals with selected areas at a higher power to illustrate the intensity of the ectopic hematopoiesis in the red pulp and the depletion of cellularity in the white pulp of  $Sr^{90}$ -injected animals (Hematoxylin-eosin-azure II low power  $\times 15$  high power  $\times 70$ )

Peyer's patches appeared essentially normal and the germinal centers were active. Granulocytopoiesis, erythrocytopoiesis, and megakaryocytopoiesis were definitely increased in the medulla of the lymph nodes of some of the  $Sr^{90}$ -injected mice as compared with control mice. This increase in ectopic hematopoiesis in lymph nodes was observed as early as fifteen days after injection but was more prominent in later stages. No increase or decrease in plasma cells in lymphatic tissue was observed. No histologic changes which could be directly attributed to  $Sr^{90}$  were observed in the thymus.

(c) *Observations on Lymphatic Tissue After Second Injection of  $Sr^{90}$  at 119 Days* Only a relatively few stages were studied. These were at fifteen, twenty-four, and seventy-seven days after the second injection.

The histologic effects as far as lymphatic tissues were concerned were again limited to the spleen. The lymph nodes, Peyer's patches, and the thymus appeared essentially normal except for a moderate increase in granulocytopoiesis, megakaryocytopoiesis, and erythrocytopoiesis in the lymph nodes. At the time of the second injection, the erythrocyte and hemoglobin values were essentially normal in both groups of mice which had originally received  $Sr^{90}$  (Figs 1 and 2). The marked ectopic erythrocytopoiesis, megakaryocytopoiesis, and granulocytopoiesis, however, persisted in the spleens of the  $Sr^{90}$ -injected animals sacrificed at 119 days at a time comparable with

that at which selected animals received a second  $\text{Sr}^{90}$  injection. Although moderate atrophy of the white pulp was also apparent at this time active lymphatic germinal centers were present and in general the white pulp was more cellular than in earlier stages.

By the fifteenth day following the second injection of  $\text{Sr}^{90}$  ectopic erythropoiesis, megakaryocytopoiesis and granulocytopoiesis were more intense than at the 119 day stage. Ectopic granulocytopoiesis however was only moderate in degree. Again as after the first injection of  $\text{Sr}^{90}$  little evidence existed of active cellular disintegration in the form of pyknosis, karyorrhexis, or phagocytosis. The white pulp which showed recovery to some extent after the original injection of  $\text{Sr}^{90}$  at 92 and 119 days in that it constituted a more normal percentage of the splenic tissue and was richer in medium and small lymphocytes, again was reduced in amount with a depletion of lymphocytes in the periphery of the white pulp fifteen days after the second injection. In the two other stages studied following the second injection namely twenty four and seventy seven days the recovery of the white pulp was only moderate, atrophy and decreased cellularity persisted.

As was true after the initial injection of  $\text{Sr}^{90}$  essentially 'maximum' increased ectopic erythropoiesis and megakaryocytopoiesis were apparent fifteen days after the second granulocytopoiesis was progressively more intense at the twenty four and seventy seven day stages. Pigment filled macrophages scattered throughout the red pulp were increased in number at all stages studied after the second injection.

(d) *Observations on Bone Marrow After a Single  $\text{Sr}^{90}$  Injection* The observations made on bone and bone marrow are limited to the effects of  $\text{Sr}^{90}$  on hematopoiesis in the marrow spaces. A vertebra and a femur were taken for study from each animal sacrificed. Since the effects of  $\text{Sr}^{90}$  on vertebral or femoral marrow were essentially comparable in the mice with intact spleens and in those that were splenectomized prior to the injection, no attempt to differentiate between the two groups will be made in the description of marrow changes. In general the destructive effects of  $\text{Sr}^{90}$  on hematopoiesis were comparable in femoral and vertebral marrow in that if complete or partial atrophy were found in the entire femur the condition was also present in the vertebral bone marrow and vice versa. However moderate decrease in cellularity with or without fibrosis was not infrequently found in the metaphyseal region of the femur immediately adjacent to the epiphyseal cartilage without evidence of such localized changes in the vertebral marrow. The destructive effects of  $\text{Sr}^{90}$  and the subsequent depletion of the normal hematopoietic cells were most severe in the metaphyseal region of equal or slightly less severity in the epiphyseal marrow and least in the diaphysis of the femur. In some instances essentially complete depletion of normal hematopoiesis was found in the entire femoral and vertebral marrow spaces of mice sacrificed at fifteen through eighty days. In others although general cellularity of the femoral diaphysis and vertebral marrow space was reduced complete depletion was present only in the metaphyseal and epiphyseal regions of the bone.

In spite of the cellular depletion that occurred after  $\text{Sr}^{90}$  injection, no stage studied either in femoral or vertebral marrow showed clear cut histologic evidence of increased death of cells. The number of pyknotic nuclei and macrophages filled with particulate debris did not exceed that that was observed in control mice. A marked depletion of cells in the epiphyseal and

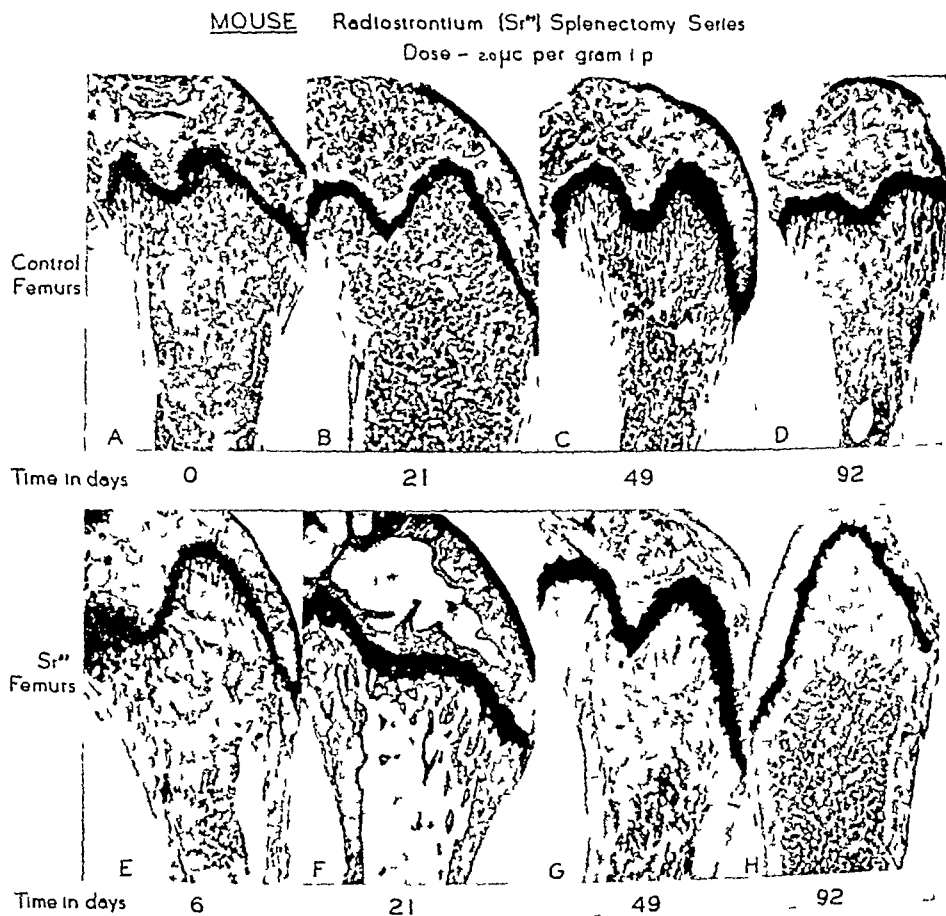

Fig 8—Photomicrographs of normal femoral marrow and of femurs of  $\text{Sr}^{90}$ -injected animals at various intervals after the  $\text{Sr}^{90}$  injection. These photomicrographs illustrate the depletion of normal hematopoietic cells in the epiphyseal and metaphyseal regions with partial sparing in the diaphysis of some animals. (Hematoxylin-eosin-azuric II,  $\times 15$ )

metaphyseal marrow space of the femur was present three days after injection. The general cellularity of the diaphysis of the femur as well as in the vertebral marrow space was moderately decreased. In the epiphyseal and metaphyseal regions of the femur only a few scattered heterophils, plasma cells, and large lymphocytes remained at this stage, whereas dilated vascular spaces and increased fat cells filled the area. Distally from the depleted metaphyseal region, the cellularity of the marrow gradually increased. The diaphyseal marrow was diffusely cellular but distinctly less so than that of

MOUSE Radiostrontium ( $Sr^{90}$ ) Splenectomy SeriesDose - 2.4  $\mu$ c per gram i.p.

Fig. 9—Photomicrographs of normal femoral marrow and femurs of  $Sr^{90}$  injected animals with selected areas at a higher power to illustrate the loss of normal cellularity and replacement by fibrous tissue (C) twenty one days after  $Sr^{90}$  injection and the residual cellular depletion in the metaphysis ninety two days after  $Sr^{90}$  injection (Hematoxylin eosin azure II low power  $\times 15$  high power  $\times 70$ )

normal control mice. The vascular spaces in this part of the marrow at three days were conspicuously dilated. Megalariocytes were fewer in number and erythrocytopoiesis was definitely decreased. The remaining cells were thus largely composed of the precursors of the granulocytic series.

The vertebral marrow was comparable with that of the femoral diaphysis at this stage. At six days the findings were essentially the same as those for the three day stage (Fig. 8 E). The degree of marrow depletion varied considerably from animal to animal at various time intervals after injection. In Fig. 8, F the femur of a mouse sacrificed twenty one days after injection is shown. In this specimen only fat and dilated vascular spaces filled with erythrocytes remained. In two other mice sacrificed at this same interval the epiphyseal and metaphyseal regions of the femurs were largely depleted of cells, the diaphyseal portions contained about as many hematopoietic cells as the controls. In still another mouse sacrificed at this interval the vertebral

and femoral marrow contained small areas of normal-appearing hematopoietic cells scattered about among the fat cells, dilated vascular spaces, and gelatinous areas, whereas the metaphyseal portion was more or less completely replaced by fibrous tissue (Fig 9, C). At later stages, i.e., 49, 71, 92, and 119 days after  $\text{Si}^{32}$  injection, the depletion of cells in the metaphyseal and epiphyseal portions of the femoral marrow remained conspicuous (Figs 8, G and 9, D). The shaft or diaphyseal portion of the femur and the vertebral marrow approached more normal hematopoietic activity. Likewise, in these stages the amount of fat and the dilation of the vascular spaces became less conspicuous.

(e) *Observations on Bone Marrow After Second  $\text{Si}^{32}$  Injection* Selected animals were given a second injection of  $\text{Si}^{32}$  119 days after the first injection. At this time (Figs 1 and 2) no anemia existed in either group which had originally received  $\text{Si}^{32}$ . Residual partial cellular depletion or fibrosis in the epiphyseal and metaphyseal region of the femur still persisted at this stage, but the diaphyseal portion of the femur and the vertebral marrow were only slightly less cellular than in normal mice. Sacrifices of mice that were given a second  $\text{Si}^{32}$  injection were made fifteen, twenty-four, and seventy seven days after the injection. The effect on the marrow of these mice was essentially the same as that observed in comparable stages after the first injection except that the number of pigment-filled macrophages was slightly increased in the injected animals.

(f) *The Effect of  $\text{Si}^{32}$  on Other Tissues or Organs* The tissues or organs, not hitherto discussed, which were studied were skin, lung, adrenal, small intestine, kidney, and liver. No cytologic evidence of destructive effect which could be attributed to  $\text{Si}^{32}$  was noted in these organs or tissues. In an occasional animal, which had been given a single injection of  $\text{Si}^{32}$  or reinjection with a comparable dose of  $\text{Si}^{32}$ , ectopic erythropoiesis was found in the liver and adrenal. In each instance, however, this was minimal.

#### DISCUSSION

In spite of the extensive cellular depletion that develops in the bone marrow of mice injected with  $\text{Si}^{32}$  in a dose of 2 microcuries per gram of body weight, no anemia develops. Intense ectopic erythropoiesis occurs with such rapidity in the spleens of these mice that the steady state of the circulating erythrocytes remains essentially normal. Splenectomized mice, on the other hand, develop an anemia after the injection of this dose of  $\text{Si}^{32}$  because of the fact that compensatory ectopic erythropoiesis in the spleen is not possible and its development in other potential sites is not adequate. Increased ectopic megakaryocytopoiesis in the spleens of  $\text{Si}^{32}$ -injected animals occurred as rapidly as ectopic erythropoiesis, but since platelet determinations on the peripheral blood were not performed, no statement can be made with reference to whether or not this compensation was sufficient to prevent platelet reduction. In experiments suggested by the results related in this communication Jacobson and associates<sup>10</sup> showed that lead protection of the surgically mobilized spleens of mice during the administration of 600 r x-radia

tion to the balance of the body obviated the development of anemia and significantly reduced the severity and the duration of the leucopenia and thrombocytopenia which regularly follow the delivery of this dose to the whole animal. Histologic studies showed that this phenomenon was due to the rapid development of ectopic blood formation in the lead protected spleens.

An interesting problem that has been posed by this experiment relates to the fact that lymphocytopoiesis was markedly reduced in the spleens of  $^{90}\text{Sr}$  injected animals whereas the lymphatic tissue in the lymph nodes from the root of the mesentery, the thymus, and in Peyer's patches of the small intestine was essentially unaltered at any stage studied. The amount of  $^{90}\text{Sr}$  found in the spleen of injected animals was minimal twenty-four hours after injection and practically none was found three days after injection. It seems unlikely, therefore, that the reduction in lymphatic tissue in the spleen extending for more than ninety days after  $^{90}\text{Sr}$  injection could be attributed to the transient presence of  $^{90}\text{Sr}$  in the spleen. Neither can one explain this reduction in splenic lymphocytopoiesis adequately on the basis of radiation originating from  $^{90}\text{Sr}$  deposited in bone since one would expect other lymphatic tissue (lymph nodes, etc.) to be affected in a comparable manner. It would be difficult to explain the reduction in lymphatic tissue in the spleen on an indirect basis for the same reason. Although differences in the radiosensitivity of lymphatic tissue in various sites throughout the body of the mouse may exist, it seems unlikely that such an explanation is warranted here. The most plausible explanation for the decrease in splenic lymphatic tissue is that it may be related to a nutritional competition between the lymphatic tissue and ectopic hematopoiesis. The compensatory granulocytopoiesis in the spleen of  $^{90}\text{Sr}$  injected mice reached a maximum at a time approximately comparable with the time at which the heterophils in the peripheral blood returned to normal values (forty-five to seventy days).

The delay in the appearance of ectopic granulocytopoiesis in the spleens of these animals suggests that this process was suppressed either primarily or secondarily, that the stimulus for an intensification of this process was less marked, or that even with a maximum stimulus the spleen had only a capacity for a gradual intensification of ectopic granulocytopoiesis.

The fact that anemia recurred in the splenectomized mice after the administration of a second injection of  $^{90}\text{Sr}$  at 119 days indicates fairly conclusively that ectopic erythrocytopoiesis in sites other than the spleen is wholly inadequate to cope with the destruction and suppression of erythrocytopoiesis which occurs in the bone marrow. The eventual recovery of splenectomized mice from the anemia induced by the first  $^{90}\text{Sr}$  injection must therefore have been largely a function of the recovery of erythrocytopoiesis in the marrow spaces.

The fact that histologic evidence of destruction in the bone marrow and spleen other than cellular depletion and the late appearance of pigment filled macrophages was not seen in  $^{90}\text{Sr}$  injected animals should perhaps be com-

mented upon. For example, as early as three days after  $\text{Sr}^{90}$  injection, partially to essentially complete depletion of hematopoietic cells in the bone marrow was seen. Only dilated vascular spaces, fat cells, a few debris-filled macrophages and occasional plasma cells, lymphocyte-like cells, etc., remained in the bone marrow of some of the animals sacrificed at this stage. It is likely that debris-laden macrophages, pyknotic nuclei, etc., would have been more in evidence had specimens been taken earlier than three days. Likewise, in the white pulp of the spleens of  $\text{Sr}^{90}$ -injected animals, active phagocytosis was minimal even though the general cellularity was markedly decreased in three days.

#### SUMMARY AND CONCLUSIONS

Radiostrontium ( $\text{Sr}^{90}$ ), a  $\beta$ -ray emitter with a half-life of fifty-five days, is largely deposited in the skeleton when administered to the experimental animal. Although deposition in bone is general, the greatest concentration of this isotope invariably occurs in areas of active bone growth.

A persistent leucopenia but no anemia of significance was produced in the peripheral blood of young mice given a single intraperitoneal injection of this isotope as the chloride in a dose of 2.0 microcuries per gram. The same dose produced a leucopenia and an anemia in splenectomized mice. Recovery from the anemia was essentially complete by 119 days after the  $\text{Sr}^{90}$  injection. Hematopoiesis was markedly reduced in the bone marrow of all radiostrontium-treated animals within three days after injection. The epiphyseal and metaphyseal regions of the long bones were largely depleted of cells, or, in some instances, the latter regions were completely replaced by fibrous tissue. Recovery of hematopoiesis in the bone marrow of the femur was essentially complete by 119 days except that some cellular depletion still existed in the metaphysis at this stage.

Ectopic erythrocytopoieses and megakaryocytopoieses were greatly increased in the spleen three days after  $\text{Sr}^{90}$  injection as was true of all other intervals studied through 119 days. Splenic lymphocytopoiesis, on the other hand, was reduced in three days and recovery was not complete by 119 days. Lymphocytopoiesis was essentially unaffected in other lymphatic tissues (lymph nodes, thymus, etc.). Ectopic granulocytopoiesis increased more slowly in the spleens of  $\text{Sr}^{90}$ -injected animals, reaching a maximum at circa sixty days. Ectopic granulocytopoiesis, megakaryocytopoiesis, and erythrocytopoiesis were not remarkable in other tissues of the animals which received  $\text{Sr}^{90}$ .

The rapid development and the persistence of ectopic erythrocytopoiesis in the spleen prevent anemia in mice given  $\text{Sr}^{90}$  intraperitoneally in a dose of 2.0 microcuries per gram.

# JAPANESE B ENCEPHALITIS REPORT OF FIVE CASES

LIEUTENANT (J G ) N F WYATT, MEDICAL CORPS, UNITED STATES NAVY

## INTRODUCTION

THE epidemic of Japanese B encephalitis in Japan in the summer of 1948 was of significant interest because of the opportunity it afforded for direct observations on this exotic disease by physicians of the occupation forces. From a panoramic public health viewpoint, it was essentially of minor import as the actual percentage of the population afflicted was exceedingly small. In view of the rapidly expanding geographical confines of the disease, it may present a diagnostic and therapeutic problem to clinicians in the United States in the near future.

## EPIDEMIOLOGICAL AND ETIOLOGICAL ASPECTS

The purpose of this article is to point out the clinical observations on a small series of five serologically proved cases observed at the Navy Dispensary, Yokosuka, Japan. Nevertheless it does not seem amiss to discuss some of the features of the epidemiological and etiological aspects.

The geographical distribution of the disease is rather widespread, cases having been reported from Okinawa and the near-by islands, Korea, China, Guam (epidemic of 1947), Siberia, the Japanese islands, and possibly many other countries of the Far East.<sup>1 2 3</sup>

**Vectors**—In our present state of knowledge, it is believed that the encephalitic virus is conveyed by a mosquito. Inada,<sup>4</sup> a Japanese investigator, and two Russian workers, Petrusheva and Shubladá,<sup>5</sup> have reported the isolation of the virus from *Culex tritaeniorhynchus* and *Culex pipiens* var. *pallens*. Animal reservoirs of infection have been discovered in horses, pigs, goats, cows, and possibly sparrows, but not in chickens.<sup>1, 2</sup> It is interesting to note, as demonstrated in studies in Japan, that outbreaks among domestic animals may occur coincident with no or few human clinical cases.<sup>6</sup> Presumably epidemic outbreaks may occur only when the factors of mosquitoes, animal reservoirs of infection, and human susceptibles exist concomitantly. The disease has presented a fluctuating course in Japan, reaching epidemic or minor epidemic proportions every few years, a feature probably related to the accumulation of susceptible persons. In July, 1924, there were 6,125 cases with a mortality rate of 62 per cent. In 1935, there was an outbreak of 5,370 cases.<sup>7</sup> One interesting aspect of the epidemic under discussion is that the conditions of temperature and rainfall were exceedingly favorable for the propagation of mosquitoes prior to the outbreak of the disease.

**Incidence in Man**—Apparently, from evidence accumulated from many sources, the clinically recognizable cases represent only a relatively small

Received for publication Aug 12 1949

proportion of the total the majority smoldering, under the blanket or sub clinical or very mild clinical infection. In 1936 one year after a large epidemic 83 per cent of 116 sera tested in Tokyo revealed virus neutralizing antibodies<sup>1</sup>. In 1937, 0.8 per cent of 525 human sera obtained from Hokkaido Japan, demonstrated these antibodies<sup>2</sup>. Hokkaido is not an epidemic nor an endemic area of the disease. In 1941 83 per cent of 104 sera from Middle China possessed neutralizing ability against the Japanese B virus<sup>3</sup> and in 1945 90 per cent of the natives of Okinawa similarly had neutralizing antibodies<sup>4</sup>. In 1946 a similar phenomenon was found in the sera of 85 per cent of thirteen Chinese residents of Shanghai and 89 per cent of nineteen Chinese residents of Tientsin<sup>5</sup>.

Sabin<sup>4</sup> reported a mortality rate for the 1945 outbreak on Okinawa of 28.6 per cent and on the near by islands of Hainan and Hamahika 30.6 per cent. Among American military forces on Okinawa in 1945 there were two deaths occurring in a series of twelve severe cases. Figures compiled by the Public Health and Welfare Section Supreme Commander for Allied Powers revealed that in the first forty-one weeks of 1948 there were approximately 6,000 cases of Japanese B encephalitis throughout the empire and 2,374 deaths were reported. The approximate mortality rate from the disease was 25.7 per cent for the Tokyo area and 35.7 per cent for all Japan. In the summer of 1948 there were three fatalities in the twenty nine proved cases of Japanese B encephalitis in occupation personnel in Japan. Because of the paucity of serologically proved cases occurring among occupation personnel in Japan a study of the features of the disease as manifested in the five cases forming the subject of this paper seemed all the more desirable.

Although superficially the number of deaths in 1948 attributable to the encephalitic virus seems fairly large it shrinks considerably when viewed relative to the 78 millions inhabiting the Japanese islands. These fatalities fade almost into oblivion when one contemplates the staggering total of approximately 147,000 deaths in Japan in 1947 directly attributable to tuberculosis. According to several attending Japanese physicians approximately 2 per cent of the patients exhibit sequelae. These include clonic muscular movements, decerebrate rigidity and twitchings of muscle groups.

The figures for the incidence in the Tokyo area in 1948 reveal a high rate for the younger age group i.e. through 1 to 20 years of age. The highest occurred in the 6 to 10 years group the rate being 117.3 per 100,000. The lowest incidence occurred in the 31 to 70 years group the rate being 9.1 per 100,000. In the early years male patients have the highest incidence of the disease but this tendency decreases after the age of 20 until there is a female preponderance in the 51 to 60 years group. In all ages the mortality among female patients is higher than that among male patients. The overall case fatality rate in Tokyo during the 1948 epidemic was 19.9 per cent for males and 33.3 per cent for females. These figures were derived from 2,067 cases.

Two cases, occurring in nonvaccinated Naval personnel are of interest in that they assist in elucidating the time requisite for the incubation period of the

disease. Two firemen from a Naval vessel stayed ashore overnight in Yokohama. The ship remained in Yokohama for two days, sailing Aug. 1, 1948. Many mosquitoes were observed aboard ship. On August 11 one man reported to the ship's sick bay with a complaint of headache of four hours' duration. He seemed drowsy and had a fever. The patient was transferred to a British hospital at Ceylon thirty hours later and died twenty-four hours after transfer. Unfortunately, no autopsy was performed. On August 21 the other fireman developed a headache and fever and became disoriented. A spinal fluid examination performed at a hospital at Bahrein Gulf showed a slight pleocytosis and an increase in protein. The patient's clinical course was similar to that of cases of Japanese B encephalitis occurring in Japan. Following complete recovery, the man returned to Japan. His complement-fixing titer one month after the original infection was 1:16, and the neutralization index was 63,000.

*Status of Vaccination*—The status of vaccine has not been established at this time. No conclusions relative to the efficacy of vaccination could be drawn from the epidemic on Okinawa. Sabin<sup>9</sup> has shown a rise in neutralization and complement-fixing antibodies in young people inoculated with mouse brain vaccine, two 1 cc doses being given six days apart and the last dose of 1 cc one month later. Very elderly persons who had no previous serologic neutralizing antibodies exhibited no response. Following the administration of a potent vaccine, many persons develop a rise in neutralizing antibodies.<sup>7</sup> In American adults, no rise in complement-fixing antibodies occurs as a result of vaccination alone, although a person previously infected with the live virus may develop complement-fixing antibodies after vaccination.<sup>7</sup> The vaccine used at present is a chick embryo vaccine, and its efficacy is under intense investigation.

Twelve patients of the twenty-nine cases occurring among occupational personnel in Japan had received complete immunization. No deaths occurred among this group. Three patients had received complete immunization except for one dose. No deaths occurred among these. Six patients had failed to obtain complete vaccination by two or more doses. There was one death among them. Two deaths occurred among eight completely nonimmunized patients.

*Symptoms*—The clinical symptoms of the disease as previously reported by Sabin<sup>1, 2</sup> include marked lethargy, confusion, high fever, nuchal rigidity, leucocytosis, and spinal fluid pleocytosis. The onset is abrupt, with sudden headache and fever. Sabin, in his Okinawa series<sup>1</sup> (ten serologically proved), observed convulsions in only two cases, both of them fatal. He stressed the duration of the fever, seven to eleven days, and the constant bradycardia present. Cells in the spinal fluid were predominantly mononuclear, whereas a polymorphonuclear leucocytosis was found in the peripheral blood smear. One patient of his series exhibited interesting sequelae, i.e., hyperirritability, mask-like facies, somnolence, and a propensity for urinating on the floor. In the Korean outbreak, two instances of bladder paralysis were recorded. One of these patients died. In the other, bladder function became normal upon convalescence.

*Serologic Studies*—Serologic studies upon the Okinawa cases revealed interesting data. Serum neutralizing antibodies were questionably or certainly positive on the fourth or fifth day of the disease. Low titers of complement fixing antibodies were found as early as two to eight days after the onset. However, these complement fixing antibodies may not appear until the fifth week. No discrepancies were noted between the results of the neutralization and complement fixing tests. For several technical reasons Sabin feels that the complement fixing test is more practical. It is interesting that many cases, initially suspected of being mild or abortive cases in his Okinawa series gave no serologic evidence of Japanese B encephalitis.

*Pathology*—Gross pathology reveals a diffuse congestion of the brain, sometimes with softening of the cervical cord.<sup>1</sup> There is diffuse involvement of the leptomeninges and the gray matter. Perivascular lymphocytes are pre dominant in the arachnoid meshes. The meningeal lesions are widespread over the surface of the brain, being minimal over the midbrain, pons, medulla, cerebellum, and spinal cord. Many nodules composed of mononuclear cells, clustered about degenerating ganglion cells or blood vessels occur in the gray matter. The cortex, thalamus, substantia nigra, nuclei of the fourth ventricle, cerebellar cortex, and the anterior horns of the spinal cord are involved. Adrenal "tubular degeneration" may occur.

#### CASE REPORTS

**CASE 1**—Patient T. H., a 23 year old white man entered the Navy Dispensary on Aug 8, 1948, complaining of a headache beginning the previous day. This headache began suddenly progressively became worse and was accompanied by malaise and chills. He had completed the course of immunization against Japanese B encephalitis approximately two months before the present illness.

*Physical Examination and Laboratory Data* T 102.4 F, P, 84, R, 22, B.P., 116/78 mm Hg. The patient appeared flushed, dehydrated and acutely ill. There was definite nuchal rigidity. The reflexes were physiologic and Kernig's sign was negative. The spinal fluid showed 30 polymorphonuclear cells and the Pandy reaction was negative. Blood leukocyte count on the second hospital day was 10,900 with 76 per cent polymorphonuclear cells. Admission urinalysis was negative. Initial chest films, as well as all subsequent chest films were negative.

*Course* Intravenous fluids, oral sulfadiazine and intramuscular penicillin were instituted. On the second hospital day the fever rose to 104.1° F. There were 162 white cells in the spinal fluid, of which 127 were polymorphonuclear. During the next two days the temperature climbed to 104.6° F, and there was no essential change in the neurological picture. The patient was relatively alert. On the fourth hospital day the spinal fluid contained 133 polymorphonuclear and 98 mononuclear cells, and the Pandy reaction at this time was two plus. The patient became completely disoriented on the fifth hospital day. He did not respond to questioning, had to be restrained in bed and was unmanageable. Paraldehyde was necessary for sedation. There were definite neurological changes. The arms developed a lead pipe type of rigidity, and there were marked gross tremors of the upper extremities and tongue with twitchings of the mouth. On the sixth hospital day, the temperature suddenly dropped and remained normal on the seventh day. The patient became more rational. A lumbar puncture at this time revealed approximately 400 cells in the spinal fluid, about three fourths of them being polymorphonuclear, and a two plus Pandy reaction. Improvement after the seventh hospital day was rapid, and the temperature remained essentially

normal During the subsequent thirteen days, the mental cloudiness, muscle twitching, and muscle tremors disappeared as well as all traces of nuchal rigidity However, the patient's voice, which had become quite husky, remained so for two months This has cleared completely at the time of the present writing, i e, approximately five months from the onset of the illness When the patient became ambulatory again, he complained bitterly of dizziness when walking, but this complaint rapidly disappeared

Fig 1

CASE 2—Patient M B, a 37 year old white man, entered the Navy Dispensary on Aug 28, 1948 The patient stated that the evening before he had experienced sudden severe head ache and chills He remembered starting to the Dispensary the next morning, but affirmed later that he did not have any recollection of his arrival nor of the immediately subsequent events There had been no immunization against Japanese B encephalitis

Physical Examination and Laboratory Data T, 103 2° F, P, 96, R, 22, BP, 142/78 mm Hg Within a few moments after admission to the medical ward, the patient experienced a severe clonic convulsion with attendant cyanosis The convulsion lasted approximately five minutes, and upon its cessation the patient was unruly and completely irrational, necessitating restraint by several men The patient was disoriented and could make no intelligent reply to questioning The administration of intravenous Sodium Amytal was necessary There was flushing of the face and extreme dehydration A foul discharge, from which pneumococci were subsequently cultured, drained from a right otitis externa The mucous membranes of the throat were injected, and the tongue had been traumatized during the convulsion A Grade II apical systolic murmur was present There was marked nuchal rigidity Kernig's sign was positive All reflexes were hypoactive, the abdominal and ankle reflexes were absent, and the Babinski was positive bilaterally The spinal fluid contained 425 cells, of which 321 were polymorphonuclear cells The Pandy reaction was two plus The initial blood leucocyte count was approximately 14,000 with 82 per cent neutrophils The urine contained a trace of protein The chest film was negative

*Course* Therapy, in the form of oral sulfadiazine intramuscular penicillin intravenous fluids, and intranasal oxygen was instituted. On the second hospital day the patient developed a lead pipe rigidity of the arms and gross tremors of the lips and upper extremities. Similar but less marked rigidity of the lower extremities was also evident. This clinical picture persisted for six days. On the seventh day the temperature dropped to 99.8 F. The gross tremors of the lips, tongue and arms were still present. The ankle jerks

Fig. 2

were absent the Babinski was negative and all other reflexes were hypoactive. Transient weakness of the external ocular rectus muscles appeared. It was necessary to discontinue oxygen for approximately thirty minutes because of a mechanical defect in the apparatus and at the end of that time it was noted that the slightest stimulus could precipitate violent movements bordering on a convulsion. Following resumption of oxygen inhalation for a few minutes the patient became much more responsive and much less hyperirritable. After the eighth hospital day he became much clearer mentally and rapidly regained his normal sensorium. Likewise, the muscle tremors cleared. Neurological abnormalities disappeared and no physical sequelae of the encephalitis remained. His convalescence was complicated by a spondylitis.

**CASE 3**—Patient W.P., a 24-year-old white man entered the Navy Dispensary on Aug. 19, 1948, complaining of headache, fever, malaise and nuchal rigidity of two days' duration. He had been immunized against Japanese B encephalitis in 1946 and had received a booster dose of 1 cc in 1947 and in June 1948.

**Physical Examination and Laboratory Data.** T 104 F 110 R 24 BP 1—/—4 mm Hg. The patient was acutely ill and markedly dehydrated. The skin was red and flushed. There was slight stiffness of the neck and transient weakness of the external rectus muscles of both eyes. All reflexes were normal and the Babinski signs were normal. Initial spinal fluid studies revealed 143 white cells, 107 of them being polymorphonuclear and a one plus Pandey reaction. The blood leucocyte count was 10,000 with 53 per cent polymorphonuclear cells. The urinalysis was negative. Initial and subsequent chest films were normal.

CASE 5—Patient M W, a 29 year old white woman, entered the Navy Dispensary on Aug 19, 1948, complaining of fever, malaise, and headache. These symptoms had begun suddenly three days before admission. The evening before admission she had become disoriented and irrational. There had been no immunization against Japanese B encephalitis.

*Physical Examination and Laboratory Data* T, 105.5° F, P, 120, R, 24, BP, 110/80 mm Hg. The patient was flushed and dehydrated. She was irrational and could not respond to questioning. A gross tremor of the upper extremities and twitching of the mouth

Fig 5

were present. Definite nuchal rigidity could be elicited. There was mild injection of the mucous membranes of the nose and throat. All reflexes were physiologic except for a questionably positive Babinski on the right. There were 97 polymorphonuclear cells and 47 mononuclear cells in the spinal fluid. The Pandy reaction was one plus. The blood leukocyte count was 13,000, 75 per cent of these cells being polymorphonuclear. The urinalysis was negative. Initial and subsequent chest films were negative.

*Course* Intravenous fluids, oral sulfadiazine, and intramuscular penicillin were administered. During the following four days the patient remained delirious and continued to have the gross tremors described. Lead pipe rigidity of the upper extremities also appeared. On the sixth hospital day the temperature decreased to 100.5° F and on the seventh hospital day the patient became much clearer mentally. Thereafter improvement was rapid and all neurological abnormalities quickly disappeared. No sequelae remained.

#### DISCUSSION

The diagnosis in each of the five patients was proved by a rise in complement-fixing antibodies in the serum. The results of the complement fixation tests and the neutralization indices are shown in Table I.

Six other patients, having the same type of symptoms, spinal fluid pleocytosis, and clinical picture, are omitted from this discussion because positive serologic proof was not obtained. The question arises as to whether

TABLE I COMPLEMENT FIXATIONS AND NEUTRALIZATION INDICES

these were indeed cases of Japanese B encephalitis and whether it is possible that in some instances the threshold of immunologic response is not reached

The therapeutic regimen adopted was necessarily varied to compensate for the individual needs of the patient. One of the characteristic features of the disease was the marked dehydration present initially. The nonprotein nitrogen determinations were elevated in two patients even after several days of rehydration and in a third before rehydration was accomplished. Probably the nonprotein nitrogen would have been elevated in the other two patients had this value been determined at the beginning of their hospitalizations.

Blood chloride values were generally within normal limits, and blood nonprotein nitrogen determinations were consistent with the degree of dehydration evidenced by the patient. In no patient could it be demonstrated that renal disease was a factor in the elevation of the nonprotein nitrogen. A few fasting blood sugar determinations were normal. Several blood calcium determinations in two patients experiencing convulsions were normal.

Large quantities of saline and glucose were administered intravenously until adequate oral intake could be assured. As these individuals were quite young large quantities could be infused with relative safety. In all cases adequate urinary flow was achieved. In no instance did edema occur except in one patient who developed pulmonary edema following repeated convulsions. This edema quickly responded to morphine.

Intravenous barbiturate sedation was essential in two men to control multiple convulsions. Paraldehyde was requisite for one man who had become aggressive and irrational.

Sulfadiazine and penicillin were instituted in all patients because at that time, the exact nature of the disease had not been ascertained. It is

doubtful whether this therapy altered the course of the disease itself in any way. However, since among the Japanese bronchopneumonia was a common complication after the lysis of the encephalitic fever, chemotherapy may have had some value in the prevention of secondary infection.

One of the most valuable therapeutic adjuncts was oxygen. Many observers have expressed the opinion that the pathologic changes demonstrable at autopsy are to a large degree contingent upon anoxia. The salutary effect of oxygen was seen definitively in one patient. Patient M. B., Case 2, was receiving intranasal oxygen. After his initial convulsion had been controlled with Sodium Amytal and intranasal oxygen had been started, no further convulsions occurred even in the absence of further sedation. At one period in the illness, oxygen was discontinued for thirty minutes because of a mechanical defect in the apparatus. At the end of this period of time, the patient became much more restless and more delirious and upon slight stimulation developed convulsive movements which threatened to culminate in a generalized grand mal type of attack. Intranasal oxygen was then reinstituted, and after fifteen minutes the patient could respond to some questions intelligently, the hyperirritability of the central nervous system had subsided, and even strong stimuli failed to elicit convulsive movements. Oxygen was again discontinued temporarily, this time purposefully, and in half an hour the patient had reverted to his former state of lethargy and hyperirritability. Thereafter oxygen was administered continuously, and the clinical response was swift and gratifying. It is interesting to note that oxygen was almost specific when there were absolutely no signs of circulatory distress. The chest and heart were normal clinically and roentgenologically, and no clinical cyanosis nor respiratory distress was apparent.

A second patient, Patient W. P., Case 3, already receiving oxygen, experienced recurrent convulsions and developed pulmonary edema. Intravenous Sodium Amytal controlled the convulsions, and a hypodermic injection of morphine controlled the pulmonary edema. Thereafter, with intranasal oxygen, in the absence of further sedation, the patient remained calm and free of convulsions. The role of oxygen in controlling the convulsions in this case is less clear-cut than in that of Patient M. B., Case 2, but it was difficult to escape the clinical impression that oxygen was at least partially responsible in the suppression of convulsions. In retrospect, oxygen probably should have been administered to all patients.

Headache was a very distressing symptom. Frequently the simple procedure of withdrawing 10 cc of spinal fluid for study ameliorated the headache considerably. All of the patients had slight elevations of the spinal fluid pressure. Aspirin and codeine were valueless. Some clinicians of the occupation forces employed intramuscular caffeine and sodium benzoate with good results. We had no experience with this method of treatment.

Incontinence of urine and feces was a problem only so long as the patient was comatose.

The remainder of the therapy was purely symptomatic and similar to that employed in any acute infectious disease. Respiratory and intestinal isolation

techniques were instituted, but it is dubious whether the disease is contagious via the respiratory route. Those persons entrusted with the care of encephalitic patients in Japanese hospitals practice no precautions and seem none the worse for their multiple exposures. Throughout Japan there are extremely few instances of the disease occurring in more than one member of a family. The necessity of adequate mosquito screening seems obvious.

Many of the features of the disease can be discerned readily by a brief study of the charts. Necessarily from such a small series no sweeping conclusions can be drawn. These charts represent only the clinical picture in five patients seen at this Dispensary. Good correlation has been obtained however, with much larger series occurring among Japanese nationals throughout the empire.

Initially, all patients were febrile the height of the elevation ranging from 102° F. to 105° F. plus. Definite lysis of the fever occurred on the seventh day of the illness in two patients on the eighth and ninth days in two others, and on the tenth day in one. Temperature lysis about the seventh day of the illness is characteristic of Japanese B encephalitis. It is interesting to attempt to correlate the degree of the febrile response with the prevailing disturbance of the sensorium. Four patients had markedly disturbed sensoria. The fifth, Case 4 Patient J S. with an equally high temperature and with the most marked spinal fluid pleocytosis was mentally alert and cheerful throughout his illness.

Relative bradycardia was present initially in only two patients. This quickly disappeared.

The blood leucocyte count varied from 10 000 to 15 000 on admission and in the majority of these counts there was a decided 'shift to the left'. The count returned to normal in three to seven days.

Pleocytosis in the spinal fluid ranged initially from 30 to 552 cells. In four patients there was a preponderance of polymorphonuclear cells. In the fifth, no differential was done on admission. However the next day the majority of cells in the spinal fluid were polymorphonuclear. The ratio of neutrophilic leucocytes to mononuclear cells was soon reversed and subsequent spinal fluid examinations revealed a decided majority of mononuclear cells. The Pandy reactions were positive semiquantitatively from a trace to two plus. There were no strongly positive Pandy reactions in any stage of the disease. Spinal fluid sugars and chlorides were normal in all instances. Repeated smears of the centrifuged spinal fluid were negative for organisms. No bacterial growth was obtained on repeated cultures. Because of the difficulty in following these patients after their discharge from the Dispensary and in order to avoid repeated lumbar punctures, it was impossible to ascertain exactly the length of time requisite for all abnormalities to disappear from the spinal fluid. In the five patients definite abnormalities were found on the tenth, twentieth, twenty first, thirty second and thirty second days respectively.

During the febrile episode there was transient, mild proteinuria, but this finding disappeared upon lysis of the fever.

The neurological picture during the course of the illness has been described in the case histories. Nuchal rigidity was present in all, although the rigidity was quite mild. In only one patient, Case 3, Patient W P, did a cranial nerve palsy develop (seventh nerve), although a transient weakness of the external (lateral) ocular rectus muscles was present in Case 3, Patient W P, and in Case 2, Patient M B. All except one, Case 4, Patient J S, experienced gross tremors of the upper extremities, lips, and tongue. It is noteworthy that the Japanese physicians consider a tongue tremor to be one of the first signs of recovery. This observation was not well correlated with the clinical course in this series. The ocular fundi were normal in all patients. Reflex changes were varied and transient. At various stages of the illness there were hyperactive, hypoactive, and absent knee jerks, ankle jerks, and abdominal jerks. Kernig's sign was positive in some but not all patients. The Babinski was transiently positive in some. There was rapid disappearance of neurological reflex abnormalities after lysis of the fever. All patients, except Case 4, Patient J S, exhibited a lead-pipe type of rigidity of the upper extremities. The sensoria of all patients, except Case 4, Patient J S, were markedly deviated from normal. These patients were restless and aggressive, with alternate periods of lethargy. This is in marked contrast to the extreme constant lethargy usually prevalent among native encephalitis victims.

One characteristic of the disease which deserves special emphasis is the rapidity of the patient's recovery. He may appear moribund, and the outlook may seem virtually hopeless. Even in such instances recovery may be swift.

There were no fatalities in this small series. The Japanese mortality rate of approximately 35.7 per cent is undoubtedly excessively high because of the poor methods of treatment in their hospitals. Even during the acute stage, while the patient is comatose, only 500 cc of fluid are administered each day by intramuscular drip, according to the practice in one of their large hospitals. This amount is not varied, regardless of the degree of dehydration, age, or size of the patient. "Acidosis" is "prevented" by the intravenous administration each day of 20 cc of a 50 per cent glucose solution. Oxygen, apparently, is infrequently, if ever, employed. A further disadvantage is the marked overcrowding of their hospitals with encephalitic patients, rendering very difficult the task of individualized attention by the staff of doctors.

Two patients in this series developed minor physical sequelae. In one, Case 1, Patient T H, there was a definite change in the voice. The patient developed a very hoarse voice which improved after two months. No paralysis of the vocal cords has been demonstrated. The possibility of weakness of the superior laryngeal nerve was entertained. A second man, Case 3, Patient W P, developed weakness of the adductor of the left thumb and flexors of the left forefinger. Initially, sensory perception was lost over the dorsal and palmar aspects of the second and third fingers of the left hand. The sensory abnormalities disappeared, leaving the residual muscle weakness outlined. Physiotherapy has greatly improved this condition.

The possible permanent mental changes resulting from infection with the encephalitic virus would comprise a most interesting and fruitful field for study. Limitations of time and lack of trained psychiatric consultants pre-

vented a detailed investigation of this important aspect of the disease. Lack of knowledge concerning the behavioristic pattern of the patient prior to his illness represents an intrinsic impediment in a study of this type. Without proper controls only gross abnormalities can be attributed to the disease. None of these patients exhibited any marked impairment of the process of cerebration. Their intellectual ability was well within the normal range when tested by simple measures such as arithmetic problems, ability to exercise judgment in simple situations and general knowledge.

Emotionally a similar pattern of dependence was evident in three of them. Even when the storm of the illness had passed and the patients were alert and recuperating remarkably, there was a strong reluctance on their part to attend in any way to their own needs. Only with difficulty, with the exception of one patient (Case 1, Patient T H) were they persuaded to abandon their recumbent positions. They were very loath to accept again the responsibility of looking after themselves. One patient (Case 2 Patient M B) with a probable spondylitis was extremely happy in his prolonged convalescence and almost refused to attempt anything for himself except the actual eating of his meals. However, the remainder of the patients did bow to the inevitable and, with one exception, Case 5 Patient M W, were eager to return to their occupations. Case 5 Patient M W was anxious to return home provided she could convalesce for an indefinite period. Later it was ascertained that she promptly installed herself in bed at home and there remained for six weeks. The patient manifested extreme dependence, emotional lability and was excessively demanding of those who attended her. According to one of her friends she had definitely "changed" since her illness. Lapses in recent memory became obvious. Upon one occasion while entertaining guests her husband left the room for a few moments. Almost coincident with his departure his wife confided in a friend her anxiety concerning him as he had failed to return home that evening and had not called. Obviously with no adequate pre-confinement studies personality tendencies cannot indisputably be ascribed to the Japanese B virus.

One man (Case 1, Patient T H) who least displayed this type of personality dependence, developed a curious propensity for inserting himself into odd and dangerous situations. He had a definite proclivity for wandering through the women's ward at night. He was content to confine his wanderings to the corridors and never did he enter any of the rooms. He had no explanation for his behavior. In one instance he stopped the elevator between floors, climbed on top and was reclining comfortably when discovered. Again, there was no adequate explanation. However, these bizarre quirks of behavior disappeared rapidly, and the patient was quite embarrassed when they were recalled to his attention. Interestingly enough, these peculiar phenomena occurred when the man seemed alert and well oriented. It seems possible that the encephalitic damage occasioned these transitory abnormalities.

All of the convalescent patients were unusually cheerful. Even when residues such as facial nerve palsy or tremors were evident the patients ignored them magnanimously and refused to allow themselves to sink into the depths of depression. Only one patient (Case 5 Patient M W) was emotionally labile,

but even she usually maintained a cheerful equilibrium. This emotional lability persisted in her for approximately six weeks after discharge.

The routine course of immunization comprised the administration of 1 c c of the chick embryo vaccine at weekly intervals for two doses followed by an additional 1 c c one month later. Case 4, Patient J. S., had only two injections, Case 2, Patient M. B., had none, Case 1, Patient T. H., had completed his course of immunization, Case 3, Patient W. P., had been immunized in 1946 and had received a booster dose of 1 c c in 1947 and 1948, Case 5, Patient M. W., had received no immunization.

#### SUMMARY

1. A series of five serologically proved cases of Japanese B encephalitis is presented. Six other patients with the same signs and symptoms were hospitalized during the epidemic but are not included in the series as no positive serologic proof could be obtained.

2. Only two of the five patients had completed their immunizations against Japanese B encephalitis.

3. The clinical features are outlined.

4. In addition to rehydration and sedation when necessary, oxygen seems to be a valuable therapeutic adjunct.

5. Only two minor physical sequelae occurred in five cases. There were no deaths.

6. The possibility of personality changes, resulting from the encephalitic virus, is discussed.

7. Improved treatment will probably reduce considerably the high mortality rate for Japanese B encephalitis prevalent among the Japanese.

The author wishes to express his appreciation to the Virus and Rickettsial Section, 406th Medical General Laboratory, Tokyo, Honshu, Japan, for the determination of complement fixations and neutralization indices.

## PANCREATITIS IN INFECTIOUS MONONUCLEOSIS

JAMES MYHRE M.D. AND SAMUEL NESBITT M.D. PH.D.  
MINNEAPOLIS, MINN.

PANCREATITIS in association with mumps is often mentioned, though the literature on this point is not conclusive. Pancreatitis has been demonstrated definitely, however, in three patients with mumps, one at necropsy<sup>1</sup> and two at the time of surgical exploration.<sup>2</sup>

There are few autopsy reports of cases of infectious mononucleosis. In eight case reports<sup>3-5,6</sup> the pancreas was not mentioned. In three case reports<sup>8,9,10</sup> the pancreas was described as normal. There seems to be general agreement that infectious mononucleosis is a disease which may affect many organs.

Lucke and Mallory<sup>11</sup> in their excellent study of the pathology of hepatitis did not mention the pancreas. Capps<sup>1</sup> however mentions lesions occurring in the intestinal tract and in the pancreas. Comfort<sup>12</sup> noted in one case a persistent steatorrhea after infectious hepatitis and speculated on the association of pancreatitis with hepatitis.

In order to explore further the possibility that pancreatitis may be associated with other viral diseases, determinations of serum amylase and lipase were made at approximately weekly intervals on twenty consecutive patients with infectious mononucleosis and nine patients with viral hepatitis.

### MATERIALS AND METHODS

Serum amylase was determined by the Somogyi method.<sup>14</sup> Incubation times were determined to the nearest minute. The range of error in duplicate and triplicate determinations of the same specimen of normal serum was 0 to 36 per cent with a mean error of 6 per cent. Serum lipase was determined by the Cherry-Crandall<sup>15</sup> method as modified by Maclay.<sup>16</sup> Titrations were done with 0.1N NaOH to the nearest 0.1 cubic centimeter. The range of error on duplicate and triplicate determinations on the same specimen of normal serum was 0 to 50 per cent with a mean error of 14 per cent. The mean control amylase value based on thirty-six normal subjects was 146.4 units with a standard deviation of 55.7. Using three times the standard deviation as a criterion the upper limit of normal for this group would be 313.5 Somogyi unit. The mean control lipase value based on thirty-seven normal subjects was 0.27 cc with a standard deviation of 0.16. Using three times the standard deviation as a criterion the upper limit of normal for this group would be 0.75 cc of 0.1N NaOH.

From the Department of Internal Medicine, University of Minnesota School of Medicine and the Veterans Hospital.

Abstract of a portion of the thesis submitted by Dr. Myhre to the faculty of the Graduate School of the University of Minnesota School of Medicine in partial fulfillment of the requirements for the degree of Master of Science in Internal Medicine.

Received for publication Aug. 19, 1949.

## RESULTS

Two of the twenty patients with infectious mononucleosis presented abnormal serum enzyme values. In one patient values for both serum amylase and serum lipase were elevated, the highest serum amylase being 450 Somogyi units and the highest serum lipase being 17 c.c. of 0.1N NaOH. The second patient had abnormal values of serum lipase, the highest being 10 cubic centimeter. In this instance the values for serum amylase, although within the normal range, increased from 108 to 228 units. Liver function tests were done in nineteen of these patients and suggested an associated hepatitis in eighteen.

In nine patients with viral hepatitis, similar enzyme determinations at various stages of the disease gave normal results in all instances. Three were considered to be of the infectious type and six to be of the homologous serum variety.

Because of their particular interest, the two patients with infectious mononucleosis who, during the course of their illness, exhibited elevated serum enzyme values suggestive of an associated pancreatitis are presented in some detail (Table I).

CASE 1—A 24 year old, white, male school teacher, who had been in good health previously, was admitted to the hospital Jan. 3, 1948, complaining of headache and malaise of fourteen days' duration and of sore throat and fever up to 103° F for one week. Penicillin and sulfadiazine had been administered by his family doctor without benefit. Physical examination revealed an acutely ill patient, the temperature being 103.4° F, and the presence of cervical, inguinal, and axillary adenopathy, marked tonsillitis, hepatomegaly, and splenomegaly. The hemoglobin concentration was 12.6 grams per 100 c.c. of blood and the leucocytes numbered 20,800 per cubic millimeter of blood. The percentages of the various types of leucocytes were as follows: neutrophils 30, lymphocytes 66 (many of them atypical), monocytes 2, basophils 1, and eosinophils 1. The Kahn test was 2 plus. Albuminuria was graded 2 plus and microscopic examination of the urine sediment revealed 3 to 6 leucocytes, occasional erythrocytes, hyaline casts, and granular casts per high power field. Roentgenogram of the chest revealed moderate accentuation of the bronchovascular markings bilaterally and a faint suggestion of pneumonitis in the left lower lung field. Bromsulphalein retention was 10.5 per cent at 45 minutes using a dose of 5 mg. per kilogram per body weight. The result of the cephalin flocculation test was 3 plus in 24 hours and 3 plus in 48 hours. The one minute serum bilirubin was 0.2 mg. per cent and the total was 0.5 mg. per cent. Predominantly hemolytic staphylococci grew from a throat culture.

A clinical impression of infectious mononucleosis was corroborated by the relative and absolute lymphocytosis, the appearance of atypical lymphocytes in the peripheral blood smear, and a strongly positive heterophile antigen antibody agglutination titer. The laboratory studies are presented in detail in Table I.

On the thirty first day of illness the serum amylase was 450 units and the serum lipase was 17 cubic centimeters. In approximately twenty days these values had returned to normal. A glucose tolerance curve at the height of the elevation of serum amylase and lipase was normal.

Treatment consisted of bed rest, administration of 50,000 units of penicillin intramuscularly every three hours for the five days after admission, a high carbohydrate, low fat, and high protein diet with vitamin supplements and added brewers' yeast. The Kahn and Kolmer Wassermann tests were negative after the patient had been two days in the hospital. The abnormal urinary findings disappeared after one week. A roentgenogram of the chest, taken ten days after admission, was normal. One week after penicillin therapy was discontinued a maculopapular rash appeared over the trunk. The liver was enlarged and tender for approximately one month after admission. There was never any abdominal

pain or diarrhea but occasionally the patient complained of brackache. Appetite and strength gradually returned and the lymphadenopathy decreased. During the course of the illness the patient lost 23 pounds in weight.

CASE 2—A 21 year old, white student nurse who had previously been in good health was admitted to the hospital April 4, 1948, complaining of a slight cold and nasal congestion of five days' duration. Two days before admission she had noticed fever, fatigue, chills, sensations, and loss of appetite. Physical examination revealed an acutely ill patient with a temperature of 102° F. There was a slight mucoid nasal discharge. The throat was normal in appearance. The heart and lungs were within normal limits. A slightly enlarged, tender lymph node was found in the right anterior cervical region. The liver and spleen were not enlarged and there was no rash.

The hemoglobin concentration was 12.6 grams per 100 cc of blood and the leucocytes numbered 8,000 per cubic millimeter. The percentages of the various leucocytes were as follows: neutrophils 61, lymphocytes 34, monocytes 3, and eosinophils 2. The Kahn test for syphilis was negative. The urinalysis did not reveal abnormalities. Roentgenogram of the chest was normal. *Streptococcus viridans* and *Neisseria catarrhalis* grew from a throat culture. The heterophile antigen antibody titer was 1:448. The cephalin flocculation test gave 3 plus results in 24 hours and 48 hours. The one minute and total serum bilirubin concentrations were 0.2 and 0.5 mg per cent respectively and the bromsulfalein retention with a dose of 5 mg per kilogram of body weight was 11 per cent. Alkaline phosphatase was 10 King Armstrong units. The prothrombin time was 44 per cent of normal. Total proteins were 6.2 grams per cent with 3.3 grams per cent of albumin and 2.9 grams per cent of globulin. The blood cholesterol was 134 mg per 100 cc of serum with 42 per cent cholesterol esters. Bleeding time, clotting time, and platelet counts were normal. Two routine blood cultures and one blood culture with increased carbon dioxide tension were sterile. The blood was type O and Rh negative.

On the ninth day of illness the serum amylase was 108 Somogyi units and on the twentieth day, 158 units. On the twenty second day the serum lipase was 1.0 cc of 0.1N NaOH and on the twenty third day was 0.9 cubic centimeter. On the twenty fourth day the serum amylase and lipase were 228 units and 0.6 cc respectively. Subsequent values for serum lipase rapidly returned to normal and the serum amylase decreased to 120 units. At this time the fasting blood sugar was 96 mg per cent and the urinalysis for sugar was negative.

Subsequent development of an absolute lymphocytosis, the appearance of atypical lymphocytes in the stained peripheral blood smear, and a strongly positive heterophile antigen antibody titer established the diagnosis of infectious mononucleosis. See Table I for complete details of the laboratory studies.

On the tenth day of disease numerous petechiae were noted on the hard palate which persisted approximately four days. About the same time the normal pharynx became injected in appearance, the tonsils were covered by a grayish white membrane, and at this time the predominant organism on throat culture medium was nonhemolytic streptococcus. The sore throat accompanied by headache and pain on moving the eyes had nearly disappeared when, on the fifteenth day of illness, the patient became markedly anorexic and nauseated and vomited repeatedly. Treatment at this time entailed administration intravenously of solutions containing glucose, Parenamine, B complex vitamins, ascorbic acid, and Synkavite. The liver became tender to percussion but still was not enlarged. The patient became afebrile on the twenty second day of illness and by the twenty ninth day she was sufficiently improved to be discharged to her home for gradual resumption of activities. She had lost at least 8 pounds in weight.

#### SUMMARY AND CONCLUSIONS

1. Twenty consecutive cases of infectious mononucleosis were studied at weekly intervals and in two instances a definite elevation of the values of serum amylase and lipase was demonstrated. This finding is suggestive of an as

sociated pancreatic disturbance which to our knowledge has not been described previously in patients with infectious mononucleosis. This was possibly a pancreatitis, but lymph node obstruction of the pancreatic ducts must be considered.

2 In nine cases of viral hepatitis the serum amylase and lipase determinations were made at varying intervals and no elevated values were found. No conclusions can be drawn from this small series except that there was no evidence for pancreatitis at the time the determinations were made. This series should be extended and the possibility of pancreatitis occurring in other viral diseases should be explored.

3 It is quite possible that many asymptomatic acute subacute and chronic inflammatory changes of the pancreas exist in association with viral diseases which at the present time are not appreciated. It is conceivable that such infection may play a role in the etiology of chronic relapsing pancreatitis, the pathogenesis of which remains obscure.

## A CASE OF CONGENITAL IDIOPATHIC METHEMOGLOBINEMIA

BEN FISHER, M.D., AND J. WAIDE PRICE, PH.D.  
CLEVELAND, OHIO

THE differential diagnosis of cyanosis in the adult does not often present a difficult problem except in the instance of chronic, persistent cyanosis which does not vary. This is more interesting if the patient is middle aged or older, and if the cyanosis has been present during the greater part of his life. Proper consideration must be given to cyanosis produced by altered hemoglobin compounds within the circulating blood. The nature of the compound and its concentration in the blood are important in the diagnosis, treatment, and prognosis of these disorders. The three pigments (always intracorporeal) which most frequently produce cyanosis are reduced hemoglobin (as in cardiopulmonary disease), methemoglobin, and sulfhemoglobin. When these are present in the blood in concentrations of 5, 15, and 0.5 Gm. or less per 100 ml. of blood, respectively, cyanosis may be clinically evident.<sup>1</sup> Minute amounts of methemoglobin (0.03 to 0.13 Gm. per 100 ml.) have been reported in the blood of normal persons.<sup>2</sup> This may be a normal stage in the degradation of the pigment. The compounds have several definite chemical and physical properties by which they may be identified.<sup>3</sup>

Clinically, methemoglobinemia may be primary or secondary. The secondary type is more common and is most often due to drug toxicity. Anemia and/or granulocytopenia are usually accompanying findings in chronic cases, and the systemic effects are striking. Of much less frequent occurrence is the primary type. There is no anemia, indeed, a polycythemia is often present apparently as a compensatory measure. Systemic symptoms are exceptionally mild, and a familial incidence has been noted in many of the cases reported. Since the condition is rare, the following case is believed to be of interest.

### CASE REPORT AND EXPERIMENTAL STUDY

A 61-year-old white man was admitted to the Marine Hospital with complaints of failing vision in both eyes. On physical examination, bilateral cataracts were discovered. It was also noted that the patient had a marked cyanosis of the mucous membranes, lips, and fingers, and a slate gray color of the skin all over the body. There was no clubbing of the digits, and the conjunctival and retinal blood vessels were engorged. The patient stated that his blue gray skin coloring had been present "since birth," and that people had frequently remarked about it when he was a child. No other familial instance could be elicited. There was no history of prolonged drug ingestion, and system review failed to disclose any abnormality of gastrointestinal function. The patient had no complaints other than his visual disturbance, and cardiopulmonary disease was ruled out by physical examination, x-ray and fluoroscopic studies, and normal electrocardiographic tracings.

From the United States Marine Hospital and the Institute of Pathology, Western Reserve University School of Medicine.

Received for publication Aug. 29, 1949.

The patient was seen in consultation by Dr. A. J. Beams, who suggested a diagnosis of idiopathic methemoglobinemia. A sample of blood was examined and found to contain total hemoglobin 21.9 Gm. per 100 ml. oxyhemoglobin 14.3 Gm. and the difference 7.6 Gm., was nonfunctional hemoglobin which showed a spectroscopic absorption band similar to that of a known methemoglobin solution. Laboratory findings at this time revealed nothing of significance except an icterus index of 17.6 units, red blood cells, 6,350,000 per cubic millimeter, and a hematocrit of 68 per cent packed red cell. The red cell indices revealed a mean corpuscular volume of 106 cmm. and mean corpuscular hemoglobin concentration of 29.2 per cent. The white blood cells were normal.

Fig 1—Sternal bone marrow ( $\times 950$ ) showing normoblastic hyperplasia

The patient was operated on for a cataract of the left eye and then discharged from the hospital. Four months later he was asked to return to the hospital and was admitted to the medical service for further study of his methemoglobinemia. On this second admission he had no complaints and was not dyspneic. The physical examination was essentially the same as on the first admission except for a partial left iridectomy and absence of that lens. The blood pressure was 150/94, temperature 96.2 F, pulse 80, and respirations 24. The red blood cell count was 5,930,000 per cubic millimeter with a hemoglobin of 18.9 grams. The hematocrit was 61 per cent. When venous blood was drawn it had a dark chocolate brown color. Exposure of the blood to air over a period of twenty-four hours produced no noticeable change in color and long periods of oxygen inhalation did not affect the patient's cyanosis. The reticulocytes numbered 0.7 per cent and the icterus index was 13.0 units. The total hemoglobin measured 19.9 Gm., oxyhemoglobin, 12.5 Gm. and methemoglobin 7.4 Gm. per 100 ml. of blood prior to the beginning of therapy. Aspiration of sternal bone marrow yielded a moderately thick marrow which was also chocolate brown in color. The centrifuged marrow showed fat 5 per cent, plasma 12 per cent, buffy (myeloid erythroid) layer 9 per cent, and red cells 3 per cent. Marrow smears showed an erythroid hyperplasia at the normoblast level (Fig 1).

wished to be discharged from the hospital. He was placed on outpatient status and given a supply of ascorbic acid but he failed to return for follow up. Two months later he returned for more ascorbic acid, and further data were then obtained. His skin color was definitely a normal pink hue, and the venous blood had a normal dark red color. The laboratory findings at this time are listed as '83rd day' in Table I and Fig. 2. The bone marrow showed no significant change.

#### DISCUSSION

This case was of interest for several reasons: the chronicity of the illness, the high initial methemoglobin level and the response during the period of therapy. The patient was able to carry on strenuous work over a period of years as a merchant seaman without dyspnea, fatigue or other constitutional symptoms. Finch,<sup>1</sup> who reviewed this subject exhaustively in 1948, stated that he saw a patient with a methemoglobin level of 40 per cent who was able to carry on strenuous work; our patient had 37.2 per cent. A more remarkable point of interest arose during the course of therapy. Although the usual response with treatment is a reduction in methemoglobin and total hemoglobin, our patient exhibited a different course. As the methemoglobin decreased the total hemoglobin remained stationary and the oxyhemoglobin level rose. The red cell count and hematocrit also remained fairly stationary. This was entirely contrary to our expectations since we anticipated hemolysis of the excess erythrocytes as the methemoglobin was reduced. Undoubtedly the chronic anoxemia present for so many years proved a potent stimulus to the erythrogenic elements of the bone marrow. Had we been able to follow the patient for a longer period it would have been interesting to note how long a time elapsed before the number of circulating red cells became reduced in number.

At least sixteen proved cases of congenital idiopathic methemoglobinemia had been reported in the literature up to the time of Finch's review (1948). In eight there was a familial incidence. In 1947, Coudounis and associates<sup>2</sup> reported fourteen cases all occurring in a Greek family within four consecutive generations, four pairs of siblings were affected by the syndrome. The name of the family was Vophtochulari which the authors translated as 'people with discolored lips'. Sievers and Ryan<sup>3</sup> stated that they were able to tabulate eighteen reported cases up to 1945 and they added one of their own. Gibson and Harrison (1947)<sup>4</sup> reported five cases in one family. Bensley, Rhea and Mills (1938)<sup>5</sup> reported two cases occurring in a brother and sister and stated that these were the first in which the diagnosis was established definitely. They added that the cyanosis was constant and was not affected by any form of therapy; vitamin C was not used.

Other cases have been reported in the literature from time to time. In some, history of drug intoxication could not be ruled out. Others were given the name of "enterogenous cyanosis" supposedly associated with constipation and production of large amounts of nitrites by the bacteria of the intestinal tract.

To Lian<sup>6</sup> is ascribed the first use of ascorbic acid in the treatment of methemoglobinemia. It was believed to be superior to methylene blue. Ascorbic

acid has been used in many of the cases reported since then, almost all with excellent results<sup>10</sup> The oral route is as effective as the parenteral, and Graybiel and co-workers<sup>9</sup> have found that concomitant administration of sodium bicarbonate decreases the urinary excretion of vitamin C and the rate at which it disappears from the blood King, White, and Gilchrist<sup>10</sup> found that regardless of the amount of ascorbic acid given to their patient, the methemoglobin level could not be reduced below 7 per cent of the total blood pigment Gibson and Harrison<sup>6</sup> also found that they were not able to reduce the total methemoglobin below 10 Gm per 100 ml of blood by the use of vitamin C Our findings, over a short period of time, are similar to these

Normally, the mammalian anuclear erythrocyte reduces methemoglobin by an enzymatic process in which glucose and lactate are the principal substrates Clinical methemoglobinemia may then be produced by absence or failure of this reconversion mechanism (primary) or by the action of oxidants which produce methemoglobin more rapidly than the cell is able to reduce it (secondary) Further, the oxygen dissociation curve is normal in primary methemoglobinemia, whereas that induced by drugs shows a shift to the left<sup>1</sup>

Gibson proposes that the erythrocytes of primary methemoglobinemic patients are deficient in coenzyme factor I, which functions with those phosphoric and lactic enzymes of the red blood cell to facilitate reduction of methemoglobin to hemoglobin Methylene blue is therefore thought to catalyze reduction of methemoglobin by enzymes otherwise unable to bring about this reaction Ascorbic acid, by contrast, reduces methemoglobin directly, but is never complete<sup>6</sup>

These differential diagnostic features are important in providing the proper therapy for methemoglobinemia

#### SUMMARY

A case of congenital idiopathic methemoglobinemia in a 61-year old man is presented The patient was treated with daily oral doses of 300 mg of ascorbic acid and showed an excellent, though somewhat unusual, response to therapy The case is of interest because of the age of the patient, the chronicity of the disease, and the trend during therapy Some of the pertinent literature is reviewed briefly

# LABORATORY METHODS

## A SIMPLIFIED TURBIDIMETRIC METHOD OF AUREOMYCIN ASSAY FOR CAPILLARY BLOOD AND OTHER BODY FLUIDS

COLEMAN M. WHITLOCK, JR., M.D., ANDREW D. HUNT, JR., M.D., AND  
SYLVIA G. TASHMAN, A.B.  
PHILADELPHIA, PA.

FROM studies on various methods of bio-assay for aureomycin, a turbidimetric method has evolved which is sufficiently accurate and sensitive in the presence of body fluids for investigative purposes and is sufficiently simple for routine use. It also meets a prime requirement for pediatric use in that an amount of blood adequate for serum assay can be obtained from a single finger or heel puncture. Osgood and Graham<sup>1</sup> developed a similar turbidimetric method of assay for penicillin, streptomycin, and trivalent organic arsenicals. Meads and co-workers<sup>2</sup> adapted it to the assay of aureomycin. We found that for aureomycin the accuracy of this method in the presence of body fluids is increased appreciably by substituting a standard curve containing four points for the single standard used by the original workers and that this change also simplifies the method by eliminating most of the mathematical details involved in computing the results.<sup>3</sup> Several other minor modifications were also helpful. It therefore seems worth while to publish the details of this method as it is being used in our laboratory.

### DETAILS OF TECHNIQUE

**Materials**—A Klett Summerson colorimeter with a No. 660 filter, sterile matched colorimeter tubes with rubber stoppers, 0.85 per cent saline, 1 and 5 c.c. pipettes, a 37° C. water bath, an ice water bath in the refrigerator, and standardized, uncontaminated test organism (Oregon J strain of *Staphylococcus aureus*—American Type culture collection No. 9801) are used.

The organism is standardized as follows: 5 ml. amounts of a fresh one to three hour broth culture\* are added to 100 ml. amounts of sterile Bacto Tryptose Phosphate Broth (Difco), which is then incubated in the 37° C. water bath until the optical density of the culture is determined by colorimeter readings at fifteen minute intervals is approximately fifteen points (twelve to eighteen points) greater than that of a broth blank. This usually takes two and one half to three hours. At this point, growth is stopped by transferring the culture to the ice water bath. Thus, the standardized culture, is kept in the ice water bath until used and is made up fresh every four days.

From The Children's Hospital of Philadelphia (Department of Pediatrics School of Medicine University of Pennsylvania)

The aureomycin used in this study was supplied by Lederle Laboratories Division of the American Cyanamid Company.

These studies were conducted under contract with the Department of the Army Chemical Corps Camp Detrick Maryland.

Received for publication Aug. 1 1949.

\*This is prepared by inoculating Bacto-Tryptose Phosphate Broth from the stock culture. The stock culture is kept on a nutrient agar slant in the refrigerator. A fresh slant is prepared every two weeks. Each new slant is checked for contamination before use.

A series of previously matched cotton plugged sterile colorimeter tubes is arranged for assay as shown in Table I. As soon as all dilutions are made, sterile rubber stoppers are inserted into the tubes and the solutions agitated by inversion of the tubes. The colorimeter is set at zero with the blank tube, and the turbidity of each remaining tube is read rapidly in a predetermined order. Immediately after reading each tube is placed in the 37° C water bath. Four hours later each tube is individually removed from the water bath, wiped, agitated, and reread in the same order.

\*Contains no added aureomycin

†Aureomycin dilutions freshly made from a 5000 µg per milliliter of aureomycin solution which is made up fresh every two weeks from lyophilized aureomycin and kept at 4° C

‡Added last while still at 4° C

Computation of the results hinges on the principle demonstrated by Good† that in the case of a sensitive organism when sufficient bacterial growth has occurred to provide for differences that can be accurately measured the concentration of the appropriate antibiotic is proportional to the square of the difference between the turbidity of a control tube and the turbidity of a tube containing the antibiotic. The details are described as follows and are illustrated in Table II. The increase in turbidity between the four hour reading, and the zero hour reading is determined in each of the four standard tubes (containing known amounts of aureomycin), each of the unknown tubes (containing the body fluid to be assayed) and the control tube (containing no aureomycin). The increase in turbidity (which is the measurement of bacterial growth during the four hours of incubation) of each standard tube and each unknown tube is then subtracted from the increase in turbidity of the control tube. The difference in turbidity increase between the control

TABLE II. COMPUTATION OF RESULTS FOR A SERUM STANDARD CURVE

Concentration in saline added to tubes. Final concentration is one tenth of this

†This reading corrects for slight differences in optical density of the individual tubes and individual specimens

tube and each of the standard and unknown tubes is squared and is, by definition, proportional to the amount of antibiotic present. The squared values for the standards are plotted along the abscissa of semilog paper against the known concentrations of aureomycin per milliliter of saline (see Fig 1 and Table I). A standard curve is drawn through the four points obtained. The concentration of aureomycin in the unknowns is read off this curve using the squared values for the unknowns obtained as described.

SERUM STANDARD CURVE

Fig 1—The four standard points are plotted in large dots while twelve simultaneously determined intermediate values are plotted in small dots. The concentrations of aureomycin plotted on the ordinate of this graph are ten times the final concentration of aureomycin in the standard tubes and therefore correspond to the concentration of aureomycin in an unknown solution before it is diluted by addition of saline and standardized test culture (see Table I).

Blood is collected from a finger or heel puncture and the serum is separated for assay as previously described by one of us (A D H).<sup>4</sup> The collecting tube is made either from a three inch length of glass tubing, with one end sealed, or from a 7.5 by 95 mm shell vial. The open end is drawn out to a capillary tip and sealed. The wide portion of the tube is held over the flame and an air vent is quickly produced in the softened glass by the expanding air within the sealed tube. For the collection of blood, the capillary tip is broken off near its base. The finger or heel is punctured so that a free flow of blood is obtained. The tube is held in as nearly vertical a position as possible and the blood readily flows into the tube and down to the base. The tubes are stood upright until the blood is clotted, then the tube is filed off just above the surface of the blood. The clot is broken up with an applicator stick and the tube is centrifuged at 1,500 to 2,000 revolutions per minute for fifteen minutes. The supernatant serum is then pipetted off with a capillary pipette for assay. After a little practice with this technique, one can consistently collect 1.5 ml or more of capillary blood from a single skin puncture.

Unknown serum and spinal fluid specimens are run in 1:1 and 1:8 dilutions,\* thus bringing a maximum of 8  $\mu$ g per milliliter of aureomycin within the detectable range of the method. Similarly, unknown urine specimens are run in 1:20 and 1:160 dilutions to detect a range of 5 to 320  $\mu$ g per milliliter of aureomycin. These predilutions are made in the type of body fluid being assayed. Serum† for them is obtained from the blood bank,

\*For maximum accuracy a separate pipette is used for each step in the dilution of serum specimens.

†Twenty individual specimens of human serum were tested simultaneously under the conditions of this method and no significant difference was found in the growth of the test organism among these sera. Serum however does stimulate the growth of the test organism markedly when compared with the assay broth. Keeping the serum concentration constant in all the tubes of a serum assay controls this factor. However the concentration of aureomycin in an unknown specimen is calculated from the tube with the greatest predilution when there is a choice since most of the body fluid in prediluted specimens comes from the same source as the body fluid used in the standard and control tubes.

spinal fluid from air encephalographic studies and urine from laboratory personnel. All body fluid for dilution of unknown specimens is kept frozen until used. Correction for such dilutions is made in calculating the results.

Aureomycin in a concentration of 1  $\mu\text{g}$  per milliliter in serum and 40  $\mu\text{g}$  per milliliter in acid urine shows no appreciable loss of activity when kept at  $-20^\circ\text{C}$  for one week. However, aureomycin in spinal fluid in a concentration of 0.25  $\mu\text{g}$  per milliliter shows about a 50 per cent loss of activity if kept at  $-20^\circ\text{C}$  overnight. Therefore unknown specimens of serum and acid urine are kept at  $-20^\circ\text{C}$  until a convenient time for assay, but spinal fluid unknown specimens are assayed on the day collected. The pH of all urine used is adjusted to 7.2 just before assay.

Replicate determinations of either control standards, or unknowns do not appreciably enhance the accuracy of the method. A separate standard curve is required for each type of body fluid on each day of assay.

### RESULTS

The results of one hundred and four consecutive determinations of known concentrations of aureomycin intermediately spaced between the values used to make up the standard curve are tabulated in Tables III, IV, and V. One experiment using serum is illustrated in Fig. 1 in which it will be noticed that the standard curve approaches a straight line on semilog paper. A similar straight line is obtained with the other two body fluids tested. The percentage error of each determination has been computed. For urine, the range of error is 0 to 42 per cent with a mean of 12.4 per cent, for spinal fluid the range is 0 to 35 per cent with a mean of 12.3 per cent, for serum the range

	4	—	0 78	—	—	0 68	0 44	—	0 32	0 20	0 14

is 0 to 35 per cent, with a mean of 83 per cent. The accuracy of this method appears to be distinctly superior to that we achieved, in the presence of body fluids, with the original turbidimetric method of Meads and a serial dilution method of aureomycin assay<sup>3</sup>. Furthermore, it is possible to detect 0.1  $\mu\text{g}$  of aureomycin per milliliter or less in the presence of the three body fluids tested, so that its sensitivity compares favorably with the sensitivity of the other methods currently in use<sup>3</sup>. The method is not as accurate in concentrations below 0.125  $\mu\text{g}$  per milliliter as in higher concentrations, however.

#### CONCLUSION

A modification of Meads' turbidimetric method of aureomycin assay has been described. It appears to provide a simple and accurate means of assaying low concentrations of aureomycin in small volumes of various body fluids.

## A MICROMETHOD FOR BLOOD PENICILLIN ASSAY

GAVIN HILDICK SMITH M.D., AND MARY FELL, B.S.  
PHILADELPHIA PA

IN MAKING frequent penicillin plasma determinations in children, it is helpful if a method can be used which requires such a small amount of blood for each assay that it can be obtained from a puncture wound of the finger as opposed to withdrawal by venipuncture. Fielding<sup>1</sup> described a micromethod requiring as little as 0.25 ml. of fluid for assay in which the test organism was the Oxford strain of *Staphylococcus aureus* grown in glucose serum medium containing Andrade's indicator. The principle of the test was the detection by means of the color indicator, of the pH change induced in the medium by the breakdown of glucose during the growth of the test organism. When the growth of the organism was prevented by a given amount of penicillin then no color change would occur. The minimum amount of penicillin which prevented the growth of the organism was that present in the last tube showing no color change.

In the procedure described by Fielding, the test organism and body fluid to be tested were mixed on a paraffined slide and then taken up in capillary tubes following the technique of Fleming.<sup>2</sup> Because this technique is not commonly employed routinely in this country it seemed advisable to attempt to utilize the same principle and devise a micromethod employing the more conventional procedures involved in serial test tube dilutions. The method to be described fulfills the following criteria: (1) It requires only that amount of blood which can be taken easily from a finger prick. (2) It uses an easily prepared test medium. (3) The end point is easily read by means of a sharp color change. (4) The procedure is one commonly employed in serology. (5) Finally its accuracy appears to be superior to that obtained by the widely employed method described originally by Rammelkamp<sup>3</sup> and frequently modified.

### TECHNIQUE

*Collecting of Blood*—The tube which was found convenient for drawing blood and separating the serum has been described previously<sup>4</sup> and is illustrated in Fig. 1\*.

Blood was taken from finger or heel puncture by capillary attraction and allowed to clot in the body of the tube. The tube was then filed and broken off above the level of the blood which was then centrifuged at 1500 to 2000 rpm for ten to twenty minutes. The serum that separated was pipetted off for testing.

*Organism*—The organism used in this laboratory was *Staph. aureus* (F.D.A. strain 909). There is no reason why any penicillin sensitive easily cultivated organism could not

\*From The Children's Hospital of Philadelphia (Department of Pediatrics School of Medicine University of Pennsylvania).

The work described in this paper was done under a contract with the Biological Department Chemical Corps, M.V. Division, Camp Detrick, Frederick, Md.

Received for publication Aug. 1, 1949.

Shell vials 9, by 7.5 mm. or glass tubing of 7 mm. bore and of convenient length (90 to 100 mm.) sealed at one end can be used. The open end is drawn out to capillary tip and called a small hole is blown through the wall of the tube by heating it 1 mm. below the beginning of the capillary portion.

be used equally well. The organism, after a preliminary incubation at 37° C, was kept as a stock culture on plain nutrient agar (Difco) in a refrigerator. It was subcultured once a week onto fresh agar. When required for the test, the organism was transferred to nutrient broth (Difco) and incubated at 37° C for eighteen hours. A portion was then diluted 1:1,000 in the assay medium to be described below.

Fig. 1

*Medium*—The assay medium was phenol red dextrose broth made up as follows:

Nutrient broth (Difco)	8 Gm
Dextrose	5 Gm
Aqueous phenol red	25 ml
Distilled water	1,000 ml

This was adjusted to pH 8 with N sodium hydroxide using the phenol red (0.04 per cent concentration) as indicator, the final color being red. After autoclaving for fifteen minutes at 15 lb, the medium was ready to use without further adjustment of the pH.

*Procedure*—The test was arranged so that one half step dilutions were used, and a triplicate penicillin control test was included with each series of unknowns.

*Control*—This was included routinely to detect the sensitivity of the test organism. A penicillin solution was made up in the assay broth in such a way that the penicillin concentration was 0.5 unit per milliliter. The one half step dilutions were made as follows: Three sets, each containing thirteen plugged, sterile Wassermann tubes (100 by 13 mm), were arranged in suitable racks. In each set of tubes, the following steps were carried out. The test medium (phenol red dextrose broth) was added in 0.1 ml amounts to tubes 1, 3, and 4 to 12 inclusive. Tube 2 was left empty, and 0.2 ml of the test medium was added to tube 13. The penicillin solution was then added in 0.1 ml amounts to tube 1 which made a 1:2 dilution and to tube 13 which made a 1:3 dilution. Tube 1 (1:2 dilution) was then used after thorough mixing, for preparing one series of twofold (one step) dilutions by transferring 0.1 ml, serially to the odd numbered tubes 3 to 11, 0.1 ml from tube 11 being discarded. From tube 13, which contained 1:3 dilution of penicillin, 0.1 ml was added to the empty tube 2 (1:3 dilution) and to tube 4 which already contained 0.1 ml assay broth (1:6 dilution). Tube 13 was then discarded. Tube 4, after thorough mixing, was used to initiate the second series of twofold (one step) dilutions by transferring 0.1 ml serially to the even numbered tubes 6 to 12, 0.1 ml from tube 12 being discarded. Tubes 1 to 12 in each set then contain 0.1 ml of assay medium, with concentrations of penicillin decreasing from 1:2 to 1:96 by one half steps.

*Test Fluids*—A maximum of 0.2 ml was required for each test fluid. Except that only one set of tubes was run, this was handled in a similar manner to that just described, the fluid taking the place of the known penicillin solution.

*Test Organism*—0.1 ml of the 1:1,000 dilution of the eighteen hour culture of the test organism described was then added to every tube and the complete series incubated overnight at 37° C.

*End Point*—Since, with this indicator, a change from red to yellow indicates a lowering of pH resulting from bacterial growth, the end point was taken as the last tube in each set in which the original red color of the medium was unaltered. This end point was usually quite sharp. Since the controls were set up in triplicate, it sometimes occurred that the end point varied somewhat in one of the three sets, although this variation was seldom more than one half step off in either direction. The end point taken was that reached in two of the three control sets. If there was no such agreement, the test was considered invalid.

**Calculation**—First, the sensitivity of the organism was calculated from the controls. Since the concentration of penicillin in the first tube of each control series was 0.5 unit per milliliter the concentration in any subsequent tube could be calculated by dividing 0.5 unit per milliliter by the reciprocal of the dilution of that tube. For example, if the end point in two of the three control series was found to be tube 7 or a 1:16 dilution then the organism was sensitive to a concentration of  $\frac{0.5}{16}$  or 0.03 unit per milliliter.

The concentration of penicillin in any unknown body fluid was easily calculated by multiplying the sensitivity of the organism, as determined in the preceding paragraph by the reciprocal of the dilution of body fluid contained in the end point tube. For example, if in the test the sensitivity of the organism was 0.03 unit per milliliter and the end point of the body fluid being tested was found to be tube 5 or 1:8 dilution then the concentration of penicillin in the original body fluid was  $0.03 \times 8$  or 0.24 unit per milliliter.

In the laboratory it was found convenient to record the dilution and the end points of the controls and the test fluids on squared paper. This avoided any mistake in the dilutions (Table I).

TABLE I SAMPLE CHART FOR MICRO PENICILLIN ASSAY

TUBE	1	2	3	4	5	6	7	8	9	10	11	12	PENICILLIN (UNITS/ML.) DETECTED

PENICILLIN (UNITS/ML.)	0.25	0.17	0.125	0.085	0.065	0.04	0.03	0.02	0.015	0.01	0.0075	0.005	
Control 1							x						0.03
2							x						
3													
Pt 1	1/2 hr						x						0.06
1 1/2 hr							x						0.36
3 hr													0.12
Pt 2	1/2 hr												1.44
1 1/2 hr								x					0.48
3 hr													0.18
Pt 3	1/2 hr												0.48
1 1/2 hr													0.48
3 hr													0.24

**Accuracy of the Method**—This method was first tested on five different occasions by attempting on each occasion to determine the amount of penicillin in each of five twofold serial dilutions of a known concentration of penicillin in distilled water. Table II shows the results obtained by the method just described. It can be seen that the recoveries at each dilution were remarkably close to the amount of penicillin actually present. The average of the tests was  $\pm 8$  per cent, although individual readings sometimes deviated as much as 44 per cent. Comparison with the results obtained by the Rammelkamp method

TABLE II DETERMINATION OF ACCURACY OF MICROMETHOD OF PENICILLIN ASSAY

KNOWN PENICILLIN CONCENTRATION	UNITS/ML. OF PENICILLIN IN SERUM				
	0.1	0.5	1.0	2.0	4.0
Test 1	0.12	0.48	1.08	1.92	3.84
Test 2	0.12	0.72	1.08	1.92	3.84
Test 3	0.12	0.48	1.08	1.92	3.84
Test 4	0.12	0.72	0.72	1.92	84
Test 5	0.09	0.48	1.08	1.92	3.84
Average	0.11	0.57	1.0	1.92	84

(Table III) indicates that the micromethod was more accurate. However, there appeared to be a definite relationship between the two, the micromethod giving a consistently higher reading by a factor of 1.6. Fig. 2 shows a graphic comparison of the known concentrations of penicillin and the recoveries by the two methods used.

TABLE III DETERMINATION OF ACCURACY OF THE MODIFIED RAMMELKAMP METHOD OF PENICILLIN ASSAY

KNOWN PENICILLIN CONCENTRATION	UNITS/ML OF PENICILLIN IN SERUM				
	0.1	0.5	1.0	2.0	4.0
Test 1	0.052	0.3	0.832	1.22	2.43

Average	0.052	0.3	0.71	1.15	2.43

COMPARISON OF MODIFIED FIELDING AND RAMMELKAMP METHODS OF PENICILLIN BIO-ASSAY

Fig. 2

Following the demonstration that known amounts could be assayed with a good degree of accuracy, this test has been used successfully for hundreds of routine assays of penicillin levels in body fluids.

SUMMARY

A micromethod for the estimation of penicillin levels in blood or other body fluids, requiring only 0.2 ml for the test, is described. Sufficient blood can be collected conveniently from a single puncture wound of the finger. A convenient collecting tube for obtaining serum is described and illustrated.

The principle employed in the test is the detection of growth of the test organism in a glucose containing medium by the demonstration of acid formation by the color change of a suitable indicator. The end point is taken as the last tube to show no evidence of color change. By including controls in each test, the quantity of penicillin in an unknown penicillin fluid can be calculated. The accuracy of the method is greater in our hands than the commonly employed Rammelkamp method and it has proved a convenient assay method for routine use in children.

# THE PRODUCTION OF ANTIRABBIT HEMOLYSIN

ARDZROONY A. PACKCHANIAN, PH D  
GALVESTON, TEXAS

THE hemolytic system most commonly used in complement fixation tests consists of sheep erythrocytes and antisheep hemolysin. A supply of fresh sheep erythrocytes for the performance of the test necessitates constant maintenance of a few sheep on the premises, which is often inconvenient. Attempts have been made by Vedder<sup>1</sup> and by me<sup>2</sup> to overcome this difficulty by a different hemolytic system. The object of the present communication is to describe another modification, in which the role of rabbit and sheep is reversed. Rabbit erythrocytes are employed with an antirabbit hemolysin of the sheep.

## METHODS AND MATERIALS

Five sheep were selected for this study, two adult males, two adult females, and one female lamb.

To each 50 ml of freshly drawn rabbit blood about 2 ml of 0.4 per cent sodium citrate were added to prevent clotting. The erythrocytes were washed three times in sterile 0.9 per cent NaCl solution and the packed red blood corpuscles were resuspended in equal volume of saline for inoculum.

Hemolyzed rabbit red blood corpuscles and the stroma of rabbit erythrocytes as prepared by Vedder were tried out as an alternate inoculum.

The inoculations were either intravenous or subcutaneous or both, and the dose for each inoculum varied from 5 ml to 200 milliliters. Control blood samples were taken from the sheep before initial inoculations. Samples were taken also at the end of each course of immunization and after inactivation at 56° C for thirty minutes they were tested for hemolysin.

Antirabbit hemolysin titrations were made with 2 per cent washed rabbit erythrocytes. In some of the tests, titrations were made with blood taken from the same rabbits that had been bled previously for immunization of the sheep.

Pooled guinea pig complement in dilutions of 1:15 and 1:30 was used in the hemolysin titrations. The titration was checked by using the standard Kolmer hemolysin titration test with antisheep hemolysin and 2 per cent sheep red corpuscles.

Wassermann positive and Wassermann negative human sera were tested with the antirabbit hemolysin and 2 per cent washed rabbit erythrocytes by the modified Kolmer method and with the standard Kolmer Wassermann complement fixation test, Kolmer,<sup>3</sup> and the results were compared.

## EXPERIMENTAL DATA

The five sheep used in this study differed in their production of antirabbit hemolysin.

The sheep which were inoculated with large doses of rabbit erythrocytes at frequent intervals produced hemolysin promptly and in higher titer as compared with the sheep which were inoculated with smaller doses of erythrocytes.

From the Department of Bacteriology and the Laboratory of Microbiology, School of Medicine, The University of Texas.

This study was supported by the United States Navy Office of Naval Research.

The writer wishes to express his thanks to Dr. W. B. Sharp, Miss Lorraine Turck, Dr. Frank Wappler, and Dr. Louise Wilcox for their interest and assistance in this study.

Received for publication Aug. 1, 1949.

even when inoculations were spread over a longer period of time. When sheep were immunized for hemolysin, it was noted that agglutinin for rabbit erythrocytes occurred much sooner and in higher titer than did antirabbit hemolysin, particularly when the period of immunization was prolonged. Thus Sheep A at the end of seventeen days had no hemolysin while the agglutinin titer was 1,240. The same sheep at the end of ninety-three days of immunization had a hemolysin titer of 1/30 and the agglutinin titer was 1/10,240.

In Sheep D and L, which were immunized in massive doses and at frequent intervals, agglutinin and hemolysin occurrence were almost simultaneous.

The results of the production of antirabbit hemolysin in sheep are summarized in Table I.

Sheep A (male) which was immunized with small quantities (5 to 10 ml) intravenously of washed rabbit erythrocytes produced hemolysin after sixty-nine days of immunization; however, during the entire course of immunization (ninety-three days) hemolysin titer never exceeded 1/30.

Sheep B (male) received sixty-nine injections totaling 250 ml of lysed rabbit erythrocytes and 2,455 ml of washed rabbit erythrocytes in a period of 290 days. The immunization of this sheep was begun with small amounts (10 ml) of hemolyzed red blood corpuscles. During fifty days of immunization, this sheep was inoculated nineteen times with 190 ml of hemolyzed erythrocytes. At the end of this period, the hemolysin titer was only 1/4. Since the lysed corpuscles failed to produce a significant hemolysin titer and inasmuch as Sheep A already had produced hemolysin following injection of intact erythrocytes, at this stage the inoculation of lysed erythrocytes was discontinued. Subsequent inoculations with rather large doses (25 to 100 ml per inoculum) of intact erythrocytes increased the hemolysin titer to 1/80. Prolongation of immunization instead of increasing decreased the hemolysin titer to 1/20 (see Table I).

Sheep C (female) received thirty injections totaling 1,400 ml of washed rabbit erythrocytes and 110 ml of stroma of rabbit erythrocytes during a period of 234 days. The immunization of this sheep was begun with rather large doses of washed rabbit erythrocytes and the highest hemolysin titer obtained was 1/20. Since the sheep manifested mild anaphylactic symptoms, intravenous inoculations were substituted with stroma. In spite of further immunization with stroma, which subsequently was followed with intact erythrocytes, the hemolysin titer did not increase (see Table I).

Sheep D (pregnant female) was immunized with fifty-four injections totaling 200 ml of washed rabbit erythrocytes in a 212-day period. The immunization of this sheep was done with massive doses and at frequent intervals. Hemolysin with titer of 1/40 was present as early as twenty-three days following initial inoculation. While the sheep was undergoing immunization, it gave birth to a lamb. Four days after the lamb was born, blood samples taken from the sheep showed hemolysin titer of 1/320. Subsequent inoculations with 50 and 100 ml of washed erythrocytes were at times accompanied with slight to moderate anaphylactic reactions such as sneezing, coughing, discharge of feces and bloody urine, weakness, inability to move, salivation, tremors, and dyspnea.

	30 30	210	-	-	-	-	SC	1 to 12	12	190	1 10

In spite of continuation of immunization the hemolysin titer never exceeded 1:320, but diminished to 1:40. During the last intravenous inoculation, the sheep died of anaphylactic shock.

**Sheep D.** This female lamb born to immunized Sheep D was tested at the age of 2 months for the presence of possible anti-rabbit hemolysin with negative results. This was followed by forty injections of rabbit red blood corpuscles totaling 2510 ml during 180 days. The first seven inoculations were made intravenously in 200 ml amounts every other day. The highest hemolysin titer obtained at various stages of immunization was 1:20 (see Table I).

Anti-rabbit hemolysin with a titer of 1:40 or above and a 2 per cent suspension of washed rabbit erythrocytes was tested with Wassermann positive and Wassermann negative human sera by Kolmer technique because of the low hemolytic titer of anti-rabbit hemolysin. Relatively large amounts of this hemolysin were used. As a control parallel tests were made with Kolmer Wassermann method. Forty two syphilitic and forty two normal sera were run by each method. The results of this test were clear cut and known positive samples gave positive readings and negative samples gave negative readings by both procedures. The findings by the experimental method were identical with those obtained with anti-sheep hemolysin and washed sheep erythrocytes as used in the usual Wassermann test.

#### SUMMARY

Anti-rabbit hemolysin was produced in sheep by inoculating them intravenously and subcutaneously with washed rabbit red blood corpuscles. The hemolysin titer required by these animals ranged from 1:10 to as high as 1:320.

Hemolyzed erythrocytes and stroma injected into sheep for the production of hemolysin did not produce as high a titer as washed erythrocytes.

Anti-rabbit hemolysin and 2 per cent washed rabbit erythrocytes were used in testing syphilitic and normal sera by modified Kolmer Wassermann technique. The results obtained in every instance were clear cut and of diagnostic value.

# DIFFERENTIATION AND ENUMERATION OF EOSINOPHILS IN THE COUNTING CHAMBER WITH A GLYCOL STAIN, A VALUABLE TECHNIQUE IN APPRAISING ACTH DOSAGE

THERON G. RANDOLPH, M.D.\*  
CHICAGO, ILL.

THE decrease in the circulating eosinophils following the intramuscular injection of adrenocorticotrophic hormone (ACTH, Airmoun) was first described by Hills, Foisham, and Finch<sup>1</sup> and subsequently by Hellman.<sup>2</sup> The increasing importance of ACTH in the diagnosis<sup>3</sup> and treatment<sup>4, 5</sup> of various clinical conditions as well as in other clinical studies of the effects of this hormone<sup>6, 7</sup> underscores the importance of a simple, reliable technique for enumerating eosinophils, as the level of these cells in the peripheral blood may be a general index of the sensitivity of the gland stimulation and may be a general guide to adequacy of dosage in a given case.<sup>8, 9</sup>

In this connection the merits of a white blood cell diluting fluid of equal parts propylene glycol and water containing phloxine and methylene blue as stains should be re-emphasized because it is the simplest and most accurate method of enumerating blood eosinophils. This point is important because the number of circulating eosinophils is a general guide of adequate dosage of ACTH in treating various disease syndromes. Although our own observations in this respect† are not ready for publication, a review of the technique applied in enumerating eosinophils seems indicated because of the rapidly increasing medical interest in adrenocorticotrophic hormone (ACTH).

Hypotonic diluting fluids of the type originally described by Dungei<sup>10</sup> or as modified by Hills, Foisham, and Finch<sup>1</sup> and Thoin and associates<sup>3</sup> are not entirely satisfactory for counting eosinophils in the peripheral blood. This statement is based on the experience of employing Camaia and Alvarez<sup>11</sup> modification of Dungei's diluting fluid consisting of 5 parts of 1 per cent aqueous eosin, 5 parts acetone, and 100 parts distilled water for a period of three years in studying cases of food and drug allergy. The staining fluid used by those studying the effects of ACTH is identical except that 2 per cent instead of 1 per cent aqueous eosin was employed.

The inadequacies of this type of diluting fluid were first pointed out in 1944.<sup>12</sup> It was determined that the counting chamber estimation of eosinophils by means of hypotonic diluting fluids containing eosin as modified from Dungei's original description remains subject to considerable error in that the ruptured or "ghost" cells are identified by clumps of eosin-staining granules retained in portions of the cell membrane. In 1947 it was again emphasized by me<sup>13</sup> that the use of such diluents was fraught with considerable error in that one frequently encountered indeterminate forms that could not with certainty

Received for publication Aug. 19, 1949.

†These studies were conducted through the cooperation of Dr. David E. Markson and Dr. Smith Freeman who are studying the effect of ACTH on disease syndromes. The ACTH was obtained through the courtesy of Dr. John R. Mote of the Armour Laboratories.

be classified as eosinophils. In addition, a greater absolute number of eosinophils usually was obtained from employing this type of hypotonic diluent than was determined from performing parallel stained film differential counts. It was further pointed out, however, that the errors inherent in this method became less significant if the determinations were made with a short but constant time interval elapsing between the dilution of the sample and the completion of the counting. These observations have recently been confirmed by Henneman, Wexler, and Westenhaver<sup>14</sup>. In their experience with the Dunger technique as modified by Thorn and associates there was a large and rapid decrease in the eosinophil cell count with passage of time after dilution of the blood and with ageing of the oxalated blood. Because of this and other reasons, these authors were unable to recommend the use of this type of diluent.

The so called "hemolytic" and solvent properties of propylene glycol suggested its use as a white cell diluting fluid and staining base in 1943<sup>15</sup>. Upon closer observation it was learned that the apparent hemolytic action of the glycols, as reported by Von Oettingen and Jirouch<sup>16</sup> was not a true hemolysis, but that the disappearance of human erythrocytes suspended in equal parts propylene glycol and water was due to the fact that the red blood cells rapidly assumed the same density as the surrounding media and thus became relatively nonrefractile. This phenomenon was studied in more detail by Randolph and Mallery<sup>17</sup> who were able to demonstrate that a mixture of human blood in equal parts propylene glycol and water appearing to be hemolyzed as viewed grossly in a test tube or under the light microscopic field actually was not hemolyzed when viewed through the dark field microscope. Under these circumstances the erythrocytes retained their normal contours.

The technique described in 1944<sup>12</sup> and employed in subsequent studies consists of the following:

Given amounts of stock solutions containing 0.1 per cent methylene blue in propylene glycol and 0.1 per cent phloxine in propylene glycol are each diluted with an equal volume of distilled water and placed in dropper bottles. For example:

Solution I*		
0.1 per cent methylene blue in propylene glycol	50.0 cc	
Distilled water	50.0 cc	
Solution II		
0.1 per cent phloxine in propylene glycol	50.0 cc	
Distilled water	50.0 cc	

The final white blood cell diluting fluid is made by mixing an equal number of drops of Solution I and Solution II in a test tube; this remains usable for approximately four hours. After standing for longer periods differential staining detail may become impaired and precipitation of dyes may occur. Curiously, prior to four hours the two dyes do not seem to mix completely as shown by the ability of the phloxine to disperse in a filter paper at a greater rate of speed than does the methylene blue; a drop on such a medium separating as to color and leaving a blue center and a red periphery in a manner akin to the principle employed in paper chromatography.

\* It has been pointed out the effect of propylene glycol on erythrocytes as far as the timing of the reappearance phase is concerned is dependent upon concentration of the glycol and the temperature. Occasionally the loss of water from the stock or working solutions due to evaporation increases the relative concentration of propylene glycol to the point that in summer weather the red cells may "reappear" before one has an opportunity to enumerate the leucocytes. This is remedied by making up solutions containing 40 or 45 per cent propylene glycol instead of the recommended 50 per cent.

Because of the variation in staining ability between lots of dyes, optimum acid and basic staining may sometimes be obtained by making a slight change in the relative proportions of Solution I and II in the final diluent. For example, four parts of Solution I and six parts of Solution II might result in better staining technique than if equal parts of the two were mixed.

Under certain circumstances the phloxine tends to crystallize out in long narrow crystals from Solution II, this may occur after the solution has stood several weeks and may be remedied readily by simple filtration or by preparing Solution II from the stock at monthly intervals.

Experience indicates that it is helpful to clean the pipettes with agents other than acids or to be certain that acid residues are completely removed from the interiors of the pipettes as a result of repeated rinsing. Cleaning the pipettes with water and drying by a final rinse with acetone and avoiding the use of a series of bottles also employed in cleaning pipettes containing acid diluents aids in avoiding complications in the use of this technique.

Total and differential white blood cell counts are made using the standard pipette and counting chamber. The pipette is shaken during the course of and immediately after filling. If the chamber is charged immediately after diluting the blood and shaking, a period of from three to five minutes is required for the "disappearance" of the red blood cells and settling of the leucocytes prior to determining the total white cell count. A total period of from ten to fifteen minutes is recommended for maximum staining of eosinophils and other leucocytes. Blood may be left in the pipette for varying periods, including over night, without a significant change in the staining qualities of the cells or in the total leucocyte count, an obvious advantage over the use of hypotonic diluents employed in enumerating eosinophils.

Under the low magnification (16 mm objective) eosinophils may be differentiated from other cells by their brilliant red color and slightly larger size. The contrast in color is intensified by increasing the light and raising the condenser of the microscope. The eosinophils in one side of the counting chamber (0.9 cmm) or in the entire ruled areas of both sides of the chamber (1.8 cmm) are counted and multiplied, respectively, by 22 and 11 to obtain the number per cubic millimeter of blood.

The differentiation and enumeration of polymorphonuclear and mononuclear cells are accomplished to best advantage by the use of high magnification (4 mm objective and 15× eyepiece). The first 100 cells encountered are so classified.

In this diluting fluid all white blood cells remain intact, round in contour, and relatively large in size. The granules of the eosinophils stain brilliant red, the nuclei of all cells aquamarine, this permits the differentiation of eosinophils from other white blood cells even in the presence of highly fragile leucocytes as observed in leucemia and other blood disorders<sup>18</sup>.

The increased viscosity of this medium is advantageous in that the end point in filling the pipette may be reached accurately, there is little settling and clumping of white cells, and there is no tendency toward overflow in charging the chamber. The clear background of the counting chamber and the relatively slow rate of evaporation from it are also advantageous.

The differentiation of eosinophils in the same sample of blood employed in determining the total leucocyte count results in a minimum possible error in comparison with alternative methods.

Finally, the glycol stain technique also permits the counting chamber enumeration of polymorphonuclear and mononuclear leucocytes even in the presence of many young myeloid elements as observed in the course of acute allergic reactions following the ingestion of allergenic drugs<sup>10</sup>

The accuracy of the counting chamber enumeration of eosinophils on one side of the chamber (0.9 cmm) using the propylene glycol technique as compared with the standard method of enumerating eosinophils that is by determining their number as a result of performing 200 cell film differential counts and applying the percentage obtained to the total leucocyte count, was studied by Randolph and Stanton employing parallel observations from the same freely bleeding puncture wound. Such determinations were made in 100 normal persons and in 400 instances in allergic individuals who had varying degrees of eosinophilia. Finally, ten of the latter subjects were subjected to ten parallel eosinophil counts each by the two techniques.

Table I lists the maximum minimum mean and standard deviation determined as a result of the statistical analysis of these ten observations per subject by each of the two techniques.

TABLE I EOSINOPHIL COUNTS AS DETERMINED IN ENUMERATING THE EOSINOPHILS IN ONE SIDE OF THE COUNTING CHAMBER (0.9 cmm) COMPARED WITH THE DIFFERENTIAL ENUMERATION OF EOSINOPHILS FROM PERFORMING 200 CELL DIFFERENTIAL COUNTS FROM THE STAINED FILM

From these studies it was determined that the enumeration of eosinophils on one side of the counting chamber (0.9 cmm) was a more accurate method of determining the number of these cells than the result of a differential count of 200 leucocytes from the stained film employing the cover slip technique and a standard method of sampling the stained area.

Henneman, Wexler, and Westenhaver<sup>14</sup> recently compared the effectiveness of phloxine in equal parts propylene glycol in water (Solution II of this combined stain) with Thoms' modification of Dungey's hypotonic diluting fluid in enumerating eosinophils. In their experience with these two chamber techniques, the diluent composed of phloxine in propylene glycol not only provided more consistent results and no evidence of destruction of eosinophils but

also was preferred by them because of the ease in identification of cells, decreased evaporation of the diluent from the counting chamber, greater reproducibility of results, and because no refrigeration of the diluent was required. They confirmed our experience in using the eosin-acetone hypotonic diluent, commenting specifically on the rupturing of eosinophils in this medium and the large and rapid decrease in cell count with passage of time after dilution of the blood and with ageing of the oxalated blood.

Because of the more accurate enumeration of eosinophils permitted with the use of the glycol counting chamber stains, either the phloxine part of the diluent alone or the combined stain diluting fluid is preferred over alternative methods in following the levels of blood eosinophils in patients under treatment with adrenocorticotrophic hormone (ACTH).

#### SUMMARY

A white blood cell diluting fluid of phloxine and methylene blue dissolved in equal parts propylene glycol and water permits the counting chamber differentiation of eosinophils on the same blood specimen used in determining the total leucocyte count. In this medium the eosinophils stain bright red and are readily differentiated in the counting chamber from other polymorphonuclear and mononucleated leucocytes. This technique is the most accurate method of determining the number of eosinophils in the peripheral blood in that it permits the enumeration of intact stained cells in contrast to the previously described counting chamber techniques employing hypotonic diluents in which ruptured or "ghost" eosinophils are counted. It is a particularly valuable method to use in following the clinical course of patients under therapy with adrenocorticotrophic hormone (ACTH), those suffering from acute allergic reactions or infections in which one is primarily interested in the variations in serial determinations of the peripheral blood eosinophils.

This direct counting chamber technique makes it possible for the first time to express accurately the number of eosinophils existing in the peripheral blood, the expression of the number of eosinophils per cubic millimeter of blood is obviously more accurate and meaningful than to consider eosinophils in terms of the relative percentage of the total leucocyte count.

# WARBURG MANOMETER CALIBRATOR\*

ARNOLD LAZAROW, M.D., PH.D.  
CLEVELAND, OHIO

## INTRODUCTION

IN CALCULATING the constant for a Warburg manometer it is necessary to know the volume of the Warburg vessel plus the volume of the manometer to the 150 mm mark. To determine the latter volume the manometer is usually filled with mercury to the 15 cm mark and the volume is determined from the weight and density of mercury. This method of calibration is very time consuming since it is somewhat difficult to introduce the requisite amount of mercury to just fill the manometer to the 15 cm mark. The manometer calibrator herein described greatly simplifies and shortens the calibration procedure. The principle employed is similar to that used in the construction of the Scholander microburette †

## CONSTRUCTION OF CALIBRATOR

The apparatus consists of a metric micrometer (Fig. 1 A) which is calibrated in hundredths of a millimeter. A stainless steel plunger (B) with a cross sectional area equal to 1 sq. cm (1.000) is pressed onto the micrometer spindle (C). A stainless steel collar (D) is pressed over the end of the micrometer. The upper end of this collar is threaded to accommodate the Lucite top (E). This plastic top is turned to a standard taper joint at H so that it fits the conventional Warburg manometer. A doughnut shaped "O" ring (F) fits over the plunger (B) and is compressed between the plastic (E) and the collar (D). This "O" ring seals the plunger within the plastic, yet it permits advancement of the plunger into the space (G).

## METHOD OF CALIBRATION

In use, the plastic cylinder is filled with water and the spindle is nearly withdrawn from the chamber (G). The cleaned manometer is inserted in the standard taper (H) of the plastic and fixed in place with rubber bands (Fig. 2). It is desirable to have just sufficient water in the calibrator chamber (G) so that only a small air bubble remains within the plastic cylinder when the manometer is in place. The manometer is held in the vertical position and the stopcock (M) of the manometer is opened and the other ends of the manometer are sealed by rubber tubes (N) and pinch clamps (O). The micrometer plunger is advanced and all the air is carefully expelled from the calibration chamber (G). The water meniscus is adjusted to coincide with the calibration mark of the manometer (J) (Fig. 2) (i.e. the mark used in calibrating the vessels) and the micrometer scale is read. The manometer is now turned to a horizontal position

†Scholander, P. F., Edwards, C. A., and Irvine, L. Improved Micrometer Burette. *J. Biol. Chem.* 148: 195, 1943.

Fig. 1—Construction of Warburg manometer calibrator (for explanation see text)

Fig 2—Calibrator inserted on Warburg manometer (for explanation see text)

and the plunger is advanced until the water meniscus reaches point *K* (Fig. 2). Further advancement of the water meniscus fills the capillary between point *K* and the stopcock (*M*). When water reaches the bore of the stopcock (*M*), the stopcock is closed and the pinch clamp (*O*) is opened. The liquid is advanced to the 15 cm mark (*L*) of the manometer. The micrometer is again read and the volume determined by subtracting the initial from the final reading. The liquid is then removed from the manometer by reversing the foregoing procedure and the calibration may be repeated.

Results of several calibrations are shown in Table I. It will be noted that the volume of the manometer as determined in the first trial is slightly greater than that observed in subsequent trials. This difference is due to the residual water which is left in the manometer after the first calibration. It is further

TABLE I WARBURG MANOMETER CALIBRATION

REMARKS	TRIAL	VOLUME (CC)		
		13	18	34
Manometer dry	1	746	803	839
Manometer wet	2	720	787	820
Manometer wet	3	723	789	
Water left in manometers		025	014	019

noted that repeated runs on a wet manometer differ by less than 0.05 cubic centimeter. The accuracy of the volume measurement obtainable with this calibrator far exceeds the accuracy required for the calculation of the manometer constant. The accuracy of the calibrator itself may be checked by inserting a 2 cc pipette through a one holed rubber stopper and inserting the stopper into the standard taper (*H*) of the calibrator. Since the plunger has a cross sectional area of exactly 1 sq. cm, each millimeter advancement of the micrometer plunger corresponds to 0.100 cubic centimeter. Since it takes two revolutions of the micrometer to advance the spindle 1 mm and since there are fifty small divisions per revolution of the micrometer, each small division of the scale of the micrometer corresponds to a volume of 0.001 cubic centimeter.

## SUMMARY

A simple rapid calibrator for the Warburg manometer is described.

## A NEWLY DEVELOPED ELECTROMAGNETIC FLOW METER

A. W. RICHARDSON, PH D, J. E. RANDALL, B S, AND H. M. HINES, PH D  
IOWA CITY, IOWA

THE general principle of an electromagnetic flow meter is not new. It was first developed by Koln<sup>1</sup> in this country and independently by Wetterer<sup>2</sup> in Germany. Koln<sup>3, 4</sup> developed both an A C model and a D C model, the latter was subsequently modified by Jochim.<sup>5</sup> These methods featured sleeves of various design which contained electrodes in positions so that when the sleeve surrounded a blood vessel, the electrodes were in contact with the outside surface of the blood vessel. While such devices possessed the advantage of not requiring incision into the blood vessel, they incurred the disadvantages of voltage drift and minor artifacts due to vessel drying, varying vessel diameter, and extraneous potential pickup. In order to avoid these disadvantages, a new method of potential pickup was developed in this laboratory which has proved exceedingly practical for the measurement of blood flow when used with an A C amplifier and suitable recorder. This newly developed electromagnetic blood flow meter has been found to be unusually accurate in its measurement of blood flow and to possess negligible voltage drift.

### PRINCIPLE

The basic principle upon which the operation of an electromagnetic flow meter depends is that when an electric conductor moves across the lines of force of a magnetic field, a potential difference is created in the conductor. If the field is uniform, the conductor moves in a plane at right angles to the magnetic field and the length of the conductor extends at right angles to both the field and the direction of motion, the resulting electromotive force will be directly proportional to field strength, speed of the conductor, and length of the conductor within the field. Therefore

$$E = B l v 10^{-8}$$

where  $E$  is the potential difference in volts,  $B$ , field strength in gauss,  $l$ , length of the conductor within the field in centimeters (across the electrodes), and  $v$ , speed of the conductor in centimeters per second. By use of the A C system, including an A C magnet, there is an additional constant to be accounted for because of the electrodes and their leads acting as a one turn transformer. Therefore, the total equation of an A C system must be altered to read as follows

$$E = B l v 10^{-8} + A$$

where " $A$ " voltage is the potential developed by the electrodes and leads, this voltage being proportional to  $B$  field strength. In order to cancel out a portion of " $A$ " voltage on the magnet a turn is made which is phased oppositely to that of the leads. The canceling potentiometer is turned in a manner to diminish " $A$ " voltage to a minimum. Once

From the Department of Physiology College of Medicine The State University of Iowa  
Received for publication Aug 10 1949

this point is established the voltage is of a constant and easily accountable magnitude. If  $B$  and  $l$  are kept constant  $K$  may be stated

$$K = B l v$$

and

$$F = K v + A$$

As shown by the equations when the voltage  $V$  is subtracted the electromotive force is a function of the single variable the velocity of flow which theoretically is linear. However, for practical considerations one is interested in volume flow in cubic centimeters per minute, rather than velocity flow in centimeters per second. The quantities are related as follows

$$Q = 60 v \frac{2 \pi d^2}{4}$$

where  $Q$  is the volume flow in cubic centimeters per minute,  $v$  the velocity flow in centimeters per second, and  $d$  the diameter of the tube or vessel. While this formula shows the relations of quantities it is not required for the use of the newly developed meter because due to the manner of its construction calibrations may be made of actual flow during an increment of time to read directly as cubic centimeters per minute blood flow.

Fig 1—Cannula used with electromagnetic blood flow meter

#### MATERIALS AND METHODS

*Description of Apparatus*—The complete flow meter consists of a specially constructed cannula, an A C magnet, an A C amplifier, and an Esterline Angus 3 Ma recorder.

The construction of the cannula consists of a glass or plastic tube of previously determined diameter to equal the size of the lumen of the blood vessel to be cannulated. The cannula and pickup shown in Fig. 1 has a diameter of 3 millimeter. This particular cannula which is designed to fit the femoral artery of a dog is 4 cm. in height and 2.5 cm. in width. The bottom forms an anchorage to secure ligatures. Fig. 2 better reveals the detailed construction. In the top of the cannula are inserted two tungsten (platinum may be used) wire rods with rounded tips so that the tips just touch the periphery of the

lumen. Onto these tips just outside of the glass are soldered the two pickup leads which are then tightly twisted and passed through the center of the housing and into a shielded cable which runs to the amplifier connection. On the top of the housing are two pins which fit into the magnet case in order to assure identical positioning of the cannula during each measurement.

The housing is filled with Lucite for the purpose of stabilizing the position of the lead wires in the magnetic field. This is done by dissolving a portion of Lucite in  $\text{CHCl}_3$ , pouring the solution in the housing around the cannula and leads, and letting it congeal to form solid Lucite. This operation also makes the housing repellant to liquids. The

Fig. 2—Diagram of cannula and pickup leads showing the position of the magnet.

slender base of the cannula is wrapped tightly with a single layer of No. 8 linen thread and coated with the liquid plastic to add strength to the cannula. Care is taken in the construction of the cannula that there are no constrictions in the lumen and that there are no sharp bends. The short section across the top which holds the electrodes is straight.

The cannula and pickup incorporates the following features: (a) an electrical system well isolated from the surrounding tissues, (b) a lumen of uniform size to match the size of the lumen of the blood vessel measured, with no constrictions in its length, (c) a minimum of glass or plastic surface (less than four inches in length) with which the blood is in contact, (d) a reinforced slender base around which to secure ligatures surrounding the ends of the arteries, and (e) a specially designed bronze housing surrounding the electrodes through which the tightly twisted pickup leads are inserted to traverse the center of the magnetic field and be shielded from contact with the magnetic poles. It is the design of this housing which allows a minimal and invariable background pickup and thus prevents voltage drift on the recorder.

The A.C. magnet used with the meter is made from stacked laminations of  $\frac{1}{2}$  inch 29 gauge L & audio A iron. The coil is made of 1,800 turns of No. 25 wire excited with a 110 V A.C. 60 c.p.s. source. This gives a field of about 1,000 gauss across a  $\frac{1}{2}$  cubic inch air gap between pole tips. A 60 c.p.s. power source limits the frequency response of the whole system to fluctuations of less than 60 c.p.s., but it is possible to modify this limitation by changing the carrier frequency to 400 c.p.s. if desired. Should the meter be used

Fig 3.—Recorder and amplifier showing the connections as labeled on the panel

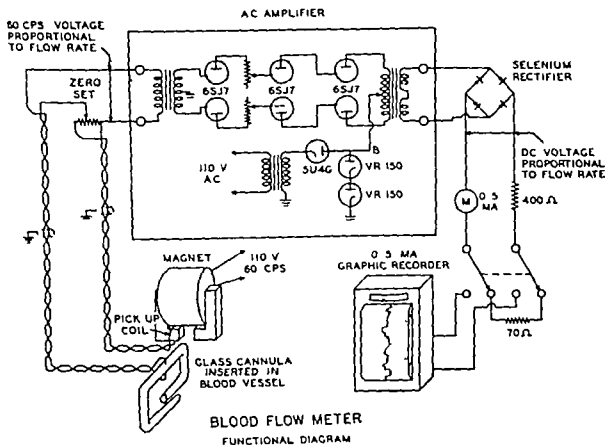

Fig 4.—Simplified diagram showing the electromagnetic pickup amplifier and recorder

with a high frequency response recorder, this modification is recommended. For convenience in adjusting the position of the magnet, a screw type lift with a crank attached is used to slowly lower the magnet into position over the cannula. The magnet is held by a ball in socket swivel which will allow it to be adjusted at a convenient angle.

The AC amplifier and recorder used are shown in Fig 3. The amplifier is adapted from the original AC amplifier of Kolin with minor modifications. Three stages of 6SJ7 tubes are used for the principal circuit with two VR 150 tubes being used on the B+ circuit

This amplifier has proved remarkably stable and features two input channels for pickup, each connected to a potentiometer to be utilized in canceling out stray background. A selenium rectifier is used in the output circuit. Any stable amplifier with sufficiently high gain would be adaptable for the electromagnetic flow meter, so long as it matches the characteristics of the pickup and the magnet used. This particular amplifier is most adaptable to a 60 cps magnet. The amplifier used here has two gain settings, the two amplifications giving a total range of blood flow measurement from zero to 300 cc per minute with different cannulae. The range of measurement may be increased by constructing the

Fig 5—Sample calibration curve showing the use of two amplifications with one cannula

electrodes of the cannula so that the distance between the tips is diminished. Conversely, greater sensitivity is achieved by constructing the electrodes of the cannula so that the distance between the tips is greater. In all cases the lumen of the cannula should be as nearly as possible identical with the size of the blood vessels.

A 5 Ma Esterline Angus recorder is used on the electromagnetic flow meter as a compromise choice of various possibilities. This instrument requires 5 Ma through an internal resistance of 70 ohms for full scale deflection. This is a heavily damped instrument and will not record events accurately under 200 milliseconds but this feature is of value in the recording of mean blood flow where a concomitant record only of heart rate and respiration is desired. When events of shorter duration are of interest, a recorder of higher frequency response should be employed. Fig 4 reveals a functional diagram of the entire apparatus as it is operated showing the position of the magnet, the general structure of the amplifier, and the recorder connections.

*Calibration of the Instrument*—Although a force pump perfusion system has been used to calibrate the flow meter, it is felt that the preferred method is to measure the flow of blood out of a blood vessel directly into a graduate over a convenient period of time. This method is to be desired for its simplicity and the elimination of extraneous intervening variables. In operation, the distal end of the cannula is attached to a plastic tubing of the same size which runs to a graduate. A previously applied clamp on the proximal artery is released for one minute so that a one minute flow of blood is spilled into the graduate. A point is made on the midline of the excursions on the record which corresponds to the milliliters of blood

measured. This is one point on the calibration curve. By constricting the end of the plastic tubing, lower rates of flow may be measured until a number of desired points on the flow curve may be calibrated. A curve of best fit may be drawn transecting the points and may be extrapolated to the base line. This point on the base line or true base will not fall on zero, but upon an electromotive force reading, which represents the "A" voltage previously described. These readings may be made identical, by means of the potentiometer adjustment. Fig. 5 shows typical calibration curves by use of two amplifications. In this calibration graph the "A" voltage has been subtracted and it may be seen that the curves are for all practical purposes linear.

Fig. 6—Sample record made with the new electromagnetic flow meter. The record reads from right to left.

Once it is calibrated, a cannula does not require recalibration unless it develops a fracture or similar defect. However, because of such possibilities, frequent recalibration may be advisable. The typical observation with a fractured cannula is an enormous base voltage, which ordinarily can be detected readily.

#### RESULTS

Fig. 6 shows a typical blood flow record which reads from right to left. This sample record shows the results of 12 cm. microwave irradiations using 100 watts output upon the limb of a dog. The wave director was placed close to the surface of the limb. In the figure, the heavily inscribed base line represents the background pickup, or "A" voltage, so that voltage induced by blood flow reads from this point to the midline of the excursions to represent mean flow. This point, the midline, was arbitrarily selected when calibrating the cannula. When this distance is read on the ordinate and multiplied by the  $k$  value of the cannula, in this case ( $20 \times 10$ ), a figure is derived which represents blood flow in cubic centimeters per minute. For example, the control flow may be calculated as follows:

$$0.24 \times 20 \times 10 = 48 \text{ cc/min}$$

The calibration should be experimentally established as suggested, and the "A" voltage reading may be conveniently adjusted. Since the "A" voltage will be  $90^\circ$  out of phase with the flow voltage, they cannot be added algebraically.

Fig 6 is a reproduction of blood flow in the femoral artery. The rapid oscillations are the result of the cardiac rhythm, while the slower oscillations are due to respirations. These events are reflected in the flow record with sufficient clarity that the record may be used to count the respirations and heart rate. It may be observed that while the rate of blood flow and respiration have been increased by the irradiations, there is not noticeable increase in heart rate. This record was made at one of the intermediate speeds. A faster speed makes the excursions much easier to analyze, while a slower speed achieves a greater economy of record.

#### DISCUSSION

While it is essentially a pulsatile flow meter, this device as described here is best adapted for the measurement of mean blood flow. As previously suggested, it is possible to better adapt this meter for the measurement of pulsatile blood flow where a finer analysis of events of a short duration is desired.

The meter as described has proved exceedingly capable for the measurement of mean blood flow in both veins and arteries. It has been found to possess less than 5 per cent error in measurement under physiologic conditions and has been operated for four- to six-hour periods with negligible voltage drift. A criticism of this type of flow meter is that general anesthesia and an anticoagulant must be used because the blood vessel is cannulated. On the other hand it is simple to operate, is substantially free from subjective factors, and possesses a relatively linear calibration curve. By use of different cannulae, the range of flow measurement is from 0 to 300 cc per minute. This range may be expanded with simple modifications. The meter may be easily cleaned following each use by means of a detergent and distilled water. This cleaning, carefully done, is important for proper measurements.<sup>6</sup> In brief, while the development of this meter entailed certain compromises it is felt that it has proved to be a practical, accurate, and easily operated device for the measurement of blood flow under many conditions encountered in laboratory measurement.

#### SUMMARY

A new electromagnetic blood flow meter has been developed which produces a continuous permanent record of mean blood flow. This device is adaptable to measure pulsatile blood flow in the respect that it readily records the effect of the heart rhythm and respiration upon blood flow. Modifications are suggested for recording events of shorter duration. The use of this meter entails the disadvantages inherent with cannulation, but such disadvantages must be weighed against the advantages of accuracy, stability, and ease of operation. The stability and accuracy of this meter is in a large measure dependent upon careful construction of the cannula and pickup leads.

The authors gratefully acknowledge the cooperation and assistance of Dr J W Clark in the development of this work.

# EVALUATION OF A NEW CAPILLARY RESISTOMETER THE PETECHIOMETER

EDWARD E. BROWN, M.D.  
ASHLAND, ORE

## INTRODUCTION

CAPILLARY resistance determinations were made on one hundred patients with two different types of suction apparatus and the readings compared. A modified Dalldorf resistometer was used on one forearm as previously described,<sup>1</sup> and a new resistometer, the Petechiometer,\* was applied to the other forearm.

## MATERIALS AND METHODS

Capillary resistance is the minimal amount of suction applied to the skin for one minute capable of producing one petechia or more. It is measured in centimeters of mercury negative pressure or suction. With the modified Dalldorf resistometer, readings were made at intervals of 5 cm, the amount of suction being read directly from a vacuum gauge. The Petechiometer, on the other hand, has no vacuum gauge but is adjusted to deliver 10, 20, and 30 cm of mercury suction. The bell of the old resistometer is 1 cm in diameter while that of the Petechiometer is 2 centimeters.

In all of the one hundred patients two readings were noted, the old instrument being used on one forearm and the Petechiometer on the other, Fig 1. Because in some studies<sup>2, 3</sup> readings were normally slightly lower on the right arm, it was decided to reverse machines in the second group of fifty patients. The 200 capillary resistance readings may be compared in Table I.

*Estimation of Capillary Resistance With the Petechiometer*—The plunger is grooved at three points, each yielding a different suction. The adjustable stop ring is inserted in the innermost groove. One then places water just below the antecubital space before applying the bell to the wet skin. The air is expelled by pressure of the right thumb on the end of the plunger and the bell placed on the skin. The bell is held in contact with the skin lightly, but firmly, with pressure from the index finger of the left hand upon the top of the bell. As the thumb pressure on the plunger is released quickly a spring action applies suction to the skin area. Suction is applied for one minute and then released by pushing inward on the plunger. After removing the Petechiometer, thirty seconds are allowed before looking for petechiae. If no petechiae are found, the test is repeated using each of the stop-ring settings, i.e., the innermost yielding 10 cm mercury suction, the middle setting 20 cm mercury suction, and the outermost slot setting 30 cm mercury suction. The determinations are not made closer together than the diameter of the suction bell.

Received for publication Aug 19 1949

\*The Petechiometer is the registered trade mark owned by the Rexall Drug Company. The Petechiometer consists of a small suction pump with a plunger and a clear plastic Bell or suction cup 2 cm in internal diameter with a magnifying glass blown into the upper surface of the cup to facilitate in situ reading of the petechiae developed.

The number of petechiae produced by the Petechiometer was noted. In the final comparison of results this procedure proved valuable, for it permitted interpolation to intervals of 5 cm when excessive numbers of petechiae were produced at the 10, 20, or 30 cm readings. For example Patient 29 showed a capillary resistance of 10 cm on the Petechiometer but had forty petechiae

Fig 1—Comparison between old and new resistometers

Obviously, because of the many petechiae produced the true capillary resistance was actually less than 10 centimeters. Using the old resistometer the capillary resistance in this patient was 5 centimeters. When comparisons were made with the two machines it was found that when six or more petechiae were produced by the Petechiometer, one could in most instances subtract 5 cm from the capillary resistance shown by this new instrument and approximate the reading given by the old machine.

\*Capillary resistance before 5 cm correction for excessive number of petechiae (six or more)

P Number of petechiae

†Corrected capillary resistance

## RESULTS

By subtracting 5 cm when six or more petechiae were noted at the capillary resistance determination with the Petechiometer, the average reading with the old instrument was 14.75 cm and with the Petechiometer 14.25 centimeters. This similarity is not so constant in individual readings. Only 43 per cent showed no difference between old and new resistometers and 90 per cent did not vary more than 5 centimeters. Of the ten patients who differed by more than 5 cm between arms, seven patients showed a 10 cm difference and three patients a 15 cm difference. One may expect, however, to find similar variations between arms even when using the same resistometer.<sup>2, 3</sup>

## DISCUSSION

A simple capillary resistometer to determine bleeding tendencies should be welcomed by physicians. It has been noted that the lower the capillary resistance, the greater is the bleeding time.<sup>4</sup> A capillary resistance of 5 cm means marked fragility. Capillary fragility accounts for bleeding in such conditions as purpura and rheumatic fever and in hypertensive patients.<sup>3, 5, 6</sup>

Without a suction apparatus for determining capillary resistance, the clinician may resort to positive pressure methods, as by use of the sphygmomanometer.<sup>7, 8</sup> The disadvantages of such methods are listed by Tey<sup>9</sup> as follows: (1) determination is time consuming, (2) test cannot be repeated for days,

(3) there is no gradation in the same subject (4) results cannot be read with accuracy, (5) positive pressure methods are unsuited for pharmacologic investigation, where several determinations must be made within a few minutes since only two body surfaces (arms) are available

On the other hand use of the Petechiometer is simple and painless. Determination of capillary resistance requires less than five minutes. The instrument is small and can be carried in one's bag.

#### CONCLUSIONS

Capillary resistance determinations were made on one hundred patients using a modified Dalldorf resistometer with vacuum gauge on one forearm and a new instrument, the Petechiometer on the other.

Although readings on both forearms differed in individual subjects, these differences were usually slight. Only 10 per cent of patients showed readings which differed more than 5 cm. between arms. Minor differences are normally noted between arms. These differences tended to balance in the final compilation for the average capillary resistance with the old machine was 14.75 cm. and with the Petechiometer 14.25 centimeters. The Petechiometer thus appears to be accurate.

The Petechiometer has the following advantages over the older resistometer: it is on the market, it is simple to use, it is compact and small.

# A SIMPLIFIED VENOUS OCCLUSION METHOD OF DIGIT BLOOD FLOW ESTIMATION USING THE BURCH-WINSOR PLETHYSMOGRAPH

CHARLES W. ROBERTSON, M.D., DOUGLAS A. FARMER, M.D., AND  
REGINALD H. SMITHWICK, M.D.  
BOSTON, MASS.

**D**IGIT blood flow studies based on the venous occlusion principle have been greatly simplified by the development of a clinical type of transmission plethysmograph by Burch<sup>1</sup>. At the present time venous occlusion blood flow determinations are being carried out as a part of the regular digit plethysmographic study on both fingers and toes in our laboratory. The basic details of this type of study have been recorded by Wilkins,<sup>2</sup> Goetz,<sup>3</sup> Abramson,<sup>4</sup> and others.<sup>6</sup> Our purpose in reporting this method is to emphasize the ease with which venous congestion methods may be adapted to the Burch-Winsor plethysmograph. Measurements with this type of apparatus depend upon volume changes in the part under study, the variables being amount and rate of volume change. For the most part an increase in the volume of a trapped part is dependent upon either increased arterial inflow or decreased venous outflow or both. If one occludes the venous outflow without disturbing the arterial inflow the volume change resulting represents an indirect estimate of the arterial inflow. The inherent limitations of this type of determination have been adequately discussed by Abramson and by others.<sup>2, 3, 4, 6</sup> We are aware of these limitations, but with increasing experience we are coming to feel that digit flow determinations are worth-while adjuncts to digit plethysmography, particularly in attempting to decide about the presence or absence of vasomotor activity in the digital blood supply.

The problem of applying an occluding pressure to the base of the digit might be mentioned first. Our first attempt was a brass-backed latex ring. This was a satisfactory method for fingers but in the case of toes a ring large enough to pass over the end of the toe was frequently too large to satisfactorily compress the toe at its base. The brass-backed latex cuffs were discarded in favor of Abramson's adhesive tape-latex tube method. In making the latex tubing for the occluding cuffs a glass rod 6 mm. in diameter which has been dusted with talcum powder is dipped into a container of prevulcanized liquid latex two or three times. After several hours of drying, the surface of the rubber on the glass rod is dusted with talcum powder and the rubber is rolled off the glass. The tubing thus obtained is thin enough to avoid bulk and strong enough to withstand the occluding pressures. The latex tubing is attached to a small catheter or plasma tubing with a fine silk binding reinforced with a turn of adhesive tape. The latex tubing is then backed with ordinary adhesive tape.

From the Department of Surgery, Boston University School of Medicine and The Massachusetts Memorial Hospitals.

Received for publication Aug. 20, 1949.

The end is turned under and covered with a tab of adhesive. The completed cuff is 8 to 10 cm in length and approximately 1 cm wide\*. These cuffs, if well made and free of bubbles, will survive a week or more of active use. In applying the cuff to the digit the cuff is wrapped around the base of the digit and a short piece of adhesive is used to secure the cuff to itself to prevent slipping (Fig 1 A and B).

The method of cuff inflation used is a simple pressure bottle arrangement similar to that of Goetz<sup>3</sup>. The essentials of the pressure system are a 1 or 2 liter widemouthed bottle, a tightly fitting rubber stopper, a large three way glass stopcock, some type of manometer—either aneroid or mercury, a blood pressure type of compression bulb and suitable tubing and glass or metal connections. The illustrations (Fig 2 A and B) are self explanatory and give a satisfactory scheme of connections for use.

In use the occluding pressures should be well below diastolic arterial pressure and we have found 60 to 70 mm (Hg) to be satisfactory for most digits. When air is allowed to flow into a single cuff the others having been excluded by clamps the bottle pressure falls 1 to 2 mm of mercury with each inflation. This is corrected prior to each occlusion by means of the compression bulb.

To summarize the steps in the digit flow determination:

- 1 The digit part is measured in the displacement tube apparatus<sup>1</sup> to a volume of 5 cubic centimeters. This volume is indicated on the digit by a weak gentian stain which is employed as the measuring fluid.

- 2 The extremity plastic cup is sealed in place at the proximal edge of the gentian stain with the sealing compound Kilk Kord previously reported.

- 3 After the cup seal has been tested the occluding cuffs are applied to the base of the digit in such a way that there is no contact with the cup or the sealing compound—and no contact between the tubing from the cup and cuff. Trial cuff inflations are then carried out to make certain the cuffs are in the best alignment to prevent unnecessary motion of the digit when the cuff pressure is introduced.

- 4 String sensitivity is adjusted to move 10 mm per 10 mm<sup>3</sup> volume change with the calibration lever. The routine plethysmographic tracings are made at slow speed standardizing each run twice. Following the second calibration, the base line is shifted to the left side of the aperture and the camera speed shifted to 'fast' just prior to the application of cuff pressure. This will require a certain amount of practice by operator and assistant. When the maximal base line shift (i.e. volume change) has occurred the camera is shifted to slow speed and cuff pressure is released by turning the stopcock to the 'exhaust' position. The base line is adjusted to the left side of the aperture if necessary following which the venous occlusion test is repeated. The camera is then stopped and the next digit is prepared for recording. With practice the volume pulses and two venous occlusion runs can be recorded on about 12 inches of paper for each digit.

\*The latex which we have found satisfactory for this use is a formul. designated No. GL 1 c furnished by the General Latex and Chemical Corp. 666 Main Street, Cambridge, Mass.

## ESTIMATION OF DIGIT FLOW (mm<sup>3</sup>) / 5 cc part / sec

AH ♀ 6/13/49

Left First Toe

B

Fig 3

5 After the tracing has been developed the digit flow can be readily determined by measuring the amount of volume change per unit of time (Fig 3, B). We have arbitrarily used millimeters per second per 5 cc of part. In drawing the tangent slope line it is desirable to avoid using the first pulse excursion if possible since positive or negative artifacts are common. In rapid flows this may not be possible because of the speed with which the string shadow crosses the entire width of the paper in which case the slope line should be placed along the most representative portion of the curve. In connection with measuring the various string deflections on the tracing a correction formula has been used to compensate for "high or low calibration errors. The correction ratio which we employ uses the following factors:

$$\frac{\text{Measured volume deflection}}{\text{Measured calibration deflection}} = \frac{\text{True volume deflection (X)}}{10}$$

Thus if the measured volume deflection were 14 mm and the standardization deflection were found to be 8 mm instead of 10 mm the measured deflection would be low and by the correction formula the true volume deflection would be

$$\begin{aligned} 14 \times \frac{X}{8} &= 9.10 \\ \frac{8X}{10} &= 140 \\ X &= 17.50 \text{ mm / 5 cc of part (corrected deflection)} \end{aligned}$$

Although this formula does not take into consideration all the variable factors which might cause minor errors, such as variation in volume of the trapped part, it is probably worth while in measuring volume pulses and blood flow where the standardization error is greater than 1 millimeter.

The illustrations demonstrate the essential details of this method of blood flow estimation in digits. The plethysmograms presented are tracings from normal individuals who have no evidence of peripheral vascular disease. The "warm room" flows have been recorded after one hour in an ambient temperature of 83° to 84° F and the "cold room" flows after one hour in an ambient temperature of 68° to 69° F. (Fig 3 A and B).

The application of this type of digit blood flow determination to normal subjects and before and after limb sympathectomy will be presented in subsequent communications.

## ABSTRACTS—Concluded

### 61 EXPERIMENTAL PRODUCTION OF MEGALOBLASTIC ANEMIA, AN INTERRELATIONSHIP BETWEEN ASCORBIC ACID AND PTEROYLGLUTAMIC ACID

CHARLES D MAY, M D , E N NELSON, M D (BY INVITATION), AND  
R J SALMON, M SC (BY INVITATION), MINNEAPOLIS, MINN

This report describes a means of producing megaloblastic and macrocytic anemia in monkeys using deficient diets alone

The diets employed were basically dried cow's milk reconstituted with water and adjusted with lactose and vegetable oils and supplemented with crystalline vitamins to provide liquid diets of the following approximate composition

	PER 100 ML
Protein	16 Gm
Carbohydrate	72 Gm
Fat	33 Gm
Calories	67
Vitamin A	800 I U
Vitamin D	50 I U
Thiamin	07 mg
Riboflavin	1 mg
Nicotinic acid	5 mg

Any other vitamins present were those contained in the milk Each experimental animal was given 137 mg Fe per kilogram in the form of non ascorbate intravenously at the start of the experiment followed by several weeks of oral therapy with 4 cc of ferrous gluconate daily

In five control periods monkeys fed this type of diet ad libitum and 50 mg ascorbic acid daily for five or more months remained in good health and did not develop anemia or changes in the bone marrow

When the experimental diet was fed to eleven monkeys without the addition of ascorbic acid, a typical sequence of events occurred For three to four months they remained in apparent good health At about this time the first symptoms of scurvy appeared They remained essentially in this state for the next three to four weeks, exhibiting only the symptoms of scurvy, without developing anemia or definitive changes in the marrow Then a precipitous deterioration began Pronounced anorexia and listlessness ushered in this phase Diarrhea commenced invariably, the stools being loose to mushy, bulky and foul but without pus or blood With one exception a histamine retractor gastric achlorhydria developed The fur lost its smoothness and luster and was shed in large amounts The periodontal gingivae became ulcerated and necrotic No changes were seen in the tongue No infections were observed in the animals at any time Anemia and neutropenia developed rapidly without evidence of additional hemorrhage The anemia was usually of a normocytic or macrocytic type

The most critical criteria were applied in designating the types of cells seen in the marrow Three monkeys developed megaloblastic marrow very similar to, if not identical with, those seen in megaloblastic anemia in human

beings. The marrows in the other eight animals became megaloblastic, a stage through which the megaloblastic marrows passed. The alterations in the granulocytes in each instance were striking, showing hypersegmentation and large curly forms with premature lobulation such as are seen in the marrow in pernicious anemia. It was the impression that all the marrows might have progressed to a frankly megaloblastic picture if the pernicious condition of the animals had not made it seem necessary to treat them in order to test the effects of various agents.

A systematic trial of vitamin B<sub>12</sub>, PGA and ascorbic acid revealed the following: (1) Ascorbic acid given relatively early in the disease gradually restored the animal to health and the marrow and blood became normal. (2) If ascorbic acid was not given until an advanced stage of the disease it did not restore the marrow to normal or prevent the death of the animal. (3) Vitamin B<sub>12</sub> alone given intramuscularly had no effect on the marrow within forty eight hours. (4) PGA given orally or intramuscularly as the free acid or the triglutamate but without ascorbic acid promptly stimulated normal hematopoiesis in the marrow and relieved all the symptoms not attributable to scurvy. When ascorbic acid was added normal health was restored even though the experimental diets were continued.

Increasing the protein in the diet to 3.3 Gm per 100 cc by adding calcium caseinate did not prevent the development of the characteristic anemia.

Thus it would appear that megaloblastic anemia developed as a result of PGA deficiency somehow induced by a chronic deficiency of ascorbic acid.

## 62 CERTAIN EFFECTS OF CHEMOTHERAPY ON THE FECAL AEROBIC AND ANAEROBIC BACTERIA OF PATIENTS WITH CHRONIC ULCERATIVE COLITIS

HOMER C. MARSHALL, M.D. (BY INVITATION), WALTER L. PALMER, M.D.  
AND JOSEPH B. KIRSNER, M.D., CHICAGO, ILL.

The role of the fecal bacteria in the pathogenesis and course of chronic nonspecific ulcerative colitis is not clear. A method of simplifying the bacterial flora of the feces and reducing the number of bacteria in the bowel would provide useful information concerning this problem. Accordingly, qualitative and quantitative studies of the aerobic and anaerobic bacteria were made before and after treatment with absorbable and nonabsorbable sulfonamides, penicillin administered orally and parenterally and the oral administration of streptomycin, aureomycin and chloromycetin. Control studies consisted in observations intended to determine the error of the method and to ascertain the spontaneous day to day variation. The drugs were administered for relatively long periods of time. Bacteriologic studies were carried out at frequent intervals in order to determine the initial and late effects of chemotherapy. All of the drugs under certain conditions, are capable of altering the aerobic flora; some also may modify the anaerobic flora of the feces; the degree and duration of effect varying considerably. For instance, sulfonamides alter the aerobic flora, when initially used for periods as long as six weeks. Streptomycin, on the other hand, exerts a marked quantitative effect which is maintained however only for several days. Chloromycetin and aureomycin exert an intermediate effect: the *B. coli* disappear and the total bacterial count initially falls and then rises with the reappearance of *B. coli* as a predominant organism. In addition, after the initial depression of bacterial counts had terminated, the counts tended to rise above the control levels and to remain high decreasing to control levels only after the drugs were discontinued.

All of the patients improved when a basic regimen was instituted which provided a diet which contained calories equivalent to twice the calculated basal requirement,  $2\frac{1}{2}$  Gm of protein per kilogram of body weight, 30 per cent of the calories as fat and the remainder as carbohydrate. The patients' clinical improvement was accelerated by the addition, to this regimen, of daily intravenous infusions of a mixed amino acid solution which was sodium free.

Restriction of the sodium intake below 10 Gm per day was a valuable adjuvant in combating fluid retention. The patients with edema and ascites showed an increased urinary output and the edema and accumulation of ascites diminished when salt intake was restricted.

No clinical benefits were observed in the patients when the basic regimen was supplemented with cystine, methionine, choline, B complex vitamins, or parenteral liver.

The infusion of large amounts of concentrated human serum albumin (salt pool) was impractical as a method of protein supplementation, even though a transient rise in serum albumin concentration and a marked increase in positive nitrogen balance attended its administration.

On the regimen described (diet, salt restriction, and supplementation with amino acid infusions) all of the patients showed increased weight gains with out fluid retention, those with edema and ascites gradually showed reduction and disappearance of these manifestations of liver disease. All patients showed a striking capacity for the retention of tremendous amounts of nitrogen, probably due to replacement of fluid in the tissues by newly synthesized muscle protein.

One patient with advanced cirrhosis and recurrent ascites was observed over a period of two years while subsisting on seven different regimens. At the peak of the patient's illness, paracenteses were necessary at ten to twenty day intervals and 16 to 19 liters of fluid were removed at a time. Albumin therapy produced no alteration in the rate of accumulation. A low salt regimen reduced the frequency of paracenteses to about thirty-day intervals. Finally, with the previously described regimen, the patient became ascites free and has remained so for 7 months. He has maintained his body weight gains and has returned to a normal active existence.

Of seven liver function tests, serum cholinesterase activity was the most reliable test of liver function in that the cholinesterase levels most accurately correlated with the patient's clinical condition.

## 67 QUANTITATIVE STUDIES OF VIBRATORY PERCEPTION IN DIABETIC AND NONDIABETIC SUBJECTS

I ARTHUR MIRSKY, MD, PERRY FUTTERMAN, MD (BY INVITATION), AND ROBERT H BROH-KAHN, MD, CINCINNATI, OHIO

Quantitative measurements of the threshold of vibratory perception were made in 102 diabetic patients and in 136 nondiabetic, nonobese, nonhypertensive subjects. Both groups of patients were chosen at random from an ambulatory population and were from 5 to 79 years of age.

No correlation was found to exist between the threshold of vibratory perception and the side of the body tested or the sex of the subject. A significant increase in the threshold was found in the diabetic group of subjects. This increase was not related to either the known duration of diabetes mellitus or the severity of the metabolic derangement as estimated by the patients' insulin requirements. Diabetic subjects with symptoms or signs of neuropathy tended to have a greater incidence and greater degree of vibratory

impairment than those without such signs or symptoms. Similar measurements in nondiabetic groups of obese and hypertensive patients revealed no differences in their thresholds from those of the control group.

Both the diabetic and nondiabetic groups of subjects showed an increasing threshold of vibratory perception with increasing age. This increase was more marked in the toes than in the fingers and was greater in the diabetic than in the nondiabetic subjects. The data revealed a more rapid increase in vibratory threshold among the diabetic subjects during the earlier decades during the later years of life. The threshold of the nondiabetic subjects rapidly approached the level of the diabetic subject.

This study provides evidence for the concept that the process of aging is more rapid or of greater initial intensity in the patient with diabetes mellitus than in the nondiabetic subject.

## 65. MECHANISM OF HYPERTHERMIA NOT DUE TO INFECTION

MAX M. MONTGOMERY, M.D. (BY INVITATION), FORD K. HICK, M.D. AND  
ROBERT WOOD KEETON, M.D. CHICAGO, ILL.

Fever usually indicates infection but also occurs when an individual cannot eliminate heat produced by his body's metabolism, a principle utilized in fever production by the various cabinets.

In the past few years a number of patients have been observed with fever not easily ascribed to infection. Records of nine such patients permitted study of the rectal temperature, state of the skin surface, pulse rate and rhythm, blood pressure and environmental conditions. Six developed fever ranging from 104 to 107.8° F during hot humid weather and three developed fever ranging from 102.8 to 106° F during moderate weather. Six were postoperative and 3 were medical patients.

Failure of transport of heat from the interior to the body surface with consequent heat retention was indicated in five of the postoperative and two of the medical patients by a cold skin and a high rectal temperature. In each case a circulatory factor was present: auricular fibrillation in two, excessive tachycardia in two, severe hemorrhage in one, shock following myocardial infarction in one, and circulatory collapse in acute liver necrosis in one.

Failure to eliminate heat from a hot skin was present in one patient with ichthyosis who was virtually unable to sweat and in whom anesthesia, surgery and excessive bed covering combined with very hot weather to produce a rectal temperature of 105° F. An overdose of barbiturate led to hyperthermia of 104.6° F in one patient found unconscious in a hot humid room. Dehydration, pulmonary edema, and anoxia plus a disturbance of the heat regulatory mechanism were contributory factors.

In each patient several factors were operative but the common factor was the inability to lose heat as rapidly as it was produced, usually due to inadequate circulation. A hot humid environment was often the precipitating factor since this interfered with heat loss. The load on the cardiovascular system was increased by heat retention and attendant tachycardia. This led to excessive tachycardia or auricular fibrillation with less efficient circulation and further heat retention.

From the study of these patients with severe hyperthermia one is led to consider the factor of heat retention in fevers of lesser degree such as occur in congestive heart failure, shock, myocardial infarction, etc. Measures aimed at facilitating heat loss at the inception of fever may prevent the serious effects of hyperthermia.

## 69 THE EFFECT OF HIGH VAGUS SECTION UPON THE CLINICAL PHYSIOLOGY OF THE BRONCHI

DOUGLAS R. MORTON, M.D. (By Invitation), KARL P. KLASSEN, M.D. (By Invitation), and GEORGE M. CURTIS, M.D., COLUMBUS, OHIO

Other than the occurrence of substernal pain in patients having acute bronchitis, little is known concerning pain of bronchial origin. Consequently, an evaluation of the quality as well as the referral of pain of bronchial origin was made in patients by direct stimulation of the bronchial mucosa, using an electrode introduced through a bronchoscope. Following recovery from the bronchoscopy, the patients described the sensation as a moderately intense aching pain, which was felt in the homolateral anterior chest or the homolateral anterior cervical region. In a series of twenty-five patients thus investigated, the referral of pain was consistent and symmetrical.

Patients found to have inoperable bronchogenic carcinoma at exploratory thoracotomy afforded an opportunity to evaluate the effect of vagotomy on the clinical physiology of the bronchi. Accordingly, in these patients the vagus nerve was transected above the pulmonary plexus, yet below the origin of the recurrent laryngeal nerve, with the following results:

(1) The *cough reflex* arising from the homolateral bronchial tree was abolished in all instances. (2) In the majority of cases *pain* of bronchial origin was abolished on the homolateral side. In the remaining few, there was referral of pain to the contralateral anterior cervical region. (3) No effect on the physiologic respiratory change in *bronchial caliber* was noted, nor was any effect observed on *bronchial motility*. (4) On bronchoscopic observation no subsequent changes were noted in the amount nor in the consistency of *bronchial secretions*, likewise, postbronchography roentgenograms revealed no impairment of Lipiodol clearance of the tracheobronchial tree. (5) In a limited number of cases, electrocardiographic tracings were unaffected by compression of the vagus nerve or its transection or by electric stimulation of either the proximal or distal ends of the transected vagus.

## 70 PYRIDOXINE DEFICIENCY IN HUMAN BEINGS INDUCED WITH DESOXYPYRIDOXINE

JOHN F. MUELLER, M.D. (By Invitation), and RICHARD W. VILTER, M.D., CINCINNATI, OHIO

Since 1934, when Gyorgy announced the existence of a new vitamin for the rat, which when synthesized was called pyridoxine, numerous reports have appeared clearly defining deficiency states in various laboratory animals. These have included seborrhea-like dermatitis, muscular weakness, decrease in lymphoid tissues, and decrease in circulating antibodies in the rat, hypochromic anemia in the dog, anemia and central nervous system lesions in swine, and lymphocytopenia and absolute increase in neutrophils in the monkey. There has never been a clear-cut demonstration that pyridoxine is essential to human beings and a pyridoxine deficiency state in man is unknown.

With the recent advent of metabolite inhibitors, a new tool has been placed in the hand of the investigator to study deficiency states. Such antagonistic activity toward pyridoxine has been demonstrated for desoxy pyridoxine in the chick. During pilot experiments to determine the toxicity of desoxypyridoxine in man, we observed a deficiency syndrome precipitated

by a vitamin B complex poor diet and desoxy pyridoxime which responded specifically to pyridoxime. These early experiments have been extended and are the basis of this report.

Eight patients suffering from various chronic illnesses were given 60-150 mg of desoxy pyridoxime intramuscularly daily while they were maintained on a diet low in vitamins of the B complex. Hematologic studies were done before and at biweekly intervals after the institution of the experimental regime. Urine assays for pyridoxic acid, thiamin, riboflavin, and N<sup>1</sup> methyl nicotinamide were done at weekly intervals in most instances. When the deficiency state developed the patient was placed on a vitamin B complex mixture devoid of pyridoxime and later on pyridoxime alone. The desoxy pyridoxime and diet were continued throughout the entire experimental period.

Seborrhea like skin lesions developed about the eyes, nose, and mouth within two to three weeks in seven of the eight patients. In three of the seven the lesions were quite severe. Half of the patients developed erosions in and around the mouth resembling cheilosis of riboflavin deficiency and glossitis resembling morphologically that seen in niacin deficiency. One patient developed severe systemic symptoms. A mild but definite lymphocytopenia appeared in seven of the eight patients. No anemia occurred. These manifestations were unchanged when the vitamin B complex mixture devoid of pyridoxime was given but responded in forty eight to seventy two hours to the parenteral administration of 100 to 200 mg of pyridoxime.

The authors feel that these lesions constitute at least one part of the human syndrome of acute pyridoxime deprivation.

## 71 PANCREATIC DYSFUNCTION AND LIVER DISEASE

R. O. MUETHER, M.D., WILLIAM KNIGHT, JR., M.D. (BY INVITATION),  
AND VINCENTE MORAGUES, M.D. (BY INVITATION), ST. LOUIS, MO

Advances have been made in the knowledge of the etiology and pathogenesis of liver and pancreatic diseases. Recent animal studies by Charkoff, Best, Gillman, Ivy, and others have shown that fatty deposition in the liver or fibrosis may follow inflammatory changes in the pancreas, pancreatic duct ligation, and pancreatectomy in dogs maintained on a diet of lean meat and insulin. The hepatic changes could be prevented by the feeding of pancreatic tissue and lipotropic agents.

Experimentally there appears to be sufficient evidence to indicate that disturbance in pancreatic function may lead to serious liver disease.

Hepatic changes have been demonstrated to accompany certain pancreatic diseases such as diabetes mellitus and acute pancreatitis. However, pancreatic dysfunction as a cause of serious permanent liver damage has largely been overlooked.

The use of frequent serum diastase determinations and the prostigmine diastase test has increased the accuracy and incidence in the diagnosis of pancreatic dysfunction and has enabled us to detect abnormalities of the pancreas when diseases of other organs in the upper abdomen may be also present.

We wish to report the case histories and laboratory data of five patients who had pancreatic disease as shown by the clinical history, elevated random diastase determinations, and abnormal prostigmine diastase tests and who also had hepatic disease. These diagnoses were confirmed by surgical exploration and biopsy.

The pathology in the liver ranged from periportal round cell infiltration, similar to that seen in cholangiolytic hepatitis, to the marked fibrosis of advanced hepatic cirrhosis.

In none of the cases could the usual etiological agents of liver disease such as toxins, infection, or malnutrition be elicited. The elevated serum diastase values which occurred at intervals in these patients as well as the abnormal prostigmine diastase test are at variance with the low serum diastase values usually found in patients with damaged livers. These findings and the experimental work of Chaikoff and others, which indicate that removal or damage of the pancreas in dogs and rats will result in fatty infiltration of the liver, as well as inflammatory changes and various types of fibrosis, lead us to suspect that pancreatic dysfunction may at times play an important etiological role in the pathogenesis of liver disease.

## 72 CHANGES OBSERVED FOLLOWING THE EXPERIMENTAL INFUSION OF THE DIURETIC SODIUM SULFATE

L. A. NALESKI, M.D., CHICAGO, ILL.

(INTRODUCED BY N. C. GIBBERT, M.D.)

The diuretic ability of sodium sulfate was established some sixty years ago in experimental animals. It was first administered parenterally to human subjects in 1934. No adverse effects were reported in normal subjects receiving moderate doses, and when given to patients with diminished urine outputs, it appeared to be nontoxic. Martland encouraged its use for anuria resulting from crush injuries during the "blitz" in England, but it was not widely adopted. Recently the Council on Pharmacy and Chemistry of the American Medical Association granted its approval for the parenteral use of sodium sulfate as a diuretic in the treatment of oliguria or anuria secondary to the crush syndrome, burns, transfusion reactions, toxic hemolysis, and obstructive lesions of the genitourinary tract.

The author observed the use of this diuretic in four patients. In two with cardiac edema, one responded well and the other expired suddenly several hours after 1 liter of isotonic sodium sulfate was administered. Two patients with anuria resulting from hemolytic reactions consequent to receiving improperly typed blood expired without diuresing. Unusually high blood sulfate levels were found following the use of sodium sulfate.

The foregoing clinical observations prompted further experimental study of this drug. Healthy female dogs were anesthetized, after which they were infused with isotonic sodium sulfate. A control group of animals was studied using isotonic sodium chloride. The infusions were maintained for a period of five hours. At hourly intervals arterial blood samples were obtained and subjected to a complete electrolyte and acid-base study. Urine was collected quantitatively during the same intervals and studied similarly. Electrocardiographic tracings were made initially and at the end of each hour. At the end of the five-hour infusion the animals were sacrificed and tissue biopsies obtained.

It was found that a true acidosis developed following sodium sulfate infusion and that this acidosis could be mitigated by the proper use of buffers in the infusion media. Histologic changes were present in the kidneys of those animals infused with sodium sulfate and absent in the control group. Electrocardiographic changes were also demonstrated during the sodium sulfate infusion.

It is concluded that the indiscriminate use of sodium sulfate as a diuretic in cases of anuria is dangerous. By utilizing a buffered solution with the sodium sulfate, it is thought that some of this danger may be eliminated.

# 73 CARDIOVASCULAR CHANGES FOLLOWING THE EXPERIMENTAL ADMINISTRATION OF BARIUM CHLORIDE

L. A. NALFFSKI MD (BY INVITATION), N. C. CHUBERT MD AND  
G. K. FENN MD (CHICAGO ILL)

During recent experiments with various heparin preparations it was found that the sodium salts of heparin increased the coronary flow volume while the barium salts of heparin did not show this effect. In earlier work in coronary flow studies we gained the impression that the soluble barium salts acted as a coronary constricting agent. We therefore decided to study the action of this drug on the cardiovascular system in detail.

Healthy mongrel dogs ranging in weight from 10 to 12 kilograms were given barium chloride orally and parenterally in a conscious state. Electrocardiographic and plethysmographic tracings were made. Blood pressures were recorded. The effect on coronary flow was determined in anesthetized animals by cannulating the coronary sinus and also by studies on the empty beating heart.

Barium chloride administration was followed (a) by electrocardiographic changes such as seen in coronary insufficiency and (b) by a variety of arrhythmias. A hypertensive effect was produced with a slowing of the heart rate. The plethysmographic tracings indicated a generalized vasoconstrictor effect. Coronary flow was markedly decreased in the experiments conducted.

There appeared to be a difference in tolerance of the drug in various animals. Some would suddenly expire with convulsions and electrocardiographic tracings in these animals indicated that death was caused by coronary insufficiency. Autopsies made immediately after death showed grossly areas which were similar in appearance to those found immediately following ligation of a coronary artery. All of these toxic effects of barium chloride could be delayed or prevented by treating the animal previously or during the experiment with aminophyllin or papaverine.

It has been shown by others that barium chloride is precipitated within a matter of several minutes by the sulfate ions normally present in the blood stream. Therefore it was difficult to explain the prolonged effects that barium chloride administration sometimes exhibits. Because of this paradox colloidal barium sulfate preparations were made and given parenterally. Similar electrocardiographic changes were obtained with this molecular preparation as with the ionized salts.

From these experiments we conclude that the clinical use of barium chloride in the Stokes Adams syndrome or for any other purpose is dangerous and unpredictable.

# 74 KIDNEY EXCRETION DURING AND AFTER HEMOGLOBINEMIA

A METHOD FOR PRODUCTION OF HEMOGLOBINEMIA BY HIGH SONIC VIBRATION

WILLIAM H. OLSON MD (BY INVITATION) AND H. NECHLES MD  
CHICAGO ILL

Our goal in this work was to obtain an experimental animal (dog) with complete suppression of kidney excretion due to hemoglobinemia, the animal to remain alive and die in nature from five to ten days after the onset of hemoglobinemia. Acute and chronic experiments were done on large healthy male dogs.

Acute experiments were performed using the following methods for producing hemolysis: thermal trauma, intravenous injection of distilled water, intravenous injection of hemoglobin solution, intravenous injection of hemolytic agents, heating and cooling blood, and, finally, use of high frequency sonic vibrations. The latter method proved to be the most useful, and it was employed throughout most experiments. Blood pressure, urine excretion, blood studies, and survival time were studied. For production of the sonic hemolysis, a magnetostriiction oscillator was used that produced high energy by giving off vibrations in the region of high sonic frequency. The magneto oscillating rod was placed into a glass cup with two side cannulas which were connected to blood vessels. The blood was hemolyzed as it flowed past the rod. An extremely high degree of hemoglobinemia could be obtained, the highest value was 11,125 mg per cent of plasma hemoglobin.

In well-hydrated animals with no hemoconcentration, hemoglobinemia may produce complete suppression of kidney excretion during the period of hemolysis. Following this the animal may develop diuresis when plasma hemoglobin is below 5,000 mg per cent, oliguria when plasma hemoglobin is between 5,000 and 8,000 mg per cent, or anuria when plasma hemoglobin is above 8,000 mg per cent. In an animal with moderate reduction of blood pressure, together with a progressing hemoconcentration, the production of hemoglobinemia with levels above 2,500 mg per cent resulted in anuria.

The duration of the period in which hemolysis was produced varied between ten and sixty minutes. It is felt that, for the study of experimental anuria, rapid hemolysis must be used, in order to obtain comparable experimental animals.

## 75 CARDIAC FACTORS IN 'NEUROGENIC' PULMONARY EDEMA

ROBERT PAINE, M D (By INVITATION), HARVEY R BUTCHER, M D (By INVITATION), AND JOHN R SMITH, M D, ST LOUIS, MO

Experimental evidence indicates that Starling's principles of fluid balance are applicable to the lung. Pulmonary edema follows either a diminution of blood osmotic tension or an increase in capillary hydrostatic pressure. Furthermore, increased pulmonary hydrostatic pressure, sufficient to provoke edema, results when cardiac overload is unequally thrown upon the left ventricle. It is likewise possible that left ventricular overload may be produced by "neurogenic" factors. Increased intracranial pressure or vagal stimulation are reported to cause pulmonary congestion and edema through cardiovascular responses extraneous to the lungs.

In open-chest preparations of dogs, pulmonary and systemic arterial and venous pressures were simultaneously recorded. The administration of epinephrine (0.25 to 1.0 mg intravenously) produced the usual striking rise of arterial pressure and marked bradycardia. Cardiac dilatation and elevation of pulmonary venous and arterial tensions occurred, with congestion and edema of the lungs. Conversely, when bilateral faradic vagal stimulation was applied, the resulting bradycardia was accompanied by a fall of systemic arterial pressure, pulmonary congestion and edema did not occur. It is suggested that sufficient elevation of systemic arterial pressure, together with critical bradycardia (reduced minute volume output), from epinephrine, may overload the left ventricle if there is continued competence of the right ventricle and optimum venous return. The experiments suggest that neurogenic influences may alter the pulmonary vascular dynamics through adjustments that lead to impaired left ventricular function.

## 76 DIABETES DETECTION

BRUNO J. PETERS, MD, MILWAUKEE, WIS.

(INTRODUCED BY MATTHEW HARDGROVE, MD)

Diabetes detection is becoming a problem of increasing importance. Early diagnosis may be the only way one can hope to modify or possibly cure the disease. This is a preliminary report on a diabetes detection survey started in September 1948 which is still being carried on at an industrial plant in Milwaukee, Wis. To date 180 patients have been tested, 69 female and 112 male, their ages ranging from 18 to 75 years. The patients are an unselected group who come to the medical department for routine physical examinations or come with minor ailments. No patient with a definite history of diabetes or symptoms suggestive of diabetes is included in the present report. The individual besides having routine laboratory examinations was given 100 Gm. of glucose on a fasting stomach and a blood sugar determination two hours after the ingestion of the glucose. The blood sugar determinations were done by the Folin Wu method. Recently the Somogyi method has been used in addition.

If the blood sugar report was 130 mg. or over, the patients were told to eat a normal diet during the next three days and warned against missing meals or fasting. After that period a glucose tolerance test was done. In those patients who fulfilled the following criteria: presence of sugar in the urine together with peak level above 170 mg. per cent (Folin Wu) after the ingestion of glucose, a diagnosis of diabetes was made. Eleven cases fell in this group.

Five patients were diagnosed as having a prediabetic state because these patients demonstrated diabetic glucose tolerance curves but did not have sugar in the urine. A diabetic curve is one with a peak level above 170 mg. per cent and a level above 130 mg. per cent two hours after ingestion of 100 Gm. of glucose. In these five patients the peak levels ranged from 196 to 216 and none had a return of B.S. to below 132 in two hours. Two patients were classed as potential diabetic patients. They had peak levels of 225 and 187 respectively, and two hour levels of 108 and 114 with no sugar in the urine.

On the basis of this survey, eleven patients or 5.1 per cent had definite diabetes as proved by an abnormal glucose tolerance and sugar in the urine. Five patients (2.8 per cent) had abnormal glucose tolerance curves but had no sugar in the urine and two (1.1 per cent) were classified as potential diabetic patients. None of these patients have symptoms of diabetes. Some have had several determinations during the year and continue to show the same abnormal tolerance curves. Only seven of these patients have fasting blood sugars above 120 mg. per cent, the highest being 151 mg. per cent.

If one considers the first two groups collectively, approximately 7.9 per cent of the patients will have diabetes. It is felt that screening methods for diabetes will uncover a large number of diabetic patients but many will still be missed unless more accurate testing is done.

## 77 INTERPRETATION OF THE RESULTS OF THE FLOCCULATION TESTS ON BASIS OF BIOPSY FINDINGS AND PROTEIN PARTITION

HANS POPPER, M D, FREDRICK STFIGMANN, M D, J DE LA HUERGA, M D  
(By INVITATION), CHICAGO, ILL, AND MURRAY FRANKLIN, M D (By  
INVITATION), IOWA CITY, IOWA

The diagnostic significance of the flocculation tests in hepatobiliary diseases is not fully understood despite their established practical value. Therefore, in 187 cases with various liver diseases (226 series of determinations), the results of cephalin flocculation (CF), thymol turbidity (TT), zinc sulfate turbidity (ZST), and the recently described gamma globulin turbidity (GGT) were compared with those of chemical and electrophoretic partition of serum proteins into albumin and the various globulins and, where available, with the findings in liver biopsy specimens. This correlation indicated the following factors as influencing the results of the flocculation tests:

- 1 Reduction of serum albumin, mostly as result of liver cell damage. This increased all flocculation tests except the GGT.
  - 2 Elevation of gamma globulins in hepatic disorders mostly related to proliferation of Kupfer cells and other mesenchymal cells and histologically recognized by appearance of cytoplasmic ribonucleic acid. This is possibly an expression of antibody formation or of stimulation by liver cell breakdown products. This factor tends to elevate all flocculation tests. It also explains the elevation of GGT and ZST in recovering viral hepatitis, being more marked with tendency for cirrhosis formation.
  - 3 Depression of gamma globulin formation in severe jaundice as result of intra- or extrahepatic biliary obstruction, apparently related to excessive bile pigment inhibition of the Kupfer cells.
  - 4 Depression of ZST but also CF and TT (despite elevation of the gamma globulins) by a humoral factor occurring in obstructive jaundice (probably of biliary nature) and occasionally in cirrhosis without jaundice (so far of unknown character).
  - 5 A factor probably resulting from qualitative changes of serum albumin producing elevation of CF and TT, not explained by changes in the albumin/gamma globulin ratio.
  - 6 Lack of a TT enhancing factor, possibly of lipid character but not related to total lipid or cholesterol concentration. This accounts for the often normal or only slightly increased TT in alcoholic cirrhosis.
- Interplay of these factors produces diagnostic patterns of the flocculation tests in most conditions. Only in toxic hepatitis was the pattern not characteristic. The third and fourth factors account for the normal flocculation tests in extrahepatic biliary obstruction and occasionally in hepatitis with intrahepatic obstruction, both even in presence of severe liver damage. Superimposed bacterial infection in extrahepatic obstruction may raise GGT, CF, and TT without necessarily elevating ZST. Understanding of these factors and the performance of all four flocculation tests increases their diagnostic value.

## 78 A PRELIMINARY REPORT ON THE STUDY OF MYOCARDIAL INFARCTION BY AURICULAR CATHETERIZATION

WALTER H PRITCHARD, M D HERMAN HELFFSTEIN, M D (BY INVITATION),  
ROBERT LEWIS, M D (BY INVITATION), AND SCOTT INKLEY M D  
(BY INVITATION), CLEVELAND OHIO

In a preliminary experience initiating a study of the dynamic effects of acute myocardial infarction six patients were studied by the right auricular catheterization technique. All patients had definite evidence of the onset of an acute infarct both from clinical and electrocardiographic studies ten to seventeen days prior to catheterization. Cardiac rhythm was normal and congestive failure absent. This postinfarction period was selected as the period of initial study because of the theoretical hazards accompanying catheterization immediately following an acute infarct. After sufficient data and experience have been acquired in the study of this period observation will be extended to the more immediate postinfarction period.

In nine control patients hospitalized for a similar period of time with diseases other than cardiac disorders cardiac indices ranged from 28 to 38 liters per minute per square meter of body surface.

No difficulties or complications have been encountered during or after catheterization. Basal oxygen consumption and right auricular pressures during the procedure were within normal limits in all patients.

In three patients cardiac output, arterial blood pressure and heart work were within normal limits. In the remaining three patients all of whom had low blood pressures work was reduced approximately 30 per cent below the lower normal range of the control values.

One patient was catheterized on the tenth and again on the thirtieth post infarction day. At the first catheterization values for output and work were low. Following the usual clinical improvement during the following three weeks, blood pressure and work rose but cardiac output remained unchanged.

These studies are of a preliminary nature and no conclusions relative to factors leading to reduced output or maintenance of a normal output following infarction can be drawn. In the present small series of cases there was no correlation between the apparent size of the infarct determined from the electrocardiogram and the level of cardiac output.

## 79 TWO RARE CASES OF CONGENITAL MALFORMATION OF THE HEART OF THE CYANOTIC GROUP RIGHT HEART CATHETERIZATION AND ANGIOCARDIOGRAPHIC STUDIES

O PREC (BY INVITATION), L N KATZ, M D W Hwang (BY INVITATION),  
AND N GROSSMAN (BY INVITATION) CHICAGO ILL

Two cases of rare anomalies of the cyanotic group which must be differentiated from the tetralogy of Fallot are presented.

The first case is that of a girl  $5\frac{1}{2}$  years of age with symptoms of mild dyspnea and cyanosis on exertion. Cardiac catheterization and angiocardiography demonstrate a complex malformation consisting of (a) a single ventricle, (b) a pseudotruncus arteriosus with probable hypoplasia of the right pulmonary artery, and (c) aberrant venous coronary drainage directly

into the common ventricle. Data and pressure tracings are presented. Differential diagnosis and certain hemodynamic factors, particularly those which may disturb the balance between the systemic and pulmonary circuits, are discussed.

The second case is that of a 4-year-old girl with persistent cyanosis. Data obtained by right heart catheterization reveal (a) transposition of great vessels, (b) intra-ventricular septal defect, and (c) patent ductus arteriosus. The problem of differential diagnosis in this case between the Eisenmenger complex and Taussig's heart, consisting of transposition of the aorta and overriding pulmonary artery, is outlined and the dynamics are discussed.

## 80 STUDIES ON THE SPREAD OF EXCITATION THROUGH THE VENTRICULAR MYOCARDIUM

RAYMOND D. PRUITT, M.D., HIRSH E. ESSEX, Ph.D. (By Invitation), and  
HOWARD B. BURCHIELL, M.D., ROCHESTER, MINN.

Direct lead electrocardiograms have been recorded on isolated perfused dogs' hearts subjected to certain injuries designed to influence the spread of the excitatory process through the ventricular myocardium. These injuries were produced by the introduction into the left or right ventricular cavity of solutions or crystals of potassium chloride, silver nitrate, phenol and cocaine.

Injuries sufficiently severe to be attended by the electrocardiographic pictures of bundle branch block did not evoke any specific effect which might be ascribed to arborization block consequent to destruction of Purkinje fibers. As complexes typical of bundle branch block developed in epicardial leads, the QRS complex in leads from the ventricular cavity into which the traumatizing agent had been introduced assumed an essentially monophasic character, with an R wave very similar to that recorded simultaneously from a contiguous epicardial lead. Apparently, endocardial and epicardial electrodes bore a similar spatial relationship to the spread of excitation through the intervening ventricular wall.

In an attempt to account for these findings, the following hypothesis was proposed. The speed at which the excitatory process spreads through a certain segment of the myocardial syncytium depends upon the orientation of the fibers in that segment to each other and to the point of origin of excitation. Spread down a strip of fibers of which the long axis is parallel to the long axis of the strip is rapid as compared with spread down a strip in which the fibers run at a right angle to the long axis of the strip. Endocardial activation is rapid not because of the presence of Purkinje fibers, but because the subendocardial bands of myocardium form a network through which excitation can move rapidly along the long axis of the fibers. Spread across the septum in bundle branch block and across the free wall of the left ventricle in the normally activated heart is slow because excitation is moving through fibers, the long axis of which is perpendicular to the advancing wave of excitation.

Testing of this hypothesis was undertaken by isolation of a segment of the ventricular wall, except for a limited attachment at one end of the strip. The spread of excitation down this segment was studied in relation to the disposition of the fibers constituting the strip. The presence of a band of fibers, the long axis of which is parallel to the long axis of the strip, appears to be essential to rapid excitation of the segment. Whether these fibers are epicardial or endocardial makes no difference.

## 81 THE PATHOLOGIC PHYSIOLOGY OF MEGA ESOPHAGUS

I DARIN PUIPEL M.D. COLUMBUS OHIO

The actual underlying physiopathology of mega esophagus is still a matter of uncertainty, in spite of many theories set forth. Because methods of determining the functional behavior of various parts of the esophagus have heretofore been so equivocal and inadequate we have felt that esophageal motility studies by the balloon and kymograph method might aid in solving this problem. We have made extensive esophageal motility studies under varying conditions of three normal persons, three patients with achalasia and five patients with organic obstructive lesions of the esophagus.

The three normal persons served as controls. They were studied under varying conditions over many hours. These studies show that organized frequent contractions of good amplitude are related normally with powerful peristaltic waves and an excellent deglutition effect as revealed by a strong pull on the Linhorn tube attached to the balloon. They play an outstanding role in Magendie's third stage of swallowing.

Information obtained by fluoroscopy and x-ray film studies during barium swallow and by observed clinical effects on the inflated balloon which acted as a bolus of food was complementary to that obtained from the esophageal motility studies. The data considered together gave adequate conceptions of the action of the musculature of the esophagus. These data indicated that the intrinsic motility of mega esophagus varies greatly being almost always irregular, uncoordinated, hyporesponsive to stimuli and not completely effective. In fact the intrinsic motility at times completely failed and in one patient was entirely absent indicating total motor paralysis. This differs from that of the organic obstructive lesions of the esophagus in which there usually occurs a normal motility in the segment proximal to the lesion but rarely a hypermotility or even a hypomotility depending upon the degree of obstruction and the stage and complications of the organic disease. Achalasia of the esophagus also differs from true esophagospasm in which there usually occurs a hypermotility and hyperirritability.

These data indicate that the disease in idiopathic mega esophagus is not localized necessarily to the cardiac end of the esophagus as is commonly believed. In our experience functional abnormalities often involve the entire length of the esophagus. These newer observations offer further evidence for and are compatible with the general theory of achalasia as an underlying mechanism of cause of idiopathic mega esophagus.

A discussion will be presented of the effects of atropine and sympatholytic and parasympathomimetic drugs upon the disturbed peristalsis. The clinical implications of these data will be set forth.

## 82 THE PROTHROMBIN ACTIVITY OF HUMAN BLOOD

ARMAND J. QUICK, M.D. AND MARIO STEFANINI, M.D. (BY INVITATION)  
MILWAUKEE, WIS.

In 1943 when the labile factor was discovered it was noted that the addition of a small amount of depiothrombinized rabbit plasma which has a high concentration of labile factor to stored plasma reduced the prothrombin time markedly below normal. Recently it was found that if blood was carefully collected and stored in silicone coated glassware the prothrombin activity decreased on storage but the addition of depiothrombinized rabbit plasma that is excess labile factor reduced the prothrombin time only to the

level of fresh plasma. By means of the direct method of determining prothrombin by adsorption with tricalcium phosphate and elution with sodium citrate, it was further found that plasma stored in glass twenty-four hours or longer contained a much greater quantity of prothrombin than fresh or stored plasma kept in a silicone-coated container.

Obviously prothrombin activity increases in plasma stored in glass. This is masked by the decrease in labile factor and only becomes evident when labile factor is readded. In a silicone-coated container such an augmentation does not occur during several days of storage. The change in prothrombin activity is explained by postulating that prothrombin in circulating blood exists both in an active and in a precursor state. In contact with a rough surface such as glass the precursor is converted to the active form. In isolated plasma the activation is relatively slow, while in native plasma it occurs in less than an hour. What factor other than the surface of the container is necessary for this conversion to active prothrombin remains undetermined. Platelets, calcium, and thrombin are not essential for this reaction.

Total and free prothrombin and the conversion to the active form are normal in hemophilia and thrombocytopenic purpura. In Dicumarol poisoning both active and total prothrombin are reduced. In one type of congenital hypoprothrombinemia both the active and total prothrombin are below normal, in a second type the active is low but the total may be normal.

In summary, prothrombin in human blood occurs partly in an active form and partly in a precursor state. Prothrombin activity as measured by the prothrombin time is dependent upon the concentrations of (1) active prothrombin (not total), (2) labile factor, and (3) bound calcium. Whether the inactive prothrombin acts as a reserve or becomes activated during standing is not known.

### 83 THE EOSINOPHIL RESPONSE IN ADRENOCORTICOTROPIC HORMONE (ACTH) THERAPY

THERON G. RANDOLPH, M.D., DAVID E. MARKSON, M.D. (BY INVITATION),  
AND JOHN P. ROLLINS, M.D. (BY INVITATION), CHICAGO, ILL.

Ten patients with diagnoses of rheumatoid arthritis, ulcerative colitis, bronchial asthma, and other allergic disturbances were observed prior to, during, and, in some instances, following the cessation of therapy with ACTH Armour by means of serial direct counting chamber eosinophil determinations of the peripheral blood with propylene glycol-phloxine stain diluting fluid as previously described by one of us (T.G.R.).

An average of eleven blood eosinophil determinations was made per patient prior to starting ACTH therapy. The average number of circulating eosinophils was found to be 472, the range varying from a minimum of 55 cells to a maximum of 2,354 cells per cubic millimeter of blood.

Eosinophils disappeared from the peripheral circulation following the intramuscular administration of ACTH in all instances, confirming the observations of Hills, Forsham, and Finch. An absence of circulating eosinophils was first noted in one case at six hours and in another at seventy-two hours, with an average of twenty-eight hours. The dosage of ACTH ranged from 40 to 200 mg per day. The total quantity required for this eosinophil response varied from 15 mg in one individual to 400 in another, averaging 112 mg per twenty-four hours.

One patient was treated with 100 mg daily for seventy-eight hours, two for fifty-four hours, receiving a total of 325 and 225 mg ACTH, the eosinophils

returned to pretreatment levels three four and six days respectively following cessation of therapy. One patient treated at a level of 200 mg daily for thirteen days developed an elevation in eosinophils to twice his pretreatment average level coincident with a reduction of his dose to 150 mg.

Pretreatment examinations of the nasal secretions and sputa in three patients revealed high levels of eosinophils. These cells disappeared from the nasal and bronchial secretions between twelve and twenty four hours after the onset of ACTH therapy.

#### 84 ALLERGIC REACTIONS FOLLOWING THE INTRAVENOUS INJECTION OF CORN SUGAR (DEXTROROSE OR GLUCOSE)

THERON G RANDOLPH MD AND JOHN P ROLLINS MD (BY INVITATION)  
CHICAGO, ILL, AND CLYDE K WALTER MD (BY INVITATION) YOUNGSTOWN OHIO

Pyrogen contamination has been considered as the major cause of reactions associated with intravenous dextrose therapy. Although the institution of sterile vacuum packed fluid containers and sterile packed disposable recipient sets has largely controlled these factors, disturbing clinical reactions still occur. The fact that these reactions appear in selected individuals suggests that the cause may be due to some peculiarity of the recipient.

So completely have the terms dextrose and glucose been dissociated from their source material that it is not generally realized that all dextrose or glucose is prepared from the simple hydrolysis of corn starch. The fact that the ingestion of corn starch and corn sugar (dextrose or glucose) causes allergic responses in corn sensitive individuals raises the possibility that corn sugar might also act as an allergen when it is injected.

Of several patients previously shown to be highly corn sensitive four were selected for this report. In each case the diagnosis of corn sensitivity was made as a result of the experimental feeding of corn meal gruel and corn sugar after four days of complete corn avoidance. Twenty five cubic centimeters of 5 per cent dextrose were injected slowly intravenously under sterile and pyrogen controlled conditions. In each case severe constitutional reactions occurred which were clinically similar to those observed following the ingestion of corn sugar and corn meal. The control injection of invert sugar of cane origin failed to produce a similar response with the exception of one patient clinically sensitive to both corn and cane. Similarly the control injection of normal saline was without effect.

The importance of these observations cannot be dismissed inasmuch as corn sensitivity and wheat sensitivity are of approximately equal occurrence ranking as the first two foods responsible for the production of chronic food allergy.

Clinical reactions from the intravenous injection of corn sugar occur both in undiagnosed and diagnosed cases of corn sensitivity. More violent reactions may be expected in the corn sensitive individual who has avoided sources of corn in the diet either intentionally or inadvertently for several days prior to the intravenous administration of dextrose or glucose.

## 85 THE DETERMINATION OF THE BASAL METABOLISM BY PERIODIC MAXIMAL EXHALATIONS

HENRY W RYDER M D , AND VIRGINIA M ESSELBORN, M D (BY INVITATION)  
CINCINNATI, OHIO

The measurement of the basal metabolism is subject to considerable variation through the natural inability of many subjects to breathe evenly. We have investigated the possibility that the chest position after a voluntarily forced exhalation might be less variable than after a quiet expiration and therefore lead to a more reliable method of estimating the basal oxygen consumption.

One hundred and fifty consecutive subjects of both sexes, with great diversity in age, height, weight, intelligence, and illness, were studied clinically. Then oxygen consumption was measured by the test and standard methods. The test method was a modification of the standard in that every minute the subject was directed to force a maximal exhalation. The first sixty-two subjects were tested by both methods. For the second group of fifty-four subjects a third method was introduced, which modified the test method by continuing for twelve or fourteen minutes and by including early in the test the performance of the maximal breathing capacity. The last group of thirty-four subjects performed the standard and test methods in duplicate. The order in which all tests were done in each series was determined from a prearranged schedule derived from a table of random numbers.

The test procedure does not measurably affect the rate of oxygen consumption. It results in significantly less variation between duplicates. It usually corrects for systematic or irregular deviations in the depth of undirected breathing that commonly lead to either an indeterminate conclusion or to a fallacious inference as to the true rate of oxygen consumption. The uniformity of the end point of forced exhalation is unaffected by such factors as lung disease, congestive heart failure, dysthyroidism, lack of training, or low intelligence of the subject and is less affected by consciousness of breathing than is the standard method.

Therefore this simple modification of the standard method of measuring the basal metabolism allows the rate of oxygen consumption to be estimated in some subjects when the standard method is unreliable, and in all subjects the estimate is usually significantly more precise.

## 86 IDIOPATHIC DILATATION OF THE PULMONARY ARTERY

FRANCIS F ROSENBAUM, M D , AND JOSEPH F KUZMA, M D  
MILWAUKEE, WIS

Increased interest in the differential diagnosis of congenital heart disease has attracted attention to an unusual disorder characterized by dilatation of the main pulmonary trunk with or without dilatation of the pulmonary arterial branches. This change in the pulmonary artery is unaccompanied by any other structural cardiac or pulmonary disease. It is considered a congenital cardiovascular disorder but its etiology is undetermined. Less than twenty cases which are acceptable by relatively strict criteria have been reported, but there is evidence to suggest that this anomaly is more common than has been assumed.

Five examples of idiopathic dilatation of the pulmonary artery have been observed. In two of them the diagnosis was established at autopsy and in

one of these the diagnosis was made ante mortem. This patient was observed over a period of ten years. The dilated pulmonary arteries were demonstrated angiographically six months before her death. At that time the right, main pulmonary arterial branch was completely occluded by a calcified thrombus. The post mortem examination disclosed a pulmonary trunk which was actually considerably larger in diameter than the heart itself. The three additional patients are living but the clinical picture seems compatible with the diagnosis in all respects.

This disorder seems to predominate in female subjects. It has been observed from childhood to old age. Dyspnea, cough, cyanosis and hemoptysis are common symptoms although the patient often has few complaints until late in his course and the final illness may be very brief. The tolerance for exercise and pregnancy is usually surprisingly good. The major abnormalities disclosed by physical examination are a systolic murmur and a systolic pulsation in the pulmonic area, accentuation of the pulmonic second sound, and often a diastolic murmur along the upper left sternal margin. The abnormally dilated right outflow tract is easily visualized radiographically as well as in angiocardiograms and abnormal pulsations of the pulmonary arteries are common. The electrocardiograms usually show incomplete or complete right bundle branch block or evidence of right ventricular hypertrophy. Recent studies by Cournaud and associates have indicated that in these cases the systolic pressure within the dilated pulmonary artery is not elevated and in fact is lower than in the right ventricle.

#### 87 THE EFFECT OF AUROMYCIN ON UROBILINOGEN FORMATION AND THE FECAL FLORA

V. M. SBOROV, M.D. (BY INVITATION) PHOENIXVILLE PA. AND A. R. JAY, M.D. (BY INVITATION) AND C. J. WATSON, M.D. MINNEAPOLIS MINN.

The effect of aureomycin on urobilinogen formation has been studied in a series of fifteen patients. The amount of fecal urobilinogen was determined serially in seven of these single determinations being made in the remainder. Bacteriologic studies of the feces were carried out on eleven samples in four cases. In addition the amount of urobilinogen in the bile obtained by duodenal tube was determined in eight cases.

These studies reveal that following aureomycin and concomitant with a great reduction or practical disappearance of coliform organisms in the feces the urobilinogen of the feces, urine and bile markedly diminishes the values often falling into the range which characterizes complete biliary obstruction. The bile urobilinogen was entirely absent in seven of the eight instances, only a trace being demonstrated in the eighth. This may be contrasted with the uniform presence of small amounts in fifty individuals not receiving aureomycin. The Harrison test for bilirubin applied to the feces often became positive after aureomycin but the amounts did not appear to correspond with the reduction in amount of urobilinogen.

In a case of subacute bacterial endocarditis in which urobilinogen studies were first carried out after one month of continuous aureomycin therapy the feces contained very little bilirubin but gave a fairly intense Ehrlich reaction for urobilinogen. It was possible to demonstrate however that no stereo-bilirubinogen was present; polarimetry revealed that the only urobilin represented was dextro-rotatory rather than levo-rotatory. It was believed significant that the bile was now Ehrlich negative indicating that the fecal urobilinogen was not hepatic in origin. The feces at this time contained colon aerogenes inter-

mediates but no typical *E coli*. Nonproteolytic clostridia were also present. This combination is of interest since Kammeier and Miller, and, more recently, Baumgartel have ascribed the reduction of bilirubin in the colon to *E coli* and spore-forming anaerobes. In the present study *E coli* was regularly lacking in the feces after automycin and it is evidently essential to the reduction of bilirubin to stercobilinogen. It appears, however, that other organisms of aerogenes type are at times able, perhaps in association with clostridia, to effect a partial reduction of bilirubin, either to mesobilinogen or a dextrorotatory derivative thereof.

These results strongly support the belief that the urobilins of the feces, bile, and urine are wholly enterogenous. In recent years Baumgartel and co-workers have described evidence suggesting that, of the two urobilins, mesobilinogen is hepatogenous, only stercobilinogen being enterogenous. The present study reveals, however, that automycin markedly depresses the total urobilinogen formation and that under its influence urobilinogen completely disappears from the bile. These findings are incompatible with the hepatogenous concept unless one were to assume that automycin interferes with liver function, for which there is no evidence.

## 88 PAROXYSMAL MYOHEMOGLOBINURIA WITH FATAL RENAL TUBULAR INJURY

FRANCES E SCHIAAR, M D, J W LABREE, M D, AND D F GLEASON, M D  
MINNEAPOLIS, MINN

(INTRODUCED BY C J WATSON, M D)

A fatal case of paroxysmal myohemoglobinuria in a 23-year-old man is presented.

The history was suggestive of a familial occurrence. Fifteen cases have been described in the literature, in three of which there was a history of familial incidence.

Death was due to renal insufficiency and pulmonary edema. The myohemoglobinuria, which had been observed for the first three days of observation, disappeared six days before death. Myohemoglobinemia was carefully looked for but never demonstrated.

In the present case, the myohemoglobin in the urine was identified and distinguished from ordinary hemoglobin by virtue of its spectral distribution curve. Preliminary study of porphyrin metabolism revealed a moderate increase in fecal coproporphyrin, 60 per cent of which was type III.

Significant histologic changes were found in the striated muscles and kidneys. The uremia and subsequent death were the result of tubular injury, as indicated by the demonstration of hydropic degeneration of the proximal convoluted tubules. Although pigment casts were found, they did not appear to be sufficient in number to have been the cause of the uremia, as has been suggested by others. The finding of these casts supports the concept that the precipitation of pigment is more likely the result of disturbed renal function rather than the cause of it.

## 89 THE CLINICAL AND LABORATORY EFFECTS OF HYPOTONIC INTRAVENOUS INFUSIONS

JOHN A LAYNE M D F R SCHEMM M D JOHN S GILSON, M D  
(BY INVITATION), AND WILLIAM W HURST M D (BY INVITATION)  
GREAT FALLS MONT

We have found hypotonic solutions given by vein effective in furnishing water whenever the customary amounts of sodium chloride and dextrose present in standard isotonic solutions were undesirable or unnecessary. The use of hypotonic solutions has in our experience been attended with good clinical results and has permitted a more exact maintenance of water and electrolyte balance. Hypotonic solutions of dextrose and of sodium chloride were first used in correcting disturbances of the extracellular fluid (pattern disturbances, volume losses and plasma water deficits) in diabetes. Further experience has shown that these solutions are equally valuable in the more seriously ill patients who have a large antecedent plasma water deficit or who have a continuing excessive demand for plasma water. For the most part we employed solutions of one half isotonic strength and the three most commonly used solutions had the following composition: (1) 25 Gm of dextrose per liter of distilled water (2) 4.5 Gm of sodium chloride per liter (3) 12.5 Gm of dextrose and 2.25 Gm of sodium chloride per liter.

Thus far our clinical experience embraces more than fifty patients who have received hypotonic solutions in amounts varying from 1,000 cc in twenty-four hours over periods of from one to twenty-two days.

Immediate observations on the blood were made in twenty-three patients after 1,000 cc of a hypotonic solution had been given: twelve patients received 2.5 per cent dextrose and eleven received 0.45 per cent sodium chloride. The infusion was completed in periods of time varying from thirty to ninety minutes. Determinations of the plasma hemoglobin, total plasma protein, plasma specific gravity, hematocrit percentage, the number of erythrocytes, and the hemoglobin were made before the intravenous infusion was started, immediately after it was finished, and one hour after it was finished. As in earlier studies made after the prolonged use of large amounts of these solutions, but on blood drawn four to twelve hours after the last intravenous infusion had been given, none of these immediate determinations showed any evidence of harmful degrees of dilution. A transient slight fall in their values shown in most of the determinations made immediately at the end of the intravenous infusion was followed in the majority by a tendency to rise toward the original levels at the end of one hour. The blood showed no plasma hemoglobin except in two patients; in the one in whom the experiment was repeated with the same intravenous solution, no plasma hemoglobin was found.

## 90 STELLATE BLOCK IN THE MANAGEMENT OF NARCOLEPSY AND CATAPLEXY

ROBERT W SCHNEIDER, M D AND W JAMES GARDNER, M D (BY INVITATION)  
CLEVELAND OHIO

The effect on narcolepsy of the injection of procaine into the cervical sympathetic chains in four patients with narcolepsy and cataplexy, one patient with narcolepsy and one patient with hypersomnolence forms the basis of this report. Because of observations on alterations of cerebral function by temporary interruption of sympathetic impulses to the brain it was decided to ob-

serve the effect in narcolepsy. Associated symptoms and signs in these six subjects have been reviewed, and an attempt has been made to correlate these with the response to stellate blocks. Other common causes for excessive drowsiness were excluded by a number of laboratory procedures. An attempt was made to correlate the response of symptoms to stellate blocks and to the administration of Benzedrine and closely allied drugs.

The urinary excretion of gonadotrophic hormone (FSH) prior to and following stellate blocks was studied whenever possible. An electroencephalogram tracing in one subject discloses a very abnormal deep sleep pattern prior to stellate block. Repetition of the electroencephalogram in this same subject after stellate block injection shows a distinct difference, with a tendency toward a more normal pattern.

In general, patients with narcolepsy and cataplexy have their symptoms controlled for a period of time following stellate block injection, but the effect is more favorable upon the narcolepsy than upon the cataplexy. No change in urinary gonadotrophin excretion was seen to follow the procedure.

## 91 A SYNDROME OF HYPERTENSION, OBESITY, MENSTRUAL IRREGULARITIES, AND EVIDENCE OF ADRENAL CORTICAL HYPERFUNCTION

HENRY A. SCHROEDER, M.D., DEAN F. DAVIES, M.D., PH.D. (BY INVITATION),  
AND HELEN E. CLARK, M.D. (BY INVITATION), ST. LOUIS, MO

Twenty-four women suffering from arterial hypertension were found to possess certain common clinical and laboratory findings which suggested that they belonged to a previously undescribed symptom-complex. These were (1) relatively sudden onset of obesity occurring at menarche, menopause, after multiple pregnancies or gynecologic operation, (2) obesity of the "central type," with pale striae on thighs and sometimes on upper arms, (3) menstrual irregularities, (4) good or excellent therapeutic response of blood pressure levels to diets low in salt, with reversals when the intake of salt was raised, (5) abnormally low concentrations of sodium and chloride in sweat. Secondary and less common signs and symptoms included an aversion to salty foods and high fluid intakes, unexplained periods of oliguria, inconstant glycosuria or a diabetic type of glucose tolerance curve which was accompanied usually by increased sensitivity of the blood sugar levels to intravenously injected insulin, plasma chloride levels above or at upper limits of normal, hirsutism, a tendency to easy bruising and ecchymoses, a relatively benign type of hypertension with little albuminuria or other signs of renal damage, and sensitivity of the blood pressure to injected desoxycorticosterone acetate or glucoside. In no instance were the cardinal manifestations of Cushing's syndrome present. Because these symptoms, signs, and findings were seen rarely in other types of hypertension and because concentrations of sodium chloride in sweat were normal in most subjects, including obese nonhypertensive women, it is believed that these patients represent a separate pathogenetic entity. The evidence is strongly suggestive that certain functions of the adrenal cortex are specifically disturbed in these patients, but not in other forms of hypertension or obesity.

## 92 A LONG TERM EVALUATION OF THE THERAPY OF PERNICIOUS ANEMIA WITH FOLIC ACID

STEVEN O SCHWARTZ MD SHERMAN R KAPLAN MD (BY INVITATION),  
AND BERTHE ARMSTRONG MD (BY INVITATION) CHICAGO ILL

Folic acid (pteroylglutamic acid) was introduced in 1945 as a specific therapeutic agent for 'liver extract principle' deficiency diseases. Numerous short term observations quickly confirmed its value. Because the natural history of pernicious anemia is characterized by exacerbations and remissions it was felt that long term studies were necessary in order to critically evaluate any new therapeutic agent.

Early in 1946 ninety eight patients with pernicious anemia were selected for such a study from the Out patient Anemia Clinic of the Cook County Hospital. Their course liver extract requirements neurological status and other characteristics were well established the patients having been followed by the same group of observers and maintained in remission with liver extract for periods ranging from months to years. Folic acid was administered orally in a daily dose of 5 milligrams. The patients were seen at four week intervals for interviews and neurological and hematologic examinations.

The present report summarizes the observation made during the three and a half years the study has been in progress. There have been thirty one neurological and thirty hematologic relapses with eight patients showing a combination of both. In three patients the folic acid was discontinued because of persistent weight loss and/or soreness of the mouth. Twenty nine patients discontinued their therapy for reasons beyond our control. Most of these patients disappeared from observation many however only after insisting that they felt better while on parenteral liver therapy which they wished resumed. Of the ninety eight patients only thirteen have been able to remain on continuous oral folic acid therapy and maintain themselves in remission.

Without exception every hematologic relapse was quickly reversed with a change to parenteral liver therapy. In fourteen patients with neurological relapse however the changes have not been reversible in spite of intensive therapy with liver extract for six months or more. Bone marrow aspirations were performed in five patients at the time of relapse. Megaloblastic changes were demonstrable in all instances.

The original plan envisioned an attempt to increase the dose of folic acid in those patients who showed evidences of relapse but the impression (gained from the current reports of the time) that larger doses of folic acid precipitated neurological relapses faster than small doses deterred us.

## 93 HEMOPOIETIC CHANGES DURING CHLOROMYCETIN ADMINISTRATION

ITALO F VOLINI MD STEVEN O SCHWARTZ MD IRVING GREENSPAN MD  
(BY INVITATION), LEE EHRLICH MD (BY INVITATION) JAMES A GONNER MD  
(BY INVITATION) AND OSCAR FELSENFELD MD (BY INVITATION)  
CHICAGO ILL

Toxic manifestations of oral administration of chloromycetin have not been reported. Recently we have observed three patients in whom hematologic abnormalities were encountered during chloromycetin therapy.

Two patients with typhoid fever and one with acute brucellosis were treated with oral chloromycetin for periods ranging from nine to nineteen days. The total dose of chloromycetin ranged from 30 to 60 Gm and was given in a uniform dose of 3 Gm per day (0.5 Gm every four hours).

A significant fall in the white blood cell count, attributable to the diminution in the number of granulocytes, could be demonstrated as early as the sixth day of therapy. White cell counts as low as 3,000 and absolute neutrophil counts of 264 were observed. No significant changes in the total number of lymphocytes were demonstrated. A slight drop was seen in the red cell count and the hemoglobin. In one instance this drop was out of proportion to a fall ascribable to the underlying infection.

The marrow was studied in all patients. In the first, a marked granulopenia and left shift in erythropoiesis were present on the eleventh day of therapy. In the second patient the marrow was studied three and thirteen days after the discontinuance of the chloromycetin. On the third day a left shift in granulopoiesis as well as erythropoiesis was seen, with an increase in eosinophils. By the thirteenth day the left shift had disappeared in both series and evidences of marked regeneration accompanied by an extraordinary eosinophilia were seen. In the third patient, the marrow was studied at the beginning of therapy and revealed the changes expected with infection. Eleven days later (two days after discontinuance of therapy) granulopoiesis had markedly diminished and a left shift had occurred in erythropoiesis.

Upon the discontinuance of the chloromycetin there was an immediate spontaneous reversal of the downward trend in the blood values.

In the three patients studied there is evidence that within a few days chloromycetin produces a marrow hypoplasia more marked in the granulocyte series but also involving a maturation arrest of erythroid elements. The peripheral blood simply reflects the more fundamental changes in the marrow. In the therapeutic doses employed in the present series the marrow alterations are reversible.

Both clinical and experimental studies are in progress to verify and extend these findings.

#### 94 EXPERIMENTAL SYPHILIS IN THE RABBIT THE RELATIONSHIP OF METACHROMASIA TO FIBRINOID DEGENERATION OF COLLAGEN AND THE LOCALIZATION OF SPIROCHETES IN THE TESTIS

VIRGIL SCOTT, M.D. (BY INVITATION), AND GUSTAVE J. DAMMIN, M.D.  
ST. LOUIS, MO

Since the earliest studies of experimental syphilitic orchitis there has been recognized, as a characteristic feature of the inflammatory reaction in the testicular stroma, the deposition of a relatively acellular, loosely constructed material resembling Wharton's jelly. The term "mucous (or mucoid) degeneration" of the connective tissue has been applied to this change. The material stains metachromatically and has been found in greatest abundance in the tunica albuginea, particularly around blood vessels.

We have confirmed the preceding observations in a study of syphilitic orchitis in the rabbit using the Nichols' strain of *T. pallidum*. In addition, we have found that previous incubation of the sectioned tissue in hyaluronidase (Scheering) abolishes the capacity for metachromatic staining with thionin and with toluidine blue. No metachromasia is found in the stroma of the nor-

mal testis. Focal fibrinoid degeneration of collagen has been observed in the metachromatic areas and the highest concentration of spirochetes has been noted in and around these sites.

It may be concluded that the loosely constructed relatively acellular material which appears in large amounts in the stroma of the syphilitic rabbit testis and which stains metachromatically contains hyaluronic acid or a closely related substance. It would appear that the sites of localization of the metachromatically staining material, the fibrinoid degeneration of collagen and the highest concentrations of spirochetes are intimately related spatially. A sequential study of syphilitic orchitis in the rabbit is now in progress to investigate the possible causal or temporal relationships between the multiplication of spirochetes, the development of metachromasia and the appearance of fibrinoid degeneration of collagen.

## 95. CONTINUOUS DICUMAROL PROPHYLAXIS IN CORONARY DISEASE

THORNTON SCOTT, M.D., LINCOLN, KY.

It seemed reasonable to suppose that in agent which would prolong coagulation time and have a deterrent effect on blood sludging might be of value in preventing thrombosis in chronic arterial disease. Accordingly twenty-one patients have been given Dicumarol continuously for periods of three weeks to three years. Of these eighteen had clinical and electrocardiographic evidence of coronary thrombosis with myocardial infarction, two had coronary sclerosis with angina of effort and one had cerebral thrombosis with left hemiparesis.

After initial stabilization prothrombin times were determined weekly by Quick's method and Dicumarol was prescribed in daily doses sufficient to maintain prothrombin time between two and two and a half times normal control values. Individual requirement varied from 50 mg. every other day to 150 mg. daily.

Five patients showing marked sensitivity to Dicumarol and unable to take as much as 50 mg. daily without alarming fluctuation in prothrombin time were given menadione bisulfite 2 mg. daily. These showed increase in tolerance and prothrombin times thereafter were more readily controlled.

All patients were advised of the risks involved and instructed in the symptoms and signs of overdosage.

No disastrous toxic effects have been encountered. Transient hematuria occurred in three patients, rectal bleeding from hemorrhoids which had bled prior to therapy occurred in one patient, cutaneous ecchymoses occurred in three patients, epistaxis occurred in one patient. One man with previous history of bleeding duodenal ulcer bled following extraordinary dietary indiscretion although his prothrombin time was within the desired range. The drug was discontinued and coronary thrombosis recurred within ten days. Dicumarol was then resumed and he has been well and at work for the past ten months.

There have been no deaths in the series. Chest pain recurred in two patients when the drug was discontinued because of toxic effect and ceased when Dicumarol was resumed. Anginal attacks have ceased entirely in eight patients and have been markedly reduced in frequency and severity in two. All of the patients have resumed their former activities.

Electrocardiograms in five cases have shown a striking reversion toward normal.

It is surprising and worthy of note that all patients have followed instructions carefully and have expressed the desire to continue under treatment indefinitely in spite of the inconvenience involved.

Results seem to indicate that continuous and controlled Dicumarol therapy is practicable and may influence favorably the course of disease of the coronary arteries.

## 96 THE USE OF ORAL MERCUHYDRIN COMBINED WITH ASCORBIC ACID IN CARDIAC DECOMPENSATION

CARL F. SHAFER, M.D. (BY INVITATION), AND DON W. CHAPMAN, M.D.  
HOUSTON, TEXAS

The effect of the oral administration of a tablet containing 60 mg. of an inorganic mercurial compound (Mercuryhydrin), equivalent to 19.5 mg. of mercury, and combined with 100 mg. of ascorbic acid has been studied in one hundred patients with congestive heart failure. The patients' ages ranged from 12 to 60 years and the congestive failure was due to valvular, hypertensive, or arteriosclerotic heart disease. From one to three tablets were administered daily.

These tablets were equally effective as one containing 120 mg. of Mercuryhydrin alone. They were satisfactory in controlling mild congestive failure in approximately one-third of the patients when used as a primary treatment. They were effective in controlling mild to moderate congestive failure in approximately two-thirds of the patients after maximum compensation had been obtained following injectable Mercuryhydrin. They were usually ineffective in controlling severe failure when used alone, but frequently of value when used as a supplement to injections. Toxicity, when it occurred, was mild and transient in the large majority of instances.

The studies indicated that the tablets may be used either alone or as a supplement to parenteral therapy to assist in the control of congestive heart failure.

## 97 SMALL BOWEL CHANGES IN AMEBIASIS

W. H. SHLAES, M.D. (BY INVITATION), F. STEIGMANN, M.D., AND  
ERNA LEWIN-ARENDT, M.D. (BY INVITATION), CHICAGO, ILL.

Following an attack of amebiasis, many patients manifest a multiplicity of abdominal symptoms which, though nondescript and not too severe, frequently make them gastrointestinal problems. The frequent finding on cytologic examination of the stool of epithelial cells originating from the small bowel suggested the latter as the possible site of "lesions" leading to the mentioned symptoms. Hence, all patients with chronic amebiasis had x-ray films made of both the small and the large bowel for possible pathologic changes.

Of sixty patients with chronic amebiasis thus examined, twenty-seven showed changes from the normal in the small bowel, particularly the terminal ileum. These changes are not seen as a rule in ulcerative colitis, sprue, and various nutritional deficiencies.

Spasm and edema of the terminal ileum are the changes most often noted. More characteristic, however, are the edematous folds of the terminal ileum which sometimes made the terminal ileum appear almost as wide as the colon.

The nonspecific changes of segmentation and pooling as seen in sprue or the ulcerated involvement of the terminal ileum as seen in ulcerative colitis were not observed in these patients. The motility of the small bowel appeared undisturbed.

The patients demonstrating the described changes in the terminal ileum were in general more difficult to manage clinically, especially with regard to control of the cramping abdominal pain.

## 98 PHYSIOLOGIC AND PHARMACOLOGIC STUDIES IN A CASE OF PHEOCHROMOCYTOMA

ALVIN P. SHAPIRO, M.D. (BY INVITATION), HARISON M. BAKER, M.D.  
(BY INVITATION), MURRAY S. HOFFMAN, M.D. (BY INVITATION)  
AND EUGENE B. FERRIS, M.D. (CINCINNATI, OHIO)

A case of pheochromocytoma, subsequently proved at operation and at autopsy, allowed us the opportunity to compare in a single patient the physiologic and pharmacologic specificity of a number of suggested diagnostic procedures. The patient, a woman with persistent hypertension for approximately one year, preceded by at least three years of paroxysmal hypertension, had a blood pressure which ranged from 215/140 to 250/155 mm. Hg.

Benzodioxane (933I<sup>1</sup>) produced an immediate fall in pressure to normotensive levels. Dibenamine produced a similar fall which was slower in onset and persisted longer. Tetraethylammonium chloride (TEAC) produced a sharp rise in pressure with failure to return to initial levels for some time; this rise was shown to be abolished by benzodioxane. Diminished sensitivity to the pressor activity of intravenous adrenalin was demonstrated. Histamine and mecholyl each caused a fall in pressure, the rise reported to be characteristic of pheochromocytoma being absent.

The results bear out the specificity of benzodioxane and Dibenamine in counteracting the pressor activity of circulating epinephrine. Response to benzodioxane seems more specific, however, because no depressor effects have been encountered in a series of control hypertensive subjects, whereas such reactions do occur with Dibenamine. Diminished sensitivity to exogenous adrenalin would also appear to have specific meaning, in that tolerance to the effect of this drug appears to develop when it is present in the circulation in large amounts. The pressor response to TEAC would appear humoral in nature, specifically adrenergic in this instance, since it was abolished by benzodioxane. The lack of a pressor response in this case to either histamine or mecholyl suggests that these tests are not specific for diagnosis.

The results suggest the specificity of benzodioxane in the diagnosis of pheochromocytoma when the pressure is elevated and the desirability of evaluating the mechanisms of pressor responses to histamine, TEAC or other stimuli by administration of benzodioxane.

## 99 HEART BLOCK FOLLOWING MEDULLARY PERFUSION WITH BACTERIAL TOXINS

JOHN A. SIEGEL, M.D. (BY INVITATION) AND N. C. GILBERT, M.D.  
CHICAGO, ILL.

The role of bacterial and viral agents in the production of heart block has been known for many years. Of particular interest has been the occurrence of bradycardia and heart block following acute bacterial infections es-

pecially in the case of diphtheria. The question of whether myocardial damage per se or increased vagal tone or a combination of both is responsible has remained to conjecture, with the preponderance of opinion in support of cardiac damage. No adequately controlled experimental evidence has thus far been presented to note the effect of increased vagal tone in the pathogenesis of heart block.

Six commercially produced bacterial toxins were employed in this study, namely *C. diphtheriae*, *Staph. aureus*, *St. hemolyticus*, *Cl. tetani*, *Cl. welchii*, and *Cl. botulinum*. These toxins were perfused through the turtle brain which was connected with the body of the animal only by means of the vagus nerves.

Heartblock was produced with all of the toxins. The blocks produced by *C. diphtheriae*, *Cl. welchii*, and *Cl. botulinum* could be released by atropine. These results suggest an acetylcholine-like mechanism. The remaining toxins were not affected by atropine and the mechanism for their action is unknown.

## 100 THE TAKATA-ARA REACTION IN THE DIFFERENTIAL DIAGNOSIS OF JAUNDICE

B. SHULMAN, M.D. (BY INVITATION), F. STEIGMANN, M.D., H. POPPER, M.D., AND E. STEVENS, M.D. (BY INVITATION), CHICAGO, ILL.

In the work-up of jaundiced patients the Takata-Ara reaction (TAR) seemed of diagnostic help in certain types of jaundice, hence, an attempt was made to re-evaluate the differential diagnostic significance of the TAR on the basis of recent classification of hepatobiliary diseases.

The TAR was performed in 356 cases and compared with the results of cephalin-cholesterol flocculation, thymol turbidity, and zinc sulfate turbidity tests. The percentage of positive TAR's in the different types of hepatobiliary disease were as follows: Laennec's nonfatty cirrhosis, 87.8, fatty cirrhosis, 35.5, postnecrotic (nonalcoholic) cirrhosis, 100, infectious viral hepatitis, 107, homologous serum hepatitis (HSH), 68.0, toxic hepatitis, 27.6, obstructive jaundice (incomplete, benign), 2.0, and obstructive jaundice (complete, malignant), 20.0.

The TAR may therefore assist not only in differentiating a cirrhosis with jaundice from an acute hepatitis but also from an infectious hepatitis. The TAR is not related to the degree of icterus, and the high incidence of abnormal TAR's in HSH is therefore not an expression of the well-known greater severity of the latter.

Moreover, no parallelism was found between the TAR and the cephalin flocculation and thymol turbidity tests. A moderate parallelism existed between the TAR and the zinc sulfate turbidity, except in infectious hepatitis where the latter is moderately elevated and the TAR is negative, in toxic hepatitis this exception is less marked.

A discrepancy between the TAR and the zinc sulfate turbidity is also apparent during the recovery phase of hepatitis when the zinc sulfate turbidity increases while the TAR (if positive) becomes negative. While, in recovering hepatitis, a rise in the zinc sulfate turbidity and a fall in the cephalin-flocculation and thymol turbidity occurs, a rise in the TAR in addition (or the maintenance of a positive TAR) speaks for the transition from hepatitis to cirrhosis. Similarly, the appearance of positive TAR in a fatty cirrhosis seems to indicate progression to a Laennec's nonfatty cirrhosis.

The TAR may indicate certain phenomena not demonstrable by the other flocculation tests.

# 101 A STUDY OF THE MOVEMENTS AND SOUNDS OF HEART VALVES OF VARIOUS LABORATORY ANIMALS (A MOTION PICTURE AND SOUND RECORDING)

HARRY L SMITH, M D HIRSH E ESSEX, PH D (BY INVITATION), AND  
EDWARD J BALDES, PH D (BY INVITATION), ROCHESTER, MINN

The hearts of various laboratory animals were perfused with oxygenated Ringer Locke solution and were kept beating for various lengths of time. Rather large openings were made in the walls of the auricles. This afforded an excellent view of the entire valves. Colored motion pictures were made of the exact movements of the mitral, tricuspid, aortic, and pulmonary valves. A sound record, an electric record of the sound, and an electrocardiogram were made at the same time the motion picture was made. These records enable one to see the movements of the heart valves, to hear the sounds they produce, to see an electric record of the sounds and to see an electrocardiogram recorded at the same time. The results of this study furnish information that we believe will change some of our previous ideas about the factors that cause the mitral and tricuspid valves to open and close.

# 102 CARDIODYNAMIC AND RENAL CHANGES IN SPONTANEOUS AND NEPHROGENIC HYPERTENSIVE DOGS IN RESPONSE TO TISSUE INJURY

J STAMLER, M D (BY INVITATION) S ROBBARD PH D (BY INVITATION),  
L N KATZ, M D, AND A P FISHMAN, M D (BY INVITATION)  
CHICAGO, ILL

Tissue injury, particularly abscess, produces a sustained fall in blood pressure in some spontaneous and nephrogenic hypertensive dogs. This study was undertaken to investigate the cardiodynamic and renal alterations ensuing during this depressor response.

The following determinations were done before and after various types of tissue injury: (1) renal plasma flow (RPF), (2) glomerular filtration rate (GFR), (3) plasma volume, (4) thiocyanate space, (5) central venous, right atrial, right ventricular and pulmonary artery pressures, (6) blood pressure.

It is concluded from the data that (1) Spontaneous and nephrogenic hypertensive dogs exhibit the same hemodynamic pattern. The cardiac output, plasma volume, thiocyanate space, and pulmonary artery pressure are all within normal ranges. Both types of hypertension are due to an increase in peripheral resistance. (2) Spontaneous hypertensive dogs all have normal GFR and RPF. In contrast, some nephrogenic hypertensive dogs have normal clearances, others exhibit significantly reduced kidney function. (3) A sustained blood pressure fall can be readily elicited by injection of abscess-inducing substances such as turpentine, indicating that the depressor response is a nonspecific one with respect to presumed renal hypertensive mechanisms. (4) Accompanying the sustained depressor response in both nephrogenic and spontaneous hypertensive dogs is a sustained increase in RPF. GFR does not change significantly. Renal vascular resistance, particularly efferent arteriolar, is reduced. (5) The plasma volume, thiocyanate space, venous pressure, and right heart pressures are not affected by tissue injury. The blood pressure fall is not due to hypovolemia. (6) The cardiac

output is increased during the depressor response to injury. The fall in blood pressure is therefore due to a decreased peripheral resistance. Apparently the decrease in both renal and general peripheral resistance is the resultant of a common train of events elicited by injury. There is no evidence for a cause and effect relationship between them. The blood pressure fall following injury cannot be attributed to "relief of renal ischemia."

### 103 CLINICAL EVALUATION OF A NEW LIPASE PREPARATION

M. H. STREICHER, M.D., VERA PITTARD (BY INVITATION), AND BETTY WOODSON (BY INVITATION), CHICAGO, ILL.

Many agents are available which have the property of digesting fat, yet there is a need for one which would be capable of hydrolyzing a wider variety of lipids.

It was thought, on the basis of experimental evidence in animals, that lipase A may be helpful in individuals who display an inability to adequately digest all forms of food fat. The new preparation is an enzyme, protein in nature, produced during the growth of a certain type of mold (fungus).

In this study lipase A was used in patients having steatorrhea. Control studies also were made. Each capsule contained 0.4 Gm of the enzyme and each patient was given twenty-four capsules daily.

These individuals were placed on a calculated diet of low fat (50 Gm in twenty-four hours) and evaluated clinically and chemically before and after lipase was given. The chemical determinations were made on the nitrogen, on the total and neutral fat and fatty acids of the stool, the blood was studied as to content of lipase, calcium, nonprotein nitrogen, and total protein, and the urine was studied as to total output of nitrogen. These determinations were made before and after the fat content was changed in the diet.

Comparative study was also made with the use of pancreatin in the same group of patients.

A specific example will demonstrate the efficacy of the new enzyme.

A patient with carcinoma of the pancreas was placed on a 55 Gm fat diet plus adequate protein and carbohydrate. The total fat calculated in the stool before lipase A was administered was 57.0 per cent (dry method). After three capsules of lipase A were given per day for a period of three weeks, the total fat in the stool was reduced to 42.0 per cent. After the diet was increased to 152 Gm fat, the stool fat was elevated to 73.0 per cent. The administration of twelve to twenty-four capsules of lipase decreased the total fat in the stool to 53 per cent and 40 per cent respectively.

Clinically, the patient improved, the stools decreased in number and became more solid, and the cramping in the abdomen subsided. In general, the patient ate better and felt better.

**Conclusion** (1) Lipase A is helpful in steatorrhea. (2) Large quantities of the enzyme are required for optimum results. (3) Pancreatin compares favorably with results obtained with lipase A.

## 104 ANGIOCARDIOGRAPHY

GEORGE C SUTTON, M D GEORGE W FADDELL M D, HARRY GRANT, M D, AND  
HAROLD WEDFELL M D CHICAGO ILL

(INTRODUCED BY DON C SUTTON M D)

A comparison is made between angiocardiology by arm vein and direct catheterization of the heart

Direct intracardiac angiocardiology is a procedure possessing few difficulties and of negligible risk. The procedure will give contrast visualization of the heart and great vessels which is routinely superior to that obtained by peripheral injection of a radio opaque material. This is especially true for levoangiocardigrams. Simple inexpensive equipment for changing the films and low power x ray apparatus are more practical for use with intracardiac injection without loss of a very high percentage of diagnostic films. In some cases demanding a high concentration of contrast media and accurate timing of exposures, only intracardiac injection will produce satisfactory angiocardigrams.

### 105 DIVISION OF THE POPLITEAL VEIN IN VALVULAR INSUFFICIENCY OF THE DEEP VENOUS SYSTEM OF THE LOWER EXTREMITIES

GEZA DE TAKATS M D AND GUSTAV W GRAUPNER, M D (BY INVITATION)  
CHICAGO ILL

From a large number of patients exhibiting valvular incompetence of the deep veins six patients have been selected to test the possibility that the division of the popliteal vein overcomes the "bursting" type of pain on standing and decreases or eliminates postural edema. All patients have had a deep thrombophlebitis with recanalization, subsequent edema induration, and ulceration. All have been under our care for several years and were treated by compression bandages, excision of ulcers, skin grafts or saphenous vein ligation in spite of which there were recurrences. Since previous experience with femoral vein ligations gave no appreciable help division at this site was done with the following results: (1) all six patients lost their "bursting" pain on standing (2) swelling was greatly decreased or completely abolished in every instance (3) patches of recurrent lymphedema with ulceration were uninfluenced this complication requiring other forms of therapy. This simple procedure may eliminate the incapacitating sequelae of postphlebitic edema in selected cases.

### 106 QUANTITATIVE STUDIES OF TREATMENT OF ACUTE CLOSED CEREBRAL INJURY BY HYPERTONIC INTRAVENOUS GLUCOSE OR SURGICAL DECOMPRESSION

C BRUCE TAYLOR M D, AND GEORGE M HASS, M D CHICAGO, ILL

Acute closed intracerebral lesions characterized by hemorrhage, necrosis and progressive edema were produced in rabbits by freezing the brain through the intact skull with an instrument cooled by expanding carbon dioxide. The dimensions and locations of cerebral lesions were controlled so that they could be reproduced in successive animals.

Volumes of cerebral damage, ranging from 13 to 32.5 vol per cent of the brain, were produced in one hundred four untreated animals. In this group, the minimum lethal quantity of damage was 9.4 vol per cent. No animal survived with damage in excess of 18.0 per cent. The average minimum lethal quantity of damage was 14.3 vol per cent. Most animals that died had a normal postoperative period of behavior. Secondary lapse into stupor was a dependable indication of eventual death within two hours.

Twenty-five animals with acute, closed, cerebral lesions were treated with intravenous injections of hypertonic aqueous solutions of glucose given continuously or by single or multiple infusions. Intravenous infusions were started shortly after the production of lesions. This therapy was of no benefit, either from the point of view of amelioration of symptoms or survival.

When surgical decompression was done with removal of bone-flaps over cerebral lesions within forty-five minutes after production (forty-seven animals) or after onset of stupor, coma, or convulsions (eight animals), symptoms were relieved and animals survived with more cerebral damage than control, untreated animals. In these animals the minimum lethal quantity of cerebral damage was 14.6 vol per cent. The maximum survivable quantity of cerebral damage was 32.7 vol per cent. The average minimum lethal quantity of cerebral damage was 21.9 vol per cent which was about 50 per cent greater than that in the untreated group (14.3 vol per cent) and in the group treated with hypertonic solutions of glucose (14.5 vol per cent). Four animals treated by contralateral surgical decompression had no increased tolerance to cerebral damage.

These data indicate that hypertonic solutions of glucose, given periodically or continuously by the intravenous route, were of no value in the treatment of acute, closed, cerebral lesions characterized by local hemorrhage, necrosis, and edema. Surgical decompression was of great benefit when done over the site of the lesion. It was concluded that surgical decompression of the type used should be evaluated as a method of treatment of patients with localized intracerebral necrosis, hemorrhage, and edema due especially to vascular disease.

## 107 FURTHER EXPERIENCE WITH BACTERIAL PYROGENS IN THE TREATMENT OF MALIGNANT HYPERTENSION

ROBERT D. TAYLOR, M.D., A. C. CORCORAN, M.D., AND IRVINE H. PAGE, M.D.  
CLEVELAND, OHIO

Of eleven patients with malignant hypertension showing reversal, eight are alive without further treatment and lead useful lives. The average survival time for this group is now thirty-two months. Two patients have died of cerebral hemorrhage thirty-seven and sixteen months after treatment, and one has not been re-examined.

Six patients have been treated during the past year. Of these, three had  $T_{MPAH}^*$  values which exceeded 40 mg per minute. The blood pressure of the first patient was reduced from 175/118 to 140/84 mm Hg during six weeks of treatment. All signs of malignant retinopathy receded, the electrocardiogram and teleroentgenogram became normal, and  $T_{MPAH}$  increased from 55 to 77 mg per minute. There have been no further signs of malignancy.

The next two patients did equally well for seven and eight weeks of treatment. Papilledema receded from Grade III to Grade I, hemorrhages and exudates cleared completely in one and decreased from Grade II to Grade I severity in the other.

\*Tubular mass measured by para-aminohippurate excretion

These two patients objected to prolonged hospitalization, hence elected to discontinue treatment. One died during the second stage of lumbodorsal sympathectomy, the other shows no signs of progression of the disease.

A fourth patient had a  $Tm_{PAH}$  of only 33 mg per minute. He had Grade IV retinopathy, gross hematuria, and electrocardiographic and x-ray signs of hypertensive heart disease. He was treated for two months. The blood pressure was reduced from 204/125 to an average of 140/90. All signs of retinopathy and cardiac disease disappeared. Maximum specific gravity increased from 1.016 to 1.028.

Two patients having  $Tm$  (tubular mass) values of 25 and 9 mg per minute have done poorly. One died of cerebral hemorrhage during treatment and the other is showing signs of progressive renal failure, although the eye grounds and blood pressure now are improved.

Renal function with  $Tm_{PAH}$  values of at least 33 mg per minute continues to be the best pretreatment index of satisfactory response.

The pyrogen Pyromen is given by vein in doses large enough to cause a daily temperature rise to 102 to 104° F. The initial dose is 0.5 cc of solution containing 50 gamma of solids per cubic centimeter. Thereafter, the amount given is determined by the temperature peak of the preceding day. The daily injections should be continued as long as the blood pressure falls and signs of malignant hypertension regress.

When the blood pressure is no longer decreasing, the frequency of injections may be reduced. Over a period of two to six months there is usually a gradual rise in pressure in most of the patients and eventually hypertensive levels may prevail. However, signs of malignancy have so far not returned and the patients can be dealt with as having uncomplicated essential hypertension.

### 108 PNEUMOCOCCUS TYPES, MORTALITY, BACTEREMIA AND PURULENT COMPLICATIONS IN PRIMARY PNEUMOCOCCIC PNEUMONIA AT THE CINCINNATI GENERAL HOSPITAL, 1936-1949

ROBERT T. THOMPSON, M.D., JAMES M. RUEGSEGER, M.D., M. A. BLANKENHORN,  
M.D., AND MORTON HAMBURGER, M.D. CINCINNATI, OHIO

Three thousand one hundred four cases of primary pneumococcal pneumonia in patients over 13 years of age with specific typed pneumococci in sputum or blood cultures are reported here. Pneumococcus typing has been carried out as a means of specific diagnosis to evaluate various modes of therapy. The data for each year are calculated from July 1 through June 30 of the following year.

The number of cases per year decreased by gradual fluctuation from three hundred eighty-seven in 1936-37 to one hundred twenty-two in 1948-49.

Type 1 was most frequent in 1936-37, 1938-39, 1939-40, 1940-41, 1942-43, 1943-44, and 1948-49. Types 1 and 7 were equally frequent in 1944-45. Type 7 was most frequent in 1941-42, 1945-46, and 1946-47. Type 3 was most frequent in 1937-38, and Type 2 was most frequent in 1947-48.

Mortality was 36.7 per cent, 32.4 per cent, and 28.1 per cent respectively for 1936-37, 1937-38, and 1938-39 when antipneumococcal serum for certain types was the only specific treatment. However, sulfapyridine came into use in January 1939. From July 1, 1939 through June 30, 1947, sulfonamides were the mainstay of treatment. For these eight years mortality ranged from 15.3 per cent to 12.6 per cent, except that mortality was 20.2 per cent in 1940-41,

19.5 per cent in 1943-44, and 18.6 in 1944-45. In 1945-46 and 1946-47 penicillin was used for treatment if there was no response to sulfonamide, or if sulfonamide drugs were contraindicated. Penicillin was used exclusively for treatment in 1947-48 and 1948-49. Mortality was 9.7 per cent in 1947-48, and in 1948-49, when aqueous crystalline penicillin in doses of 200,000 or 300,000 units was given intramuscularly twice on the first day of treatment and once daily thereafter, mortality was 5.7 per cent.

Pneumococcus bacteremia was found in 12.9 per cent of the cases in 1940-41, and in 49.5 per cent of the cases in 1947-48. In the remaining years bacteremia was found in 16.4 to 31.8 per cent of the cases.

Empyema, meningitis, endocarditis, lung abscess, or pyaemia occurred in 13.2 per cent of the cases in 1937-38, and in 3.8 per cent of the cases in 1940-41. In the remaining years these complications occurred in 4.6 to 10.7 per cent of the cases.

Apparently penicillin therapy has reduced mortality, and the unchanged frequency of bacteremia and purulent complications results from the onset of these manifestations before the start of treatment.

#### 109 CONTROL COMPARISON OF NU-2206 (3-HYDROXY-N-METHYL MORPHINAN HYDROBROMIDE) WITH MORPHINE SULFATE FOR RELIEF OF POSTOPERATIVE PAIN

R. T. TIDRICK, M.D., L. L. ZAGER, M.D. (BY INVITATION), D. W. EASTWOOD, M.D. (BY INVITATION), D. S. WILKINS, M.D. (BY INVITATION), AND R. S. JAGGARD, B.A. (BY INVITATION), IOWA CITY, IOWA

In an earlier investigation of the analgesic properties of NU-2206 (3-hydroxy-N-methylmorphinan hydrobromide) the effect of this agent on the pain threshold in normal volunteer student subjects was determined. There followed a clinical trial to determine its effect in a variety of patient categories. It was found to have desirable analgesic properties with an apparently more prolonged effect than that of morphine sulfate in equivalent dosage ranges. It was found that the dosage range was from 3 to 6 mg. as compared with 10 to 15 mg. of morphine. The side effects did not appear to be severe or frequent. A limited study was made on a small number of patients who had received the drug over a prolonged period of time, and no withdrawal symptoms were observed.

Its prolonged analgesic effect appeared beneficial in those patients who required protracted relief and in whom frequent injections with shorter-acting analgesics were undesirable. Controlled study then was undertaken on ward patients undergoing surgical procedures on the General Surgical and Urological services. Those under the age of five years or in such condition as to be outside the preselected dosage range were excluded. Patients having intracranial surgical procedures also were omitted. They were divided into fifteen operation categories so that subsequent statistical evaluation as to the amount of pain associated with various types of operative procedures could be compared. In each operation category alternate patients were given NU-2206 or morphine sulfate. The medications were so dispensed as to preclude identification except by code letter.

The nursing staff was instructed to give 1 c.c. for each patient or  $\frac{1}{2}$  c.c. for each patient. One cubic centimeter contained either 5 mg. of NU-2206 or 10 mg. of morphine sulfate. The drugs were administered by the nursing staff to be given as required for the relief of pain not more frequently than every three hours. A special form was provided listing seven common complications

ordinarily seen in conjunction with the use of analgesic drugs. The nurses' observations were checked closely by the same member of the staff each day.

It appears, after studying 406 patients by this method that analgesic drugs are not needed in slightly more than one third of the instances. A difference in duration of action of NU 2206 and morphine sulfate was not demonstrated. NU 2206 is as effective an analgesic agent as morphine with no demonstrable increase in side actions.

## 110 SPONTANEOUS RUPTURE OF THE HEART FOLLOWING ACUTE MYOCARDIAL INFARCTION

GEORGE C TURNBULL, M.D. and DAVID A. HOWELL, M.D. (By Invitation)  
EVANSTON, ILL.

Cardiac rupture occurred in eight patients (72 per cent) of a series of 111 instances of acute myocardial infarction in patients who had been observed in the Evanston Hospital and came to autopsy during the past six years.

The eight patients were all of the white race. Their ages ranged from 51 to 86 years averaging 68 and they were equally divided in sex. Half of the group denied prior angina; three had experienced pains from one to four months; and one who died within two days after onset of illness gave no history of anginal pain or hypertension and had considered herself in excellent health. However, there was evidence of old infarction in four of these patients.

Hypertension persisted after the onset of clinical myocardial infarction in all but one of these patients and he belonged in the group of four who gave no prior history of hypertensive disease.

Death occurred rapidly after the occurrence of the rupture as evidenced by the condition of the pericardial sac and lacerated tissues. Four patients showed ante mortem clotting of the blood in the pericardial sac and one had organization of the clot, but the remaining three revealed only bright unclotted blood.

Clinical observation indicated that three expired immediately after the rupture, four within a day and only one survived sixty hours. All eight deaths occurred within two to eleven days, average 5.8, after the clinical onset of acute myocardial infarction. The rupture occurred in the left ventricle in seven of the patients, four posteriorly and three anteriorly, while the remaining one ruptured through the right ventricle and septum at the apex.

Positive electrocardiographic evidence of acute myocardial infarction was present in all of the rupture group except one patient on whom such an examination was not possible because she expired within a half hour after admission to the hospital. The clinical diagnosis of rupture was made in six of the patients prior to autopsy.

Rupture of the heart occurred in four of these patients during defecation.

The leucocyte counts and blood sedimentation rates were consistently above normal levels in both the rupture and non-rupture groups but there was no significant difference.

# 111 CLINICAL AND LABORATORY OBSERVATIONS IN FATTY INFILTRATION OF THE LIVER

HERMAN ULEVITCH, M D (BY INVITATION), LEON SCHIFF, M D,  
JEROME R. BERMAN, M D (BY INVITATION), DANIEL F. RICHFIELD, M D  
(BY INVITATION), FERDINAND G. WEISBROD, M D (BY INVITATION),  
AND EDWARD A. GALL, M D (BY INVITATION), CINCINNATI, OHIO

Fifteen patients with pure fatty infiltration of the liver demonstrated by needle biopsy were selected for study.

Thirteen of the fifteen patients were admitted to the medical service for various causes among which were hematemesis, pellagra, chronic cholangitis, diabetes mellitus, chronic pancreatitis, xanthomatosis, congestive heart failure, myocardial infarction, malnutrition, and gastritis. Two patients with mycosis fungoides and discoid lupus erythematosus respectively were studied on the dermatologic service.

The ages of the patients ranged from 29 to 85 years. Nine of the patients were women. A definite history of alcoholism was present in six. The diet was adequate in only six patients. An antecedent history of jaundice was obtained in two patients, both of whom had had previous cholecystectomies. Mild diabetes mellitus was present in two, while obesity was present in six patients. A history of weight loss of 10 pounds or more was obtained in ten of the subjects. Nausea and vomiting occurred in six, while anorexia was prominent in ten.

Hepatomegaly (ranging from one to five fingerbreadths) was observed in ten of the fifteen patients, while splenomegaly was present in only one instance. Edema of the lower extremities was encountered three times. Glossitis and evidences of peripheral neuritis were found in two patients.

Laboratory studies showed an elevation of the thymol turbidity in five of fourteen cases and a 3 to 4 plus cephalin cholesterol flocculation test in seven of fourteen cases. Serum bilirubin was elevated in two patients. Bromsulfalein retention was demonstrated in seven of fourteen patients. The prothrombin time was not significantly prolonged in any instance. Anemia was present in six subjects and was macrocytic in two.

It may be concluded that fatty infiltration of the liver occurs in a variety of conditions and presents variable clinical and laboratory findings, and requires needle biopsy for its diagnosis.

# 112 CHANGES IN TOLERANCE FOR GLUCOSE AND IN THE MORPHOLOGY OF PANCREATIC ISLET CELLS INDUCED BY INTRAVENOUS GLUCOSE IN DOGS

KEATS K. VINING, JR., M D, EVANSTON, ILL.

(INTRODUCED BY HENRY R. JACOBS, M D)

The possibility that damage to the islets of Langerhans can be caused by the continuance over long periods of time of glucose infusions in non-hyperglycemic amounts was the object of the present study and report. Previous investigators have shown that there is a response on the part of the blood sugar regulating mechanisms to administered glucose. It was postulated that continuous administration even in nonhyperglycemic amounts would elicit such a response in such a way that these mechanisms would have no chance to "rest" and would become exhausted.

Glucose was administered to female dogs by continuous intravenous infusion, and the blood sugar changes followed. The pancreas was examined microscopically at the end of each experiment. Short term infusions with hyperglycemic rates of glucose input have shown that such continuous infusions of glucose will cause an increase in the tolerance for glucose as evidenced by the markedly lower blood sugar seen at the end of such an infusion as compared with the blood sugar seen shortly after the infusion is started. Long term infusions (as long as forty eight days) of amounts well below the hyperglycemic glucose input were shown to cause pancreatic islet cell damage with beta cell degranulation, congestion, and hydropic degeneration, and resulted in a much poorer glucose tolerance as evidenced by much higher blood sugar levels in the hyperglycemic range at the end of a long term infusion than were caused by the same amount of glucose in the early part of a given infusion.

The results of this investigation would seem to indicate that the tolerance for glucose can indeed be increased and that such an increased tolerance stimulated by continuous intravenous glucose infusion will result in damage to the islet cells of the pancreas and eventual loss of glucose tolerance, probably due to exhaustion of the insulin producing cells in the islets of Langerhans. This same microscopic picture has been reported before as the result of hyperglycemia maintained over long periods of time by both anterior pituitary extract injections and again by injected glucose. It would seem from the results of this investigation that the damage and loss of tolerance for glucose is due not to the hyperglycemia but to the continued stimulation of the blood sugar regulating mechanisms.

### 113 THE TREATMENT OF UREMIA BY DIALYSIS ACROSS THE INTESTINAL MUCOSA

MAURICE H. WALD, M.D. AND ROBERT A. REID, M.D. EVANSTON, ILL.

(INTRODUCED BY N. C. GILBERT, M.D. AND GEORGE C. TURNBULL, M.D.)

The effects of dialysis across the intestinal mucosa by lavage are studied in two cases of chronic terminal uremia. The first is one of congenital polycystic kidney studied for two months. The other is a case of advanced nephrosclerosis in a woman whose right kidney had been removed surgically years ago studied for one month. The irrigating solution is lactate Ringer's with added dextrose 5 to 10 per cent. Levels of nitrogenous products in the dialysate from small bowel irrigation are equal to blood levels and the abstraction rate is inversely proportional to the rate of flow. A large inflow (priming) is required in intestinal dialysis before outflow effectively equals inflow. Irrigation of the lower ileum and colon is equally efficient and allows for control of edema. Alteration of irrigating solution concentration of glucose controls edema during irrigation. Glucose is absorbed during dialysis necessitating concentrations up to 10 per cent in the irrigating fluid to maintain isotonicity. Sodium chloride in 0.6 per cent concentration is absorbed at all levels of the intestine but sodium chloride deficient solutions will abstract as much as 0.5 Gm. per liter. In view of this an irrigating solution containing 0.45 per cent sodium chloride would seem more suitable. Sodium lactate in the dialyzing fluid in combating acidosis, hemoconcentration or dilation during dialysis did not influence blood nitrogen levels. By fastening a small bored tube four feet from the tip of a Miller Abbott tube, inflow of dialyz

ing fluid occurs through the former, and outflow through the latter, which can be allowed to remain at the ileocecal level. This was shown to cause no irritation although in place for one month. Blood nonprotein nitrogen rises rapidly in the uremic individual following intravenous administration of protein hydrolysate.

#### 114 A QUANTITATIVE STUDY OF THE SOLUBILITY OF HUMAN HEMOSIDERIN

GEORGE E. WANTZ, M.D. (BY INVITATION), AND GEORGE M. HASS, M.D.,  
CHICAGO, ILL.

Previous studies of hemosiderin, isolated by diastatic chemical methods, have indicated that the product is a form of ferric hydroxide. The present studies were an attempt to define the properties of hemosiderin by less diastatic methods and to compare the properties of intracellular hemosiderin with those of chemically isolated hemosiderin and synthetic ferric hydroxide.

Hepatic tissue of patients with hemochromatosis and hemolytic hemosiderosis, secondary to multiple transfusions, was used. Frozen sections of fresh tissue were dried in vacuo for qualitative microscopic studies. Frozen pulverized fresh tissue was dried in vacuo for use in quantitative studies of solubility of hemosiderin. Sections for microscopic study and small amounts of powdered tissue were exposed to the action of buffer solutions of different ionic composition (pH 12 to 11, ionic strength, 0.25 and 0.50). Ferric hydroxide and hemosiderin isolated from hepatic tissue by the usual alkaline methods were exposed to similar solutions. Solubility was determined quantitatively by analyses of iron in supernatant solution and in the undissolved residue.

The data indicated that chemically isolated hemosiderin and ferric hydroxide had similar solubility properties. Hemosiderin in the cytoplasm of reticuloendothelial cells had solubility properties similar to but not identical with those of chemically isolated hemosiderin and ferric hydroxide. Hemosiderin in hepatic parenchymal cells had solubility properties which were very different from those of chemically isolated hemosiderin and ferric hydroxide. Intracellular hemosiderin, chemically isolated hemosiderin, and ferric hydroxide were almost insoluble in isotonic saline and phosphate buffer solutions at neutrality. A large fraction (50 to 80 per cent) of intracellular hemosiderin, especially that present in the cytoplasm of parenchymal cells, was soluble in citrate buffer solutions, ionic strength 0.50, at or near neutrality, while chemically isolated hemosiderin and ferric hydroxide were almost insoluble under the same conditions. Furthermore, within a part of the range in which intracellular hemosiderin had a high solubility (pH 6.1 to 7.0), crystals of unknown composition appeared in the tissues near the sites of granules of hemosiderin. These crystals did not appear in normal liver cells and were not formed in the presence of chemically isolated hemosiderin or ferric hydroxide. The results indicate that the problem of isolating one or more forms of hemosiderin by chemical extraction at neutrality, or after crystallization in situ, can now be approached.

# 115 INFARCTION OF THE MUSCLE BUNDLES OF THE HEART

WILLIAM B. WARTMAN, M.D. AND JOHN C. SODERS, M.D. (BY INVITATION),  
CHICAGO, ILL.

The object of this investigation was to determine whether myocardial infarcts are confined to the muscle bundles of the heart or occur without regard to them. For this purpose the topography of seventy-two infarcts in fifty unselected hearts was plotted and compared with the known topography of the four chief muscle bundles of the cardiac ventricles (superficial sinospiral, superficial bulbospiral, deep sinospiral and deep bulbospiral muscles). It was found that all the infarcts followed definite patterns which coincided with the patterns of either one or more of the four muscle bundles. Twenty-five of the infarcts (35 per cent) in twenty-one cases (42 per cent) involved either a single superficial or a single deep bundle. The superficial muscles were involved either alone or with a deep muscle in 74 per cent of infarcts. The deep muscle bundles were involved, either alone or with a superficial muscle in 51 per cent. Depending upon the thickness of the ventricular wall involved it was possible to distinguish three types of infarcts: full thickness, massive but not full thickness, and laminar infarcts. Rupture, aneurysm formation and mural thrombosis of the left ventricle were largely dependent upon the number of muscle bundles involved and the thickness of the infarct. Atrial infarcts were present in 42 per cent of the hearts. The immediate mortality of myocardial infarction was not influenced by the thickness of the infarct, the number of muscles included in it, nor by the involvement of any specific muscle.

# 116 INTERRELATION OF PTEROYLGLUTAMIC ACID AND VITAMIN B<sub>1</sub> IN INDUCED ANEMIA OF SWINE

ROBERT W. HEINLE, M.D., ARNOLD D. WELCH, M.D. AND HENRY L. SHORR, B.S.  
(BY INVITATION), CLEVELAND, OHIO

Swine maintained on a pteroylglutamic acid (PGA) deficient diet, with "vitamin free" casein as the source of protein, develop severe macrocytic anemia with megaloblasts in the bone marrow. Such animals respond well to PGA initially, but as the deficiency is maintained the ability to respond to PGA diminishes. Administration of purified liver extracts then evokes a response. If liver extract or a source of 'extrinsic factor' is given before PGA a poor response can be elicited once or twice after which no further response can be obtained until PGA is administered.

Two animals showed a slight response to relatively large doses of anthropein, but much less than to PGA.

One pig maintained on the PGA deficient regimen for several months was given large amounts of liver extract and later vitamin B<sub>12</sub>. There was an initial partial response, after which blood values were maintained better than previously but never became normal. Very marked macrocytosis developed and persisted. Administration of PGA then caused prompt disappearance of macrocytosis and blood values became normal.

Vitamin B<sub>1</sub> deficiency was induced in swine by a diet containing alpha protein of soy beans, supplemented with methionine as the source of protein. PGA was administered daily. Severe anemia developed in which macrocytosis was less marked and developed more slowly than in the PGA deficient animals. The marrow did not contain megaloblasts. These animals responded to crystal

line vitamin B<sub>12</sub>. In one pig, there were peculiar double and triple reticulocyte peaks, each of which occurred after a single injection of vitamin B<sub>12</sub>.

These findings indicate that PGA-deficient swine fed "vitamin-free" casein develop a deficiency of both PGA and the antianemia factor(s) of liver (solely vitamin B<sub>12</sub>?). Either PGA or liver extract will induce a hematopoietic response, but both eventually are ineffectual unless the other is present. This indicates that both factors are required for normal hematopoiesis in swine.

While vitamin B<sub>12</sub> deficiency results in anemia, a deficiency of PGA appears to be importantly involved in macrocytosis and megaloblastosis. It is suggested that in human pernicious anemia a double deficiency also exists. The PGA deficiency may be the result of dietary inadequacy or of disordered metabolism of PGA. The deficiency of vitamin B<sub>12</sub> usually is dependent on an inadequacy of "intrinsic factor" in the gastric secretion but presumably can result from dietary deficiencies of vitamin B<sub>12</sub> and other factors.

# 117 CORRELATION BETWEEN RIBOSE NUCLEIC ACID DEPLETION AND OTHER SIGNS OF LIVER DAMAGE AS INFLUENCED BY VITAMIN B<sub>12</sub>

DIETER KOCH-WESER, M D (BY INVITATION), AND HANS POPPER, M D,  
CHICAGO, ILL

Disappearance of cytoplasmic ribonucleic acid compounds which are supposed to play a significant role in protein formation is one of the first signs of liver damage. Therefore, in comparison with twelve controls, the ribonucleic acid depletion (as recognized histologically) in thirty-six rats, forty-eight hours after intraperitoneal injection of a sublethal dose of carbon tetrachloride, was correlated with other signs of liver damage such as hydropic swelling of the parenchymal liver cells, increase of bromsulfalein retention, decrease of total liver proteins, and increase of histologically and chemically demonstrable fat. Chemical fractionation of total fat revealed the phospholipids remarkably constant, while all changes in the total fat were caused by variations of the neutral fat. Recent investigations had suggested that vitamin B<sub>12</sub> is important in the formation of ribonucleic acid compounds and subsequently it was demonstrated in this laboratory that the pathologic changes resulting from carbon tetrachloride (CCl<sub>4</sub>) intoxication was significantly less pronounced in rats which had previously received very large doses of vitamin B<sub>12</sub>. Therefore, forty-eight such protected rats were also included in the comparison.

In the individual animals of the intoxicated as well as the protected group, there was a parallelism in the degree of the different alterations. This parallelism was marked between the degree of fatty deposition and bromsulfalein retention. The increased bromsulfalein retention was found more related to circulatory embarrassment by the fat deposition (as judged from the presence of erythrocytes in the sinusoids) than to liver cell damage. On the other hand, there was an almost as marked parallelism between liver cell damage, ribonucleic acid depletion, and decrease in liver protein.

Since with small doses of CCl<sub>4</sub> ribonucleic acid depletion in the center of the lobules can be produced without other evidence of liver damage, the ribonucleic acid depletion is apparently one of the basic factors in this type of liver damage. Moreover, vitamin B<sub>12</sub> seems to inhibit liver damage by facilitating the formation of ribonucleic acid. That is probably related to the assumed role as synthesizing ribonucleases of growth factors such as vitamin B<sub>12</sub>. Their influence on protein formation in turn may control the enzyme regeneration in liver damage.

These experiences suggest the investigation of the effect of vitamin B<sub>12</sub> in different types of liver diseases. In view of the relatively large doses necessary for effect in rats, variations in vitamin B<sub>1</sub> content possibly explain the erratic results obtained with liver extracts in these disorders.

# 118 RONIACOL—A VASODILATOR SUBSTANCE CONVERTED IN THE ORGANISM TO NICOTINIC ACID

S MARA WHITE, M D MINNEAPOLIS, MINN

Roniacol a vasodilator substance which is converted in the organism to nicotinic acid is 3 pyridine methanol or B pyridyl carbinol (the alcohol corresponding to nicotinic acid) and has the following structural formula

During the experimental period, the code designation for the compound was Nu 2121

Roniacol is a nonvolatile solid freely soluble in water and in alcohol and of low toxicity for animals. Administration of the human dosage to dogs for three months produced no adverse effect on weight blood formation or nonprotein nitrogen. In all animals powerful vasodilator effect on both coronary and peripheral circulation was observed.

There are several conditions in which prolonged vasodilation should be of benefit particularly in treatment but also in diagnosis. These include conditions in which coronary renal or peripheral cerebral vascular spasms are involved. Collateral circulation is of paramount importance when the vascular lumen is narrowed.

To be effective in aiding nutrition in an area with deficient vascular supply brief and evanescent dilation in collateral vessels requires frequent repetition of the dilator effect. A prolonged dilator effect is to be sought and should aid in establishing permanent dilatation of the vessels involved.

Relatively free from uncomfortable or deleterious effects and capable of causing an immediate visible flushing of the skin when given by mouth the drug can be repeated as often as desired.

This preliminary report is concerned with two conditions in which vaso spasm and vasodilation in a collateral circulation are important, the angina pectoris syndrome and peripheral vascular lesions.

In angina pectoris Roniacol has appeared repeatedly to increase tolerance for exercise and to extend the range of activity without occurrence of pain. In peripheral vascular disease the drug has been used to determine whether the total circulation of the involved parts can be improved and in cases showing improvement sympathectomy may be expected to be effective.

Cases illustrative of the foregoing conditions are cited

# 119 RAPID TREATMENT OF ACUTE GOUTY ARTHRITIS BY CONCURRENT ADMINISTRATION OF PITUITARY ADRENOCORTICOTROPIC HORMONE (ACTH) AND COLCHICINE

WILLIAM Q. WOLFSON, M.D., CLARENCE COHN, M.D., AND  
RACHMIEL LEVINE, M.D., CHICAGO, ILL.

(INTRODUCED BY SAMUEL SOSKIN, M.D.)

Clinical gout appears to require two endocrine disturbances. An abnormal male sex hormone seems to regulate appearance of inherited hyperuricemia. Gout patients also appear relatively unable to meet acute relative glucocorticoid lack with a prompt increase in production. When glucocorticoid lack occurs it tends to persist and to precipitate acute gouty arthritis. Hellman and Robinson, Conn, Block, and Louis induced acute glucocorticoid lack by administering ACTH in interval gout and then withdrawing this hormone and found the procedure to precipitate acute gouty arthritis in a majority of patients. Their observations have been confirmed.

ACTH, given during acute gouty arthritis, repairs the glucocorticoid lack and rapidly terminates the episode. However, given alone, ACTH is not satisfactory therapy for acute gouty arthritis. In most patients the relative glucocorticoid deficiency which follows hormone withdrawal precipitates a renewed attack shortly after withdrawal.

Colchicine, given during or immediately after treatment of acute gouty arthritis with ACTH, effectively overcomes the tendency of ACTH withdrawal to precipitate a renewal of the attack. Single 50 mg doses of ACTH (Aimoun) have effectively terminated most attacks within four hours. Occasionally a second or third dose has been required at six-hour intervals after the first. Although a number of the episodes treated had been prolonged and resistant to previous therapy, no ACTH-treated attack has persisted more than twenty-four hours after hormone therapy was begun.

Colchicine administration has been begun either with ACTH administration or four hours following the last dose of ACTH. All patients have been colchicized to tolerance and maintained on daily subtolerance doses of colchicine for at least two weeks. No patient who has received combined ACTH-colchicine therapy has had even a minor recurrence of acute gouty arthritis within one month of treatment.

Concurrent administration of ACTH and colchicine appears to be the most rapid and effective available treatment for acute gouty arthritis. In view of the relative scarcity of ACTH, the small amounts of this hormone which are required constitute a particularly desirable feature.

# 120 EFFECT OF HYPERVENTILATION ON THE HEMORESPIRATORY EXCHANGE IN NORMAL PERSONS, PATIENTS WITH PULMONARY EMPHYSEMA, AND PATIENTS WITH CARDIAC DYSPNEA

RUSSELL H. WILSON, M.D. (BY INVITATION), CRAIG W. BORDEN, M.D.  
(BY INVITATION), AND RICHARD V. EBFRI, M.D.

MINNEAPOLIS, MINN.

Respiration aids in maintaining a normal blood pH by regulating the tension of carbon dioxide in the alveoli and hence in the arterial blood. Hyperventilation in normal persons produces alkalosis by sudden lowering of the alveolar and blood pCO<sub>2</sub>.

The purpose of this study was to determine the response to voluntary hyperventilation of patients with dyspnea secondary to heart disease or chronic pulmonary emphysema. In twelve normal persons, fourteen cardiac patients and twelve patients with pulmonary emphysema the total lung volume and its subdivisions, the minute volume, oxygen uptake, CO elimination, arterial blood pH, CO content and oxygen saturation were measured in the basal state and after two minutes of voluntary hyperventilation. The pCO of arterial blood was estimated from the nomogram of Singer and Hastings.

In the group of patients with emphysema the residual air was markedly increased with a corresponding reduction in vital capacity, the total lung volume being normal. Patients with heart disease showed a reduction in vital capacity and total lung volume with a normal residual air.

Mean values before and after hyperventilation in normal persons and patients with cardiac dyspnea were very similar. In the group of patients with emphysema the initial pCO<sub>2</sub> was elevated and the oxygen saturation was diminished, the value for the former being 50 mm Hg and for the latter 83 per cent. The blood pH was normal, is the result of a compensatory increase in plasma bicarbonate. Voluntary hyperventilation was relatively ineffective in this group and did not significantly alter the initial values.

Hence patients with cardiac dyspnea like normal persons have ventilatory control over blood pH. Inability of patients with emphysema to increase alveolar ventilation effectively by maximal effort results in serious impairment of ventilatory regulation of blood pH. This defect renders these patients particularly vulnerable to metabolic and respiratory acidosis and is a constant threat to life.

## 121. A SINGLE SCALE ABSOLUTE READING EAR OXIMETER

EARL H. WOOD, M.D., ROCHESTER, MINN.

(INTRODUCED BY C. F. CODE, M.D.)

Two modified oximeter earpieces were calibrated on the basis of their responses on empirical optical filters using the single scale circuit described by Wood and Geraci.

Earpiece 1 was used to determine arterial oxygen saturation on thirty three ears of eighteen normal subjects. Thirteen were white and five were Negroes. Ages ranged from 2 to 50 years. The average saturation obtained when the subjects were breathing air was  $96.7 \pm 0.3^*$  (93-101) per cent and  $99.4 \pm 0.4$  (94-106) per cent when breathing oxygen.

Earpiece 2 was used on twenty four ears of seventeen normal subjects. Twelve were white, two were Chinese and three were Negroes. The average arterial saturation was  $96.7 \pm 0.3$  (94-100) and  $99.7 \pm 0.5$  (96-104) per cent when the subjects were breathing air and oxygen respectively.

Eighteen simultaneous Van Slyke and oximetric determinations of arterial oxygen saturation were made on six patients with congenital heart disease during supine rest breathing air or oxygen, standing and walking. The per cent arterial oxygen saturation by Van Slyke analysis of radial artery blood averaged 85 and ranged from 39 to 100 per cent. The standard deviation of the differences between simultaneous Van Slyke and ear oximeter determinations in these hypoxic patients was 4 per cent.

\*The number following the  $\pm$  sign is the standard error of the mean  $N = 23$

The instrument can be A C 01 battery operated, is compact, relatively inexpensive, simple to operate, and is apparently accurate enough to warrant its use for most clinical estimations of arterial oxygen saturation

## 122 STUDIES OF HEMAGGLUTININS IN CONGENITAL AND ACQUIRED HEMOLYTIC ICTERUS

CLAUDE-STARR WRIGHT, M D , MATTHEW C DODD, PH D (BY INVITATION), AND BERTHA A BOURONCLE, M D (BY INVITATION), COLUMBUS, OHIO

WITH THE TECHNICAL ASSISTANCE OF CHARLES A CUNNINGHAM, B S

The immunohematologists studying the Rh mechanisms developed a series of techniques for demonstrating incomplete (blocking) antibodies which have proved useful in investigating other hemolytic anemias. To the Coomb's, "developing" and "conglutination" tests, Wheeler, Lohby, and Scholl have recently added a technique,\* previously suggested by Buinet, Pickels, and Quilligan, using enzyme-treated normal red blood cells for detecting incomplete Rh antibodies in sera. They found the technique a simple, reliable, sensitive, inexpensive, and rapid screening test for demonstrating incomplete Rh antibodies in sera of Rh-negative women. We have added this to the battery of techniques in the study of congenital and acquired hemolytic icterus. The following observations have been made: (1) 255 normal sera gave no agglutination with trypsinized red blood cells. (2) In twenty cases of acquired hemolytic icterus, one or both tests were positive in sixteen cases, fourteen with trypsinized red blood cells, fourteen with Coomb's serum. (3) In twenty-one cases of congenital hemolytic icterus, one or both tests were positive in eight cases, six with trypsinized red blood cells, four with Coomb's serum.

It is concluded that (1) the trypsinized red blood cell test is a valuable adjunct for demonstrating incomplete antibodies in acquired and congenital hemolytic icterus. (2) In acquired hemolytic icterus the avidity and titers of the trypsinized red blood cell test are generally greater than with the Coomb's test, however, they run a closer parallel in acquired than congenital types. (3) The Coomb's test, contrary to recent claims, has not been a reliable means of differentiating acquired and congenital hemolytic icterus thus far in our hands.

## 123 CAVITY POTENTIALS OF THE HUMAN VENTRICLES

HENRY A ZIMMERMAN, M D , AND HERMAN K HELLERSTEIN, M D , CLEVELAND, OHIO

(INTRODUCED BY ROY W SCOTT, M D )

The intracavitary potentials of the human left ventricle have been studied by retrograde arterial catheterization. In eight men, 48 to 74 years of age, the left ventricle was entered successfully in six, while in two the tip of the

\*The trypsinized red blood cell technique (modified after Wheeler). 1 ml of washed (three times in cold normal saline) packed type O red blood cells is added to 15 ml of a 0.1 per cent trypsin (Difco 1250 activity trypsin) saline (buffered to pH 7.2) solution. Suspension incubated thirty minutes 37° C with frequent agitation. Centrifuge, remove supernatant and wash enzymized red blood cells three times with cold saline. Make a 2 per cent cell suspension in saline. Suspension is checked for nonspecific agglutination with normal sera.

Serial dilutions of the patient's serum are made with 0.1 ml of serum and 0.1 ml of saline. Two drops of the above suspension of trypsinized red blood cells are added. Incubate at 37° C thirty minutes and read for agglutination.

Normal sera are run as controls.

catheter electrode was obstructed by the aortic valve. All patients had aortic insufficiency, with an average pulse pressure of 98 mm Hg. The right ventricle potentials were obtained by venous catheterization.

In the region of the upper part of the interventricular septum, curves from the right ventricle showed a small R wave and a deep S wave, in the corresponding region of the left ventricle the complex was of the QS variety, with an initial slurring on the downward limb corresponding to the R wave of the right ventricular lead. In no case was a positive deflection recorded in the left ventricle in this region. These findings are consistent with the current belief, proposed by Wilson, that the upper part of the interventricular septum is depolarized from left to right.

In one case, however, curves from the apex of the left ventricle showed a definite R wave and a deep S wave. The origin of this R wave is obscure and may be due to (1) depolarization of the lower septum from right to left, or (2) to the tip of the catheter electrode being situated in the apex which would be "facing" the wave of depolarization passing down the Purkinje system of the left ventricle.

Premature beats were most frequently produced when the catheter first entered the cavity of the left ventricle in the upper septal region. In several cases runs of ventricular beats occurred for two to four seconds, spontaneously disappearing when the catheter was withdrawn or passed forward toward the apex. Premature beats originating from the endocardium of the left ventricle produced a wide QS complex, and usually a positive QRS complex in the right and left arm unipolar leads and a negative QRS complex in the left foot unipolar lead.

Tracings were also obtained above the aortic ring and in the arch of the aorta. The ventricular complexes resembled those of the right arm unipolar lead. Thus in a patient with ST elevation in aVr, and depression of the ST segment in V<sub>1</sub>, and in aV<sub>1</sub>, the ST elevation in the lead from the arch of the aorta indicated that essentially cavity potentials were being recorded in aVr and aortic leads. However aVr did not resemble the intracavitary lead in all cases. One patient with marked left axis deviation and left ventricular hypertrophy had positive aVr and aV<sub>1</sub>, but the cavity leads of the right and left ventricles had net negative values.

## 124 A STUDY OF PULMONARY HEMODYNAMICS DURING PNEUMONECTOMY

### A PRELIMINARY REPORT

HENRY A. ZIMMERMAN, M.D., HARVEY MENDELSON, M.D., AND  
ARTHUR ADELMAN, M.D., CLEVELAND, OHIO

(INTRODUCED BY ROY W. SCOTT, M.D.)

Cournand has studied pulmonary hemodynamics before and after pneumonectomy in human beings, but there are no published data on the changes occurring during the actual operative procedure. We have studied five patients undergoing pneumonectomy by the technique of right heart catheterization during the operation, when a sudden burden may be expected to be thrown on the vascular bed of the remaining lung following ligation of the opposite vessel. A catheter is placed in the pulmonary artery opposite to the one to be ligated sixty minutes before the induction of anesthesia. Basal cardiac output and initial pressures are recorded and subsequent pressure

levels are determined at fifteen-minute intervals throughout the entire procedure, including the period immediately following ligation of the pulmonary artery. Intra-arterial brachial pressure, phase of respiration, pulmonary arterial pressure, and the electrocardiogram are recorded simultaneously on a six-channel oscillograph described elsewhere. In two patients who had lesions which were not resectable, pulmonary artery pressure measurements were obtained after temporary ligation of one pulmonary artery.

We have demonstrated a consistent average rise in pulmonary arterial pressure of 50 per cent above the basal level in all instances immediately following ligation. Pulmonary artery pressures dropped to near basal levels by the end of the operation in the three patients in whom resections were done. This took an average time of forty-five minutes. These findings agree with the recent work of Long and associates in dogs.

We believe that the preoperative measurement of pulmonary arterial pressure is an important adjunct in the evaluation of the patient's suitability for pneumonectomy. This immediate rise in pulmonary arterial pressure, with the sudden load thrown on the right ventricle, may be responsible for unexpected deaths which occur after ligation of a pulmonary artery.

Scott and Zimmerman have shown that elevated pulmonary arterial pressures due to a variety of causes may be lowered by aminophylline. The effect of this drug administered prior to ligation of the pulmonary artery is under investigation.

# SUBJECT INDEX

- Abscesses and tumors radioactive silver for detection of, 1376  
 Ac globulin prothrombin methods in control of Dicumarol therapy, with remarks on 806  
 Achylia gastrica etiologic relationship of to pernicious anemia, observations on 1502  
 Acid and alkaline salt effect of on urinary excretion of iron 932  
 4 amino pteroylglutamic effect of on urinary excretion of 17 ketosteroids and corticosteroids in acute leukemia 1806  
 phosphatase test for identification of semina stains 728  
 Acquired hemolytic anemia Coombs titer variations in 1614  
 ACTH and colechieme rapid treatment of acute gouty arthritis by concurrent administration of 1766  
 dosage technique in appraising 1696  
 therapy eosinophil response in 1740  
 Actinomyces bovis in tissues and body fluids 677  
 Adrenalectomized dogs renin sensitivity and hypertensinogen levels in 1594  
 Adrenalectomy subtotal metabolic changes induced by resulting in cure of Cushing's syndrome effects of later administration of ACTH 1591  
 Adrenocorticotrophic hormone induction of diabetes in man with metabolism of uric acid glutathione and nitrogen and excretion of 11 oxysteroids and 17 ketosteroids during 255  
 therapy eosinophil response in 1740  
 Aerosporin (Polymyxin B) laboratory and clinical observations on 751  
 Agglutination and inhibition in two Lewis antibodies, studies of 538  
 sensitized sheep cell failure of to clarify diagnosis of rheumatic disease 1216  
 Alcohol and pancreatitis 844  
 serum amylase determinations in normal individuals following ingestion of 844  
 Allergic reactions following intravenous injection of corn sugar (dextrose or glucose), 1741  
 Allergy nasal and bronchial nebulized Pyribenzamine in, 1878  
 Alloxan diabetes in mice exacerbation of, by injection of typhoid vaccine, 487  
 treated rats hyperglycemia and glucosuria following thyroid administration in 492  
 Allylthiomethyl and n butylthiomethylpenicillin, pharmacology of 126  
 Aluminum absorption of lack of effect of Tween 80 on 1443  
 Amebiasis small bowel changes in 1750  
 Amino acid composition of proteins excreted by the nephrotic child, significance of, 326  
 excretion in degenerative diseases of nervous system 1623  
 mixtures intravenous administration of nausea and vomiting after serum glutamic acid levels and the occurrence of 1238  
 Analgesic agent, a new, clinical experience with 1615  
 Anaphylaxis in guinea pigs production of with weakly antigenic protein hydrolysates factors influencing 531  
 Anastomosis sterilization of defunctionalized loops of colon in preparation for with other viscera 1569  
 Anemia acquired hemolytic Coombs titer variations in 1614  
 induced, in swine interrelation of pteroyl glutamic acid and vitamin B<sub>12</sub> in 1763  
 megaloblastic experimental production of 1724  
 pernicious, etiologic relationship of achylia gastrica to observations on 1502  
 lingual manifestations of response of to pteroylglutamic acid and vitamin B<sub>12</sub> 439  
 therapy of with folic acid a long term evaluation of 1747  
 vitamin B<sub>12</sub> in oral administration of 1590  
 sickle cell sickle cell trait and pernicious anemia carbonic anhydrase activity in 1249  
 Anemias spherocytic hemolytic Coombs developing test in 768  
 Anesthetic gases concentration of viscosity effusion meter for measuring, 566  
 Aneurysm arteriovenous Streptococcus viridans endarteritis of an, cured by penicillin and surgical excision 221

- Angina pectoris, effect of cold application in, 1583  
papaverine in treatment of, re evaluation of, 992
- Angiocardiography, 1755
- Angioneurotic edema, hereditary, report of a case, 524
- Animals, laboratory, heart valves of various, study of movements and sounds of, 1753
- Antibodies, formation of, in human subjects after ingestion of heat killed *Brucella abortus*, 744  
Lewis, agglutination and inhibition in two, studies of, 538
- Antibody formation, effect of  $\gamma$  irradiation on, 1612
- Antidiuretic substance in urine of patients with cardiac failure, 1585
- Antigen D ( $R_h$ ), intentional isoimmunizations against, 270
- Antigens, fungus, serologic relationship of, 1096  
sonic vibrated leptospirae as, in complement fixation test for diagnosis of leptospirosis, 1411
- Antirabbit hemolysin, production of, 1692
- Antithrombin and heparin in human blood, 631
- Aorta, coarctation of, surgical resection and repair of, intra aortic blood pressure during, 1601
- Aortic wall, phosphatase in human, presence of, 1617
- Apparatus for desiccation of bacteria and other substances, simple inexpensive, 1315  
for recording blood pressure, an electronic, 143  
mixing and shaking, a simple, 140
- Arsenic<sup>76</sup>, biologic studies with, 1366
- Arterial disease of leg, inhibition by normal sympathetic vasoconstrictor tone of spontaneous development of a collateral circulation in chronic obliterating, 1581  
oxygen saturation in man, photoelectric determination of, 387
- Arteriovenous aneurysm, *Streptococcus viridans* endarteritis of an, cured by penicillin and surgical excision, 221
- Artery, pulmonary, idiopathic dilatation of, 1742
- Arthritis, gouty, rapid treatment of acute, by concurrent administration of pituitary adrenocorticotrophic hormone (ACTH) and colchicine, 1766  
rheumatoid, neutropenia and splenomegaly associated with, 1726
- Arthus and tuberculin hypersensitivity, a comparison, 1596
- Ascites, effect of rigid sodium restriction in, 1029
- Ascorbic acid and pteroylglutamic acid, in terrelationship between, 1724
- Aseptic grinding of small amounts of tissue, simple method for, 1021
- Atherosclerotic lesions, retrogression of, on cessation of cholesterol feeding in the chick, 1427
- Atropine sulfate and Dibutoline, effect of, on nocturnal gastric secretion in man, 1620
- Aureomycin assay for capillary blood and other body fluids, simplified turbidimetric method of, 1682  
blood and cerebrospinal fluid concentrations of, after oral and intramuscular administration, 366  
effect of, on urobilinogen formation and the fecal flora, 1743  
in vivo action of, upon pleuropneumonia like organisms associated with various rheumatic diseases, 1404
- Auricles, pathologic and electrocardiographic study of the, 1617
- Azoalbumin, use of, as a substrate in colorimetric determination of peptic and tryptic activity, 428
- ### B
- Bacteria, desiccation of, simple inexpensive apparatus for, 1315  
fecal aerobic and anaerobic, of patients with chronic ulcerative colitis, certain effects of chemotherapy on, 1725  
gram negative, in vitro effects on, of streptomycin combined with penicillin and/or sulfadiazine, 186
- Bacterial pyrogen, typhoid, febrile response to intravenous injection of, influence of various disease states upon, 1400  
pyrogens in treatment of malignant hypertension, further experience with, 1756  
toxins, heart block following medullary perfusion with, 1751
- Bacterimetric studies, 501
- Bacteriologic course of chronic typhoid carrier, effect of cholecystectomy on, 549
- Bacteriophage typing of *Salmonella typhi*, 739
- Balantidium coli* in feces, concentration of, galvanotactic procedure for, 1154
- Barbiturates, quantitative determination of, modified ultraviolet spectrophotometric method for, 1462
- Barium chloride, experimental administration of, cardiovascular changes following, 1733
- Basal metabolic rate, measurement of, use of urinary pigment excretion for, 482  
use of urinary pigment creatinine ratio for, 1512  
metabolism, determination of, by periodic maximal exhalations, 1742
- Beta hemolytic streptococcal pulmonary infections, cardiovascular lesions in rats subjected to group A, 1604
- Bilirubin in urine, new tablet test for, 1145

- Biologic decay periods of sodium in normal man, in congestive heart failure and in nephrotic syndrome as determined by Na as the tracer 1
- rates of isotopes, theoretic considerations of 14
- material determination of phenol in 270
- studies with arsenic<sup>76</sup>, 1366
- Biuret and Kjeldahl determinations of serum proteins studies of differences between 1170, 1178, 1183
- Blood and bronchial secretions, recovery of Histoplasma capsulatum from primary histoplasmosis with 1290
- and cerebrospinal fluid concentrations of aureomycin after oral and intramuscular administration 366
- and tissue fluids, quantitative spectrographic analysis of 616
- and urine bromate in, detection of 424
- antithrombin and heparin in human 631
- capillary aureomycin assay for simplified turbidimetric method of 1682
- clotting defect protamine titration as in detection of in certain hemorrhagic states 473
- coagulability as influenced by digitoxin studies on 1620
- coagulation defect in thrombocytopenic purpura 761
- dynamics of, 1570
- effect of plasma proteins on 477
- in leucemia and polycythemia 1321
- component A (prothrombin) in human state of 1203
- concentration of its assay and relation to labile factor, 973
- creatinine and glucose approximate estimation of in one procedure simple test for, 720
- donors causes for rejections of 814
- enzyme studies on human 477
- flow estimation digit simplified venous occlusion method of using the Burch Winsor plethysmograph 1718
- glucose in determination of true by reduction of ferricyanide, 713
- hemophilia like disease in women 151
- iodine effect of retained bronchial Lipiodol on 1518
- level studies on teropterin metabolism 501
- levels vitamin A and glucose effect of epinephrine on in normal and cirrhotic subjects 1279
- penicillin assay micromethod for 1687
- pressure intra aortic during surgical resection and repair of coarctation of aorta 1601
- of ambulatory hypertensive subjects effect of minimal sodium diet on 1330
- recording of, electronic apparatus for, 143
- prothrombin activity of human 1203 1739
- pump suitable for design of 1561
- Blood—Cont d
- rate of disappearance of transfused gamma globulin from immunochemical estimation of in hypoproteinemia, 1666
- red cell and plasma cholinesterase activity electrometric method for determination of 1564
- serum cholesterol variations in human significance of 1470
- sickle cell disease study of by measuring survival of transfused red blood cells 90
- spludge phenomenon clinical evaluation of 1609
- transfusions hypertection during for hemorrhagic shock in patient with unilateral renal ischemia 784
- types distribution of in the leucemias 1587
- Body fluids Actinomyces bovis in 6
- aureomycin assay for capillary blood and other simplified turbidimetric method of 1682
- radioactive phosphorus ( $P^{32}$ ) in methods for determinations of 1601
- sodium in man determination of total with radio-sodium 1509
- Bone marrow radioisotopes of strontium zirconium and columbium in controlled selective localization of 305
- studies in polyethenium of high altitudes 637
- Bound glucosamine of serum mu in diabetes mellitus 116
- Bowel small changes in anebiasis 130
- Brain oxidations depression of studies on 846
- tumors malignant uptake of radioactive phosphorus by 587
- Bromate in blood and urine detection of 420
- Bromsulfalein and rose bengal tests a comparison of 246
- clearance 965
- Bronchi chemical physiology of effect of high vagus section upon 1730
- Bronchial Lipiodol retained effect of on blood iodine 1516
- Bronchospasm methacholine induced in guinea pigs appraisal of anticholinergic activity by prevention of 1010
- Brucella abortus heat killed formation of antibodies in human subjects after ingestion of 744
- Brucellosis human histopathology of liver in 40
- Bubble flow meter optically recording adapted for measurement of renal blood flow 146
- Burch Winsor plethysmograph simplified venous occlusion method of digit blood flow estimation using 1718
- type plethysmographic cups substance to seal 438

## C

- Cadmium reaction, practical test for evaluation of serum lability, comparison with cephalin cholesterol flocculation and thymol turbidity test, 1162
- Capillary fragility studies (Gothlin test) on 100 patients receiving Dicumarol, 448
- resistometer, evaluation of a new the Petechiometer, 1714
- Carbon dioxide incubator, conversion of a standard incubator to, 865
- Carbonic anhydrase activity in sickle cell anemia, sickle cell trait, and pernicious anemia, 1249
- Cardiac decompensation, oral Mercuhydrin combined with ascorbic acid in, 1750
- factors in "neurogenic" pulmonary edema, 1734
- failure, antidiuretic substance in urine of patients with, 1585
- output of normotensive and hypertensive patients, effect of tetraethylammonium bromide on, 1622
- Cardiodynamic and renal changes in spontaneous and nephrogenic hypertensive dogs in response to tissue injury, 1753
- studies in chronic pericarditis with effusion, with particular reference to the mechanisms of fluid accumulation, 1598
- Cardiovascular changes following experimental administration of barium chloride, 1733
- lesions in rats subjected to group A beta hemolytic streptococcal pulmonary infections, 1604
- Caronamide, colorimetric determination of, some factors involved in, 509
- Catheters, intravenous, expansile needle for introduction of, 584
- Cavity potentials of human ventricles, 1768
- Central Society for Clinical Research, Twenty Second Annual Meeting, Nov 4 and 5, 1949, Proceedings of, 1579, 1724
- Cerebral injury, acute closed, quantitative studies of treatment, by hypertonic intravenous glucose or surgical decompression, 1755
- Cerebrospinal fluid and blood concentrations of aureomycin after oral and intramuscular administration, 366
- histamine content of, observations on, 250
- Chemotherapy, certain effects of, on fecal aerobic and anaerobic bacteria of patients with chronic ulcerative colitis, 1725
- Chloride and chloride space in dogs, rates of turnover and biologic decay of, determined with the long life isotope,  $\text{Cl}^{36}$ , 1589
- Chloromycetin administration, hemopoietic changes during, 1747
- Cholecystectomy, effect of, on bacteriologic course of chronic typhoid carrier, 549
- Cholesterol desoxycholic acid, stable antigen in flocculation test for liver dysfunction, 1049
- Cholesterol feeding in chick, retrogression of atherosclerotic lesions on cessation of, 1427
- variations in human blood serum, significance of, 1473
- Cholesterol free diet, effect of, on serum cholesterol of normal and thyroid treated dogs, 1602
- Choline, effect of, on changes in liver composition during protein depletion, 953
- Cholinesterase activity in the blood in hematologic disease, studies of, 178
- Chorioallantoic membrane, isolation of herpes simplex virus on, 402
- Chorionic gonadotropin and extracts of male urine, quantitative response of prostatic and phosphatase of immature rat to, 1727
- renal and extrarenal disposal of, in immediate post partum period, 1613
- Circulation, collateral, inhibition by normal sympathetic vasoconstrictor tone of spontaneous development of, in chronic obliterating arterial disease of leg, 1581
- peripheral, measurement of, 1614
- time in man, estimation of portal, 674
- Circulatory reactions to ephedrine and neosynephrine in normal man, influence of Dibenamine upon, 669
- Cirrhosis of liver and ascites, effect of rigid sodium restriction in, 1029
- Clinical and laboratory effects of hypotonic intravenous infusions, 1745
- observations in fatty infiltration of the liver, 1760
- of Aerosporin (Polymyxin B), 751
- evaluation of a new lipase preparation, 1754
- physiology of bronchi, effect of high vagus section upon, 1730
- Clinical pathological survey of 108 tuberculous patients, 1592
- Clotting defect, protamine titration as indication of, in certain hemorrhagic states, 473
- Coagulability of blood as influenced by digitoxin, studies of, 1620
- Coagulation defect in thrombocytopenic purpura, 761, 1227
- dynamics of, 1579
- effect of plasma proteins on, 477
- in leukemia and polycythemia, 1321
- Coarctation of aorta, surgical resection and repair of, intra aortic blood pressure during, 1601
- Cold application, effect of, in patients with angina pectoris, 1583
- effects of, on man, 1616

- Colitis chronic ulcerative fecal aerobic and anaerobic bacteria of patients with, certain effects of chemo therapy on 1725
- ulcerative Viodenum in treatment of 1621
- Colloidal red test as index of liver dysfunction, 662
- Colloids containing radioisotopes of yttrium, zirconium, columbium and lanthanum studies with 297, 305
- Colon, loops of, sterilization of defunctionalized, in preparation for anastomosis with other viscera, 1509
- Colorimetric determination of Caronamide some factors involved in 509
- of peptic and tryptic activity, azoalbumin as a substrate in 428
- Complement fixation test clinical and epidemiologic studies of mumps employing the 1599
- for diagnosis of leptospirosis some vibrated leptospirae as antigens in 1411
- Component A (prothrombin) in blood concentration of its assay and relation to labile factor 973
- state of, 1203
- Congenital idiopathic methemoglobinemia 1876
- malformation of heart, two rare cases of cyanotic group right heart catheterization and angiocardigraphic studies 1737
- Congestive heart failure biologic decay periods of sodium in as determined by  $\text{Na}^{22}$  as the tracer 1
- Connective tissue response of to piezoelectrically active crystals 51
- Coombs developing test in spherocytic hemolytic anemias 765
- titer variations in acquired hemolytic anemia 1614
- Corn sugar allergic reactions following intravenous injection of 1741
- Coronary disease continuous Dicumarol prophylaxis in, 1749
- flow volume effect of heparin and Dicumarol in increasing, 797
- Corpuscular constants hematologic slide rule for calculating 434
- Corynebacterium diphtheriae, modified Loeffler's medium for cultivating 582
- Creatinine and glucose in blood approximate estimation of, in one procedure simple test for 720
- Cryoglobulin high concentration of in plasma of multiple myeloma, 1057
- Cushing's syndrome cure of metabolic changes induced by subtotal adrenalectomy resulting in effects of later administration of ACTH 1591
- D
- Depressions of brain oxidations, studies on 846
- Desiccation of bacteria and other substances simple inexpensive apparatus for 1315
- Desoxycorticosterone acetate and anterior pituitary extract experimental vascular changes due to comparison of functional change 446
- effect of in experimental hypertension further studies on 1535
- Desoxytyrosine pyridoxine deficiency in human beings induced with 1730
- Determination of arterial oxygen saturation in man photoelectric 357
- of fat in feces using Mojonnier extraction flask 1471
- of fetal fat and fatty acids simple method for 282
- of skin appearance time method for 133
- of glucose in urine Sumner limito alkalic acid method for evaluation of a modified 144
- of phenol in biologic material 75
- of procaine and penicillin on acid spectrophotometric method for 822
- of protein in serum and in fractions obtained from serum with a buret reagent prepared with sodium hydroxide 1141
- of radioactive phosphorus ( $\text{P}^{32}$ ) in body fluids methods for 1501
- of red blood cell and plasma cholinesterase activity electrometric method for 1564
- of sulfonamide sensitivity in vitro simple method for and its clinical application 1457
- of true glucose in blood by reduction of ferricyanide 713
- of urobilinogen in urine and stool simplified equipment for 297
- Deuterium oxide and thiocyanate spaces in protein depletion 680
- Developing test (Coombs) in spherocytic hemolytic anemias 768
- Dextrose allergic reactions following intravenous injection of 1741
- Diabetes detection 1735
- induction in man with pituitary adrenocorticotrophic hormone metabolism of uric acid glutathione and nitrogen and excretion of 11 oxy steroids and 17 ketosteroids during 255
- mellitus bound glucosamine of serum mucoid in 116
- Diabetic and nondiabetic subjects vibratory perception in quantitative studies of 1728
- Dialysis across the intestinal mucosa treatment of uremia by 1761
- Diathesis hemorrhagic associated with low thromboplastic activity and a circulating anticoagulant 1606
- Dibenzamine influence of upon circulatory reactions to epinephrine and neosynephrine in normal man 669
- Dibutyltin and atropine sulfate effect of on nocturnal gastric secretion in man 1620
- as antidote for diisopropyl fluorophosphate poisoning in mice 123

- Dicumarol and heparin, effect of, in increasing coronary flow volume, 797  
 capillary fragility studies (Gothlin test) on 100 patients receiving, 448  
 prophylaxis, continuous, in coronary disease, 1749  
 therapy, one stage and two stage prothrombin methods in control of, with remarks on Ag globulin, 806  
 Diet, cholesterol free, effect of, on serum cholesterol of normal and thymura cal treated dogs, 1602  
 Digoxin, blood coagulability as influenced by, studies on, 1620  
 Diiodo fluorescein, detection of intracranial tumors by, 1580  
 Diisopropyl fluorophosphate poisoning in mice, Dibutoline as an antidote for, 123  
 Dimethylether of *d* tubocurarine iodide, 516  
 Dinitrosalicylic acid method for determination of glucose in urine, evaluation of a modified Sumner, 1447  
 Diseases of cold temperature climates, speculations on, and on nutrition and the pituitary adrenal axis, 1616  
 Diuretic sodium sulfate, experimental in fusion of, changes observed following, 1732  
 Dogs, collection of lymph from right thoracic duct in, technique for, 1576  
 spontaneous and nephrogenic, cardiodynamic and renal changes in, in response to tissue injury, 1753
- E
- Ear oximeter, a single scale absolute reading, 1767  
 Edema formation in lungs, mechanisms of, observations on, 1544  
 hereditary angioneurotic, report of a case, 524  
 Electrocardiogram of normal and malaria infected monkeys, 1106  
 Electrocardiographic patterns in persons over 80, 1597  
 Electrolymograph, mounting for, a new, 1298  
 Electromagnetic flow meter, newly developed, 1706  
 Electrometric method for determination of red blood cell and plasma cholinesterase activity, 1564  
 Electronic apparatus for recording blood pressure, 143  
 Electrophoretic pattern of serum and plasma in liver diseases, comparison of, with special reference to gamma globulin fractions, 1600  
 Emetine in tissues, distribution of, 818  
 Emission spectrograph, use of, for quantitative determination of Na, K, Ca, Mg, and Fe in plasma and urine, 625  
 Encephalitis, Japanese B, report of five cases, 1656  
 Endarteritis, streptococcus viridans, of an arteriovenous aneurysm, cured by penicillin and surgical excision, 221  
 Enteric perfusion, use of hypertonic solutions for, 944  
 Enzyme studies on human blood, 477  
 Eosin acetone and phloxine propylene glycol diluents in eosinophile counts, comparison of, 1017  
 Eosinophil response in adrenocorticotrophic hormone (ACTH) therapy, 1740  
 Eosinophils, differentiation and enumeration of, in counting chamber with glycol stain, 1696  
 Ephedrine and neosynephrine, circulatory reactions to, in normal man, influence of Dibenamine upon, 669  
 Epidemiology of infectious hepatitis, observations on, 1588  
 Epinephrine, effect of, on vitamin A and glucose blood levels in normal and cirrhotic subjects, 1279  
 Erythroblastic hyperplasia, induced, in rabbits, effects of nitrogen mustard on, 902  
 Erythrocyte iron turnover, 1480  
 Exacerbation of alloxan diabetes in mice by injection of typhoid vaccine, 467  
 Excitation, spread of, through the ventricular myocardium, studies on, 1738  
 Expansile needle for introduction of intravenous catheters, 584  
 Experimental administration of barium chloride, cardiovascular changes following, 1733  
 hypertension, effect of desoxycorticosterone acetate in, further studies on, 1595  
 infusion of diuretic sodium sulfate, changes observed following, 1732  
 malignant hypertension in the dog, effect of rutin on hemorrhagic phenomena of, 1608  
 peritonitis, 1175  
 production of megaloblastic anemia, 1724  
 study of effect of zirconium and sodium citrate treatment on metabolism of plutonium and radiostrontium, 313  
 syphilis in rabbit, 1748  
 uremia, dietary and hormonal influences in, 925
- F
- Fat emulsions for intravenous nutrition in man, 699, 1627  
 determination in feces using Mojonnier extraction flasks, 1471  
 Fatty infiltration of liver, clinical and laboratory observations in, 1760  
 Febrile response to intravenous injection of typhoid bacterial pyrogen, influence of various disease state upon, 1400

- fecal aerobic and anaerobic bacteria of patients with chronic ulcerative colitis, certain effects of chemotherapy on, 1725
- fat and fatty acids, determination of simple method for, 282
- flora, urobilinogen formation and, effect of aureomycin on, 1743
- Feces, *Balantidium coli* in, galvanotactic procedure for concentration of 1154
- fat determination in using Mojonnier extraction flasks, 1471
- Ferricyanide, determination of true glucose in blood by reduction of, 713
- Fibrin appearance time determination of method for, 133
- Fibrinogen B test and intravascular thrombosis 1352
- Fibrogenesis, ability of galvanic current flow to stimulate 610
- Flocculation test for liver dysfunction, cholesterol-desoxycholic acid a stable antigen for, 1049
- with Hayem's solution evaluation of 653
- test, interpretation of results of on basis of biopsy findings and protein partition, 1736
- Flow meter, electromagnetic, newly developed, 1706
- Fluids, blood and tissue, quantitative spectrographic analysis of, 616
- body, *Actinomyces bovis* in, 677
- cholic acid, therapy of pernicious anemia with a long term evaluation of 147
- 4-amino-pteroylglutamic acid, effect of on urinary excretion of 17 ketosteroids and corticosteroids in acute leukemia, 1606
- Free valine, tryptophane, and histidine of plasma, concentration of, in young and old, determined with microbiologic method, 234
- Freezing drying sections simplified vacuum dehydration technique for, 292
- Frog, North American (*Rana pipiens*) pregnancy test, appraisal of with suggested modification of original technique 554
- Fungus antigens, serologic relationship of, 1096

## G

- Galvanic current flow, ability of, to stimulate fibrogenesis, 610
- Galvanotactic procedure for concentration of *Balantidium coli* in feces 1154
- Gamma globulin rate of disappearance of transfused, from blood in hypoproteinemia, immunochemical estimation of 1066
- Gases, anesthetic, concentration of viscosity effusion meter for measuring, 566
- respiratory, vacuum sampling tube for, 881
- Gastric secretion in dogs and gastric ulcer formation in rats action of Thephorin upon histamine induced, 372

- Citric secretion—Cont d
- nocturnal effect of atropine sulfate and Dibutoline on 1620
- (*Glomerulonephritis* spontaneous and induced in an inbred strain of mice 209
- Glucose allergic reactions following intravenous injection of, 1741
- and creatinine in blood approximate estimation of in one procedure, simple test for 720
- in blood determination of true by reduction of ferricyanide 713
- in urine determination of Sumner diastro salicylic acid method for evaluation of a modified 1447
- renal tubular transport mechanism for studies on 1618
- spinal fluid quantitative micromethod for pediatric ward laboratory 725
- tolerance for changes in and in morphology of pancreatic islet cells induced by intravenous glucose in dogs, 1460
- Glucosuria and hyperglycemia following thyroid administration in alloxan treated rats 492
- Gothlin test for capillary fragility studies of on 100 patients receiving Dicumarol, 448
- Gram negative bacteria in vitro effects of on streptomycin combined with penicillin and/or sulfadiazine 186
- Grinding aseptic simple method for of small amounts of tissue 1021

## H

- Hanger cephalin cholesterol test comparison of with cholesterol desoxycholic acid in test for liver dysfunction, 1049
- Hayem's solution flocculation test with evaluation of 653
- Heart block following medullary perfusion with bacterial toxins 1751
- congenital malformation of, two rare cases of cyanotic group right heart catheterization and angiographic studies 1737
- failure congestive and hyponatremia, untoward effects of mercurial diuretics, 1590
- biologic decay periods of sodium in as determined by  $\text{Na}^{22}$  as the tracer 1
- infarction of muscle bundles of, 1763
- rate, control of, with an intracardiac thermode, 1607
- rupture of, spontaneous following acute myocardial infarction, 1759
- Heberden's nodes relationship of menopause to degenerative joint disease of fingers 1193
- Hemagglutinins in congenital and acquired hemolytic icterus, studies of 1768
- Hematoerit and plasma proteins of albino rat effect of hyaluronidase on, 834

## Liver—Cont'd

- dysfunction, cholesterol desoxycholic acid a stable antigen for flocculation test for, 1049
- colloidal red test in index of, 662
- fatty infiltration of, clinical and laboratory observations in, 1760
- in human brucellosis, histopathology of, 40
- needle biopsy of, using oxidized cellulose and thrombin to prevent hemorrhage, 422
- radioisotopes of yttrium, zirconium, and columbium in, controlled selective localization of, 305
- Loeffler's medium, modified, for cultivating *Corynebacterium diphtheriae*, 582
- Long life isotope,  $\text{Cl}^{36}$ , rates of turnover and biologic decay of chloride and chloride space in dogs determined with, 1589
- Lower nephron nephrosis, altered renal function in, nature of, 31
- management of, further experiences in, 1609
- Lungs, edema formation in, observations of mechanisms of, 1544
- Lymph, collection of, from right thoracic duct in dogs, technique for, 1576
- Lymphocyte, its relationship to immunologic processes in the cat, 158

## M

- Macerator for small samples of tissue, 1027
- Malaria infected monkeys, electrocardiograms of normal and, 1105
- quinine dihydrochloride in, lethal effects and electrocardiographic changes produced by, 1109
- Malignant hypertension, bacterial pyrogens in treatment of, further studies with, 1756
- Manometer calibrator, Warburg, 1702
- Measurement of renal blood flow, optically recording bubble flow meter adapted for, 146
- Mega esophagus, pathologic physiology of, 1739
- Megaloblastic anemia, experimental production of, 1724
- Menopause, relationship of, to degenerative joint disease of fingers, 1193
- Mercurhydrin combined with ascorbic acid, oral, in cardiac decompensation, 1750
- Mercurial diuresis, effects of, in congestive heart failure and hyponatremia, 1590
- diuretic, Thimerin a new, clinical studies on, 1254
- Metabolism, iron, 1480
- of plutonium and radioyttrium, experimental study of effect of zirconium and sodium citrate treatment on, 313
- of uric acid, glutathione and nitrogen during induction of diabetes in man with pituitary adrenocorticotrophic hormone, 255

## Metabolism—Cont'd

- teropterin, blood level studies on, 501
- tyrosine, in human scurvy, 1491
- Methacholine induced fatal bronchospasm in guinea pigs, appraisal of anticholinergic activity by prevention of, 1010
- Mice, adaptability of, to laboratory diagnosis of tuberculosis, 1081
- Microbiologic determination of concentration of free valine, tryptophane, and histidine of plasma of young and old, 234
- Micromethod for blood penicillin assay, 1687
- Milk, human, excretion of penicillin in, 497
- Monjonner extraction flasks, fat determination in feces using, 1471
- Monkeys, normal and malaria infected, electrocardiogram of, 1105
- Mononucleosis, infectious, false positive trichina precipitin tests in, occurrence of, 543
- pancreatitis in, 1671
- Morphine sulfate, control comparison of N<sub>2</sub>206 (3 hydroxyl N methylmorphine hydrobromide) with, for relief of postoperative pain, 1758
- Mounting for electrokymograph, a new, 1293
- Mumps, clinical and epidemiologic studies of, employing the complement fixation test, 1599
- vaccine, studies on human volunteers, 199
- Mycobacterium tuberculosis, cultivation of, 733
- infection (H37RV) in protein deficient rat, electrophoretic, circulating plasma protein, hematologic, hematopoietic, and pathologic responses to, 335
- Myeloma, multiple, high concentration of cryoglobulin in plasma of, 1057
- Myocardial infarction, acute, spontaneous rupture of heart following, 1799
- by auricular catheterization, preliminary report on study of, 1737

## N

- Narcolepsy and cataplexy, stellate block in management of, 1745
- Nasal and bronchial allergy, nebulized Pyribenzamine in, 1078
- Nausea and vomiting, occurrence of, after intravenous administration of amino acid mixtures, serum glutamic acid levels and, 1238
- Needle, expansile, for introduction of intravenous catheters, 584
- Nephrotic child, amino acid composition of proteins excreted by, significance of, 326
- syndrome, biologic decay periods of sodium in, as determined by  $\text{Na}^{22}$  as the tracer, 1
- Nervous system, degenerative diseases of, amino acid excretion in, 1623
- "Neurogenic" pulmonary edema, cardiac factors in, 1734
- Neutropenia and splenomegaly associated with rheumatoid arthritis, 1726

- Newcastle virus in human respiratory infection: occurrence of antihemagglutinins against, with a possible instance of virus isolation, 1081
- Nitrogen mustard effects of on induced erythroblastic hypoplasia in rabbits, 902
- N,N-dimethyl-N-(thiazolyl)-N'-p-methoxybenzyl ethylenediamine hydrochloride (194 B), experimental and clinical study of, 1007
- Nocturnal gastric secretion in man: effect of atropine sulfate and Dibuto line on, 1620
- Nonprotein nitrogen, hypobromite method for, photometric modification of, 81
- Nutrition intravenous, fat emulsions for, 699-1627
- parenteral, 688, 699, 1627
- Nutritional neuropathy: effect of vitamin B<sub>12</sub> on painful aspects of, preliminary report, 1582
- status and infection response, 335
- NU 06 (3-hydroxy-N-methyl morphinan hydrobromide), control comparison of, with morphine sulfate for relief of postoperative pain, 1758
- new analgesic observations on use of, 1530

## O

- Organ homogenates and urine, thrombocytopenia in, reliable test for, 1336
- Organic disease of pituitary: alterations in testicular structure, and function in, 1726
- Oxidized cellulose and thrombin: use of, in needle biopsy of liver to prevent hemorrhage, 422
- Oximeter ear: a single scale absolute reading, 1767

## P

- Pancreatic dysfunction and liver disease, 1431
- Pancreatitis, alcohol and, 844
- in infectious mononucleosis, 1671
- Paravaccine in treatment of angina pectoris, reevaluation of, 992
- Parasitism intestinal, in American troops in Germany, 1284
- Parenteral alimentation: study of complete nutrition, 688-699-1627
- Paroxysmal myohemoglobinuria with fatal renal tubular injury, 1744
- Pathologic conditions: plasma tocopherol levels in various, 648
- physiology of megaesophagus, 1739
- Pellagra: tryptophane in human, therapeutic effect of, 401
- Penicillin excretion of in human milk, 497
- micromethod for blood assay, 1687
- new products of for sustained effect, 67
- treatment of pneumococcal pneumonia by in aqueous solution at long intervals, 59

- Peptic and tryptic activity: colorimetric determination of azoalbumin as a substrate in, 428
- Perigastric intestinal perfusion: vicarious excretion by means of, 1085
- Pericarditis with effusion: chronic cardiovascular and renal studies with particular reference to mechanisms of fluid accumulation, 1598
- Peripheral circulation: effects of intravenously administered histamine on, 380
- in measurement of, 1614
- Peritonitis: experimental, 1175
- Permeous anemur: etiologic relationship of a hypergastrica to observation on, 1002
- lingual manifestations of response of hypotrichoglutamic acid and vitamin B<sub>12</sub>, 439
- sickle cell anemia and sickle cell trait: carbonic anhydrase activity in, 1249
- therapy of with toluic acid: a long term evaluation of, 1747
- vitamin B<sub>12</sub> in oral administration of, 1590
- Petechiometer: evaluation of new capillary resistometer, 1714
- Pharmacology of allylthiomethyl and n-butylthiomethylpenicillin, 126
- Phenol in biologic material: determination of, 205
- Pheochromocytoma: physiologic and pharmacologic studies in a case of, 1711
- Phloxine propylene glycol and eosin acetone: comparison of in eosinophil counts, 1017
- Phosphate in human aortic wall: presence of, 1614
- Phosphorus: radioactive uptake of by malignant brain tumor, 597
- Photoelectric determination of arterial oxygen saturation in man, 387
- Photometric modification of hypobromite method for nonprotein nitrogen, 873
- Physiologic and pharmacologic studies in a case of pheochromocytoma, 1711
- Physio pathology of megaesophagus, 1739
- Piezoelectrically active crystal: response of connective tissue to, 592
- Pituitary: adrenocorticotrophic hormone (ACTH) and calcicemic: rapid treatment of acute gouty arthritis by concurrent administration of, 1766
- organic disease of: alterations in testicular structure and function in, 1726
- Plasma: macrobiologically obtained, improved device for, 1169
- and urine, Na, K, Ca, Mg, and Fe in: quantitative determination of use of emission spectrograph for, 650
- concentration of free valine, tryptophan, and histidine of in young, and old: determination with microbiologic method, 234

- Plasma—Cont'd  
 of multiple myeloma, high concentration of cryoglobulin in, 1057  
 proteins and hematocrit of albino rat, effect of hyaluronidase on, 834  
 effect of, on coagulation of blood, 477  
 prothrombin free, stability and activity of human and bovine in determination of prothrombin by dilution method, 1356  
 radioiodine, effect of thyroid secretory activity on distribution of, 1520  
 tocopherol levels in various pathologic conditions, 648
- Platelet studies with a new photographic technique, observations of character of, 1604
- Plethysmograph, Burch Winsor, simplified venous occlusion method of direct blood flow estimation using, 1718
- Plethysmographic cups of Burch Winsor type, substance to seal, 438
- Pleuropneumonia like organisms associated with various rheumatic diseases, in vivo action of aureomycin on, 1404
- Pneumococcal pneumonia, pneumococcus types, mortality, bacteremia, and purulent complications in, at the Cincinnati General Hospital, 1936 1949, 1757  
 treatment of, by penicillin in aqueous solution at long intervals, 59
- Pneumonectomy, pulmonary hemodynamics during, study of, 1769
- Pneumonia, pneumococcal, pneumococcus types, mortality, bacteremia, and purulent complications in, at the Cincinnati General Hospital, 1936 1949, 1757  
 treatment of, by penicillin in aqueous solution at long intervals, 59
- Poisoning, diisopropyl fluorophosphate, in mice, Dibutyltin as an antidote for, 123
- Polomyelitis, Lansing type virus of, transmission of, in mouse experiments, improved technique for, 560
- Polycythemia, blood coagulation in, value of heparin clotting time and clot retraction rate, 1321  
 of high altitudes, bone marrow studies in, 637  
 vera with hepatic vein thrombosis case report with serial liver biopsies and apparent recovery, 1593
- Polymyxin B, laboratory and clinical observations on, 751
- Polyvinyl alcohol fixative as preservative and adhesive for protozoa in dysenteric stools and other liquid materials, 1554
- Popliteal vein, division of, in valvular insufficiency of deep venous system of lower extremities, 1755
- Portal circulation time in man, estimation of, 674
- Precordial leads, diagnostic value of high, 1618
- Pregnancy test, male North American frog (*Rana pipiens*), appraisal of, with suggested modifications of original technique, 554
- Procaine and *p* aminobenzoic acid, determination of, spectrophotometric method for, 822
- penicillin in oil, treatment of syphilis with, 998
- Protamine titration as indication of clotting defect in certain hemorrhagic states, 473
- Protein depletion, deuterium oxide and thio cyanate spaces in, 680  
 liver changes during, and effect of choline upon these changes, 953  
 hydrolysates, antigenic, production of anaphylaxis in guinea pigs with weakly, factors influencing, 531  
 in serum, determination of, and in fractions obtained from serum with a biuret reagent prepared with sodium hydroxide, 1171
- Protein deficient rat, *Mycobacterium tuberculosis* (H37RV) infection in, electrophoretic, circulating plasma protein, hematologic, hematopoietic, and pathologic responses to, 335
- Proteins excreted by nephrotic child, amino acid composition of, significance of, 326
- Prothrombin activity of human blood, 1739  
 determination of, by dilution method, 1356  
 estimation of, use of Russell viper venom and lecithin as thromboplastin in, 458  
 in human blood, state of, 1203  
 methods, one stage and two stage, in control of Dicumarol therapy, with remarks on A<sub>2</sub> globulin, 806
- Prothrombin free plasma, stability and activity of human and bovine, in determination of prothrombin by dilution method, 1356
- Protozoa in dysenteric stools, polyvinyl alcohol fixative as preservative and adhesive for, 1554
- Pteroylglutamic acid and ascorbic acid, interrelationship between, 1724  
 and vitamin B<sub>12</sub>, interrelation of, in induced anemia of swine, 1763  
 response of lingual manifestations of pernicious anemia to, 439  
 antagonists, hematologic changes induced in guinea pigs by prolonged administration of, 833
- Pulmonary artery, idiopathic dilatation of, 1742  
 edema, "neurogenic," cardiac factors in, 1734  
 hemodynamics during pneumonectomy, study of, 1769  
 streptococcal infections, group A beta hemolytic cardiovascular lesions in rats subjected to, 1604
- Pump suitable for blood, design of, 1561

- Purpura, idiopathic thrombocytopenic simultaneous cesarean section and splenectomy in 1580  
thrombocytopenic, coagulation defect in observations on, 1227  
Pyribenzamine nebulized in nasal and bronchial allergy 1078  
Pyridoxine deficiency in human beings induced with desoxyypyridoxine, 1730

## Q

- Quantitative determination of barbiturates modified ultraviolet spectrophotometric method for 1462  
of Na, K, Ca, Mg and Fe in plasma and urine use of emission spectrograph for, 625  
indirect method for estimation of heparin activity in vitro 1619  
spectrographic analysis of blood and tissue fluids 616  
spinal fluid glucose micromethod for pediatric ward laboratory, 725  
studies of vibratory perception in diabetic and nondiabetic subjects 1728  
Quinidine gluconate a new intramuscular preparation of quinidine 1118  
Quinine dihydrochloride in malaria infected monkeys, lethal effects and electrocardiographic changes produced by, 1109

## R

- Radioactive phosphorus in body fluids do termination of methods for 1301  
uptake of by malignant brain tumors 587  
silver for detection of abscesses and tumors use of, 1376  
Radionodine in plasma effect of thyroid secretory activity on distribution of, 1520  
Radioisotopes of yttrium zirconium columbium and lanthanum colloids containing, studies with 297  
Radosodium <sup>4</sup>, determination of total body sodium in man with, 1599  
Rana pipiens pregnancy test appraisal of with suggested modifications of original technique 554  
Recording blood pressure, electronic apparatus for 143  
Red blood cell and plasma cholinesterase activity electrometric method for determination of, 1564  
Renal blood flow measurement of optically recording bubble flow meter adapted for 146  
capacity of normal hypertensive and cardiac failure patients to excrete sodium 1603  
function, altered, in lower nephron nephrosis nature of 31  
insufficiency fluid and electrolyte balance in management of acute 1612

- Renal—Cont d  
ischemia unilateral hypertension during blood transfusions for hemorrhagic shock in patient with unilateral, 784  
tubular injury fatal paroxysmal myohemoglobinuria with 1744  
transport mechanism for glucose studies on 1618  
Renin sensitivity and hypertensinogen levels in adrenalectomized dogs 1594  
Respiratory gases vacuum sampling tube for 881  
infections Newcastle virus in human occurrence of antihemagglutinins against with a possible instance of virus isolation 1581  
Rh factor sensitizations to in Negroes 1071  
haptens experiences with preliminary report of 1603  
negative woman intensive immunization of an already sensitized birth of mildly diseased baby 983  
Rhesus antisera and cells rare techniques to overcome lack of 1151  
Rheumatic disease diagnosis of failure of sensitized sheep cell agglutination to clarify 1216  
pleuropneumonia like organisms associated with in vivo action of aureomycin on 1404  
fever prevention of after development of a streptococcal infection an effective method for 1596  
Rheumatoid arthritis neutropenia and splenomegaly associated with 1726  
Ribose nucleic acid depletion correlation between and other signs of liver damage as influenced by vitamin B<sub>12</sub> 1764  
Rimicol a vasodilator substance converted in the organism to nicotinic acid 1765  
Rose bengal and bromsulphalein tests a comparison 246  
Russell viper venom and lecithin use of as thromboplastin in estimation of prothrombin 458  
Rutin effect of on hemorrhagic phenomena of experimental malignant hypertension in the dog 1608

## S

- Salmonella typhi bacteriophage typing of 739  
Scurvy tyrosine metabolism in human 1401  
Sections preparation of by freezing drying simplified vacuum dehydration technique for 292  
Semen inhibition of growth of Staphylococcus aureus by human 1526  
Seminal stains identification of acid phosphatase test for 728  
Sensitizations to Rh factor in Negroes 1071  
Sensitized sheep cell agglutination failure of to clarify diagnosis of rheumatic disease 1216

- Serum albumin, hydrolyzed human, intravenously administered, nutritive value of, in man, 1133
- and plasma in liver diseases, electrophoretic pattern of, comparison of, with special reference to gamma globulin fractions, 1600
- cholesterol of normal and thioracil treated dogs, effect of cholesterol free diet on, 1602
- esterase, studies on, 858
- gamma globulins, turbidimetric determination of, as checked by electrophoretic analysis, 1610
- glutamic acid levels and occurrence of nausea and vomiting after intravenous administration of amino acid mixtures, 1238
- mucoid in diabetes mellitus, bound glucosamine of, 116
- protein in, determination of, and in fractions obtained from serum with biuret reagent prepared with sodium hydroxide, 1171
- proteins, biuret and Kjeldahl determinations of, studies of differences between, 1175, 1178, 1183
- effect of occlusion of hepatic artery and ligation of gastroduodenal artery on, 1178
- sample analysis, a single, limitations and merits of, in differential diagnosis of jaundice, 1259
- sickness, unusual clinical picture resembling prolonged, "thought to be caused by trichinosis," 1611
- Sheep cell agglutination, failure of sensitized, to clarify diagnosis of rheumatic disease, 1216
- Sickle cell anemia, sickle cell trait, and pernicious anemia, carbonic anhydrase activity in, 1249
- disease, study of, by measuring survival of transfused red blood cells, 90
- Sodium, biologic decay periods of, in normal man, in congestive heart failure, and in nephrotic syndrome as determined by  $\text{Na}^{22}$  as the tracer, 1
- diet, the minimal, effect upon blood pressure of ambulatory hypertensive subjects, 1380
- nicotinate, hyperbilirubinemic effect of, 1039
- penicillins, absorption of, lack of effect of Tween 80 on, 1443
- renal capacity of normal, hypertensive, and cardiac failure patients to excrete, 1603
- restriction, effect of rigid, in cirrhosis of liver and ascites, 1029
- Solubility of human hemosiderin, quantitative study of, 1762
- Sonic vibrated leptospirae as antigens in complement fixation test for diagnosis of leptospirosis, 1411
- Soybean phosphatide preparations, vasodilator activity of, 688
- Spectrophotometric method for determination of procaine and *p*-aminobenzoic acid, 822
- for quantitative determination of barbiturates, a modified ultraviolet, 1462
- Spherocytic hemolytic anemias, Coombs developing test in, 768
- Spinal fluid glucose, quantitative micromethod for pediatric ward laboratory, 725
- Spleen protection, effect of, on mortality following  $\gamma$  irradiation, 1538
- radioisotopes of yttrium, zirconium, and columbium in bone marrow, liver and controlled selective localization of, 305
- Splenectomy, effect of, on toxicity of  $\text{Sr}^{90}$  to the hematopoietic system of mice, 1640
- simultaneous cesarean section and, in idiopathic thrombocytopenic purpura, 1580
- Splenomegaly and neutropenia associated with rheumatoid arthritis, 1726
- Sprue, vitamin A in, absorption of unemulsified and emulsified, 1140
- Sputum, comparison of hydrochloric acid and trisodium phosphate in preparation of, in *Mycobacterium tuberculosis*, 733
- Staphylococcus aureus, inhibition of growth of, by human semen, 1526
- Stellate block in management of narcolepsy and cataplexy, 1745
- Stomach, ulcer of, excisional, resistance of recently healed, to histamine induced ulcer, 228
- Stool, urobilinogen in, determination of, simplified equipment for, 287
- Stools, dysenteric, protozoa in, polyvinyl alcohol fixative as a preservative and adhesive for, 1554
- Streptococcal infection, prevention of rheumatic fever after the development of, an effective method for, 1596
- Streptococcus viridans endarteritis of an arteriovenous aneurysm, cured by penicillin and surgical excision, 221
- Streptomycin combined with penicillin and/or sulfadiazine, in vitro effects of, on gram negative bacteria, 186
- resistance of tubercle bacillus to, 358
- Sulfonamide sensitivity, determination of, in vitro, simple method for, and its clinical application, 1457
- Summer's dimethylglycolic acid method for determination of glucose in urine, evaluation of a modified, 1447
- Syndrome of hypertension, obesity, menstrual irregularities, and evidence of adrenal cortical hyperfunction, 1746
- Syphilis, experimental, in rabbit, 1748
- semiweekly treatment of, with procaine penicillin in oil, 998

## T

- Tabes dorsalis Kepler water test in 830  
 Takata Ara reaction in differential diagnosis of jaundice 1702  
 Teroplerin metabolism blood level studies on 501  
 Tetraethylammonium bromide effect of on cardiac output of normotensive and hypertensive patients 1622  
 Thephorin action of upon histamine induced gastric secretion in dogs and on gastric ulcer formation in rats 372  
 Thimerin, mercurial diuretic clinical studies on 1254  
 3 hydroxy N methylmorpholine hydrobromide observations on use of 1530  
 Thrombin and oxidized cellulose use of in needle biopsy of liver to prevent hemorrhage 422  
 Thrombocytopen studies on 1336  
 Thrombocytopenic purpura coagulation defect in 761  
     simultaneous cesarean section and splenectomy in idiopathic 1580  
 Thromboembolic disease in vitro heparin tolerance test for evaluation of 1222  
 Thromboplastin Russell viper venom and lecithin as in estimation of prothrombin 458  
 Thrombosis intravascular fibrinogen B test and 1352  
 Thymol turbidity test standardized reagent for 877  
     use of as lipid absorption test 105  
 Thyroid administration in alloxan treated rats hyperglycemia and glucosuria following 492  
     secretory activity, effect of on distribution of radiiodine in plasma 1520  
 Tissue and body fluid *Actinomyces bovis* in 677  
     aseptic grinding of small amounts of sample method for 1021  
     connective response of, to piezoelectrically active crystals 592  
     fluids quantitative spectrographic analysis of 616  
     hematopoietic tumors of effect of arsenic on clinical course of 1366  
     macerator for small samples of 1027  
     responses to physical forces 592 610  
 Titration heparin protamine experienced with 1586  
 Tracer methods of studying histochemical iron, 414  
 Trichina precipitin tests false positive in infectious mononucleosis occurrence of 543  
 Tryptophan requirement minimum and urinary excretion of tryptophane by normal adults 839  
     therapeutic effect of in human pellagra 409  
 Tubercle bacillus resistance of, to streptomycin 358

- Tuberculin and Arthus types of hypersensitivity a comparison 1596  
 Tuberculosis clinical pathological survey of, 1592  
     laboratory diagnosis of, adaptability of mice to 1081  
     Mycobacterium, cultivation of 733  
 Tumors and abscesses radioactive silver for detection of 1376  
     intracranial detection of, by diiodotri-fluorescein 1580  
     malignant brain, uptake of radioactive phosphorus by 587  
     of hematopoietic tissues effect of arsenic on clinical course of 1366  
 Turbidimetric assay of hyaluronidase 74  
     determination of serum gamma globulins as checked by electrophoretic analysis 1610  
     method of aureomycin assay for capillary blood and other body fluids a simplified 1682  
 Turbidity test thymol standardized reagent for 877  
     tests thymol and zinc sulfate experiences with under physiologic and pathologic conditions 105  
 Tween 80 lack of effect of on absorption of albumin and sodium penicillins, 1443  
 Typhoid bacteria Pyrogen intravenous injection of influence of various disease states upon febrile response to 1400  
     carrier chronic effect of cholecystectomy on bacteriologic course 549  
     vaccine, exacerbation of alloxan diabetes in mice by injection of 487  
 Tyrosine metabolism in human scurvy 1491

## U

- Ulcer of stomach excisional, resistance of recently healed to histamines induced ulcer, 228  
 Ulcerative colitis fecal aerobic and anaerobic bacteria of patients with chronic certain effects of chemotherapy on 1725  
     Viodenum in treatment of 1621  
 Ultraviolet spectrophotometric method for quantitative determination of barbiturates a modified 1462  
 Uremia experimental, dietary and hormonal influences in 925  
     treatment of by dialysis across the intestinal mucosa, 1761  
 Urinary bilirubin new tablet test for 1145  
     excretion of iron effect of acid and alkaline salt on 932  
     of pigment use of for measurement of basal metabolic rate 482  
     of 17 ketosteroids and corticosteroids in acute leukemia effect of 4 amino pteroylglutamic acid on 1608  
     of tryptophane by normal adults minimum tryptophane requirement and, 839

## Urinary—Cont'd

- pigment creatinine ratio, use of, for measurement of basal metabolic rate, 1512
- Urine and blood, bromate in, detection of, 425
- and plasma, Na, K, Ca, Mg, and Fe in, quantitative determination of, use of emission spectrograph for, 625
- antidiuretic substance in, of patients with cardiac failure, 1585
- determination of glucose in, Sumner dimethylglycolic acid method for, evaluation of a modified, 1447
- factors which cause precipitation of hemoglobin in vitro, consideration of some, 936
- lactose in, detection of, method for, 562
- thrombocytopen in, reliable test for, 1336
- urobilinogen in, determination of, simplified equipment for, 287
- Urobilinogen formation and the fecal flora, effect of aureomycin on, 1743
- in urine and stool, determination of, simplified equipment for, 287

## V

- Vaccine, mumps, studies on human volunteers, 199
- Vacuum dehydration technique for preparation of sections by freezing drying, a simplified, 292
- sampling tube for respiratory gases, 881
- Valvular insufficiency of deep venous system of lower extremities, division of popliteal vein in, 1755
- Vascular diseases, experimental, due to desoxy corticosterone acetate and anterior pituitary extract, comparison of functional changes, 1416
- Vasodepressor activity of soybean phosphatide preparations, 688
- Vein, popliteal, division of, in valvular insufficiency of deep venous system of lower extremities, 1755
- Ventricles, human, cavity potentials of, 1768
- Ventricular myocardium, spread of excitation through, studies on, 1738
- Vibratory perception in diabetic and nondiabetic subjects, quantitative studies of, 1728

- Vicarious excretion by means of pergastric intestinal perfusion, 1585
- Viodenum in treatment of ulcerative colitis, 1621
- Viral hepatitis, relation of intestinal parasitism to transmission of, 1284
- Virus, Newcastle, in human respiratory infections, occurrence of antihemagglutinins against, with a possible in stance of virus isolation, 1581
- Viruses, preservation of, in mechanical refrigerator at  $-25^{\circ}\text{C}$ , 1023
- Viscosity effusion meter for measuring concentration of anesthetic gases, 566
- Vitamin A and glucose blood levels, effect of epinephrine on, in normal and cirrhotic subjects, 1279
- in sprue, absorption of unemulsified and emulsified, 1140
- B<sub>12</sub> and pteroylglutamic acid, interrelation of, in induced anemia of swine, 1763
- response of lingual manifestations of pernicious anemia to, 439
- effect of, on painful aspects of nutritional neuropathy, preliminary note, 1582
- in pernicious anemia, oral administration of, 1590
- liver damage as influenced by, correlation between ribose nucleic acid depletion and other signs in, 1764

## W

- Warburg manometer calibrator, 1702
- Water test, Kepler, in tabes dorsalis, 830

## X

- X irradiation, effect of, on antibody formation, 1612
- mortality following, effect of spleen protection on, 1538

## Z

- Zinc sulfate turbidity and total lipid determinations in liver disease, evaluation of, 1584
- Zirconium and sodium citrate, experimental study of effect of, on metabolism of plutonium and radioyttrium, 313
